## 2 ABSTRACT

Radioastronomy is a powerful tool for the discovery of molecules in space but it requires molecular species to be polar. The observation of apolar species can be however enabled by protonation, which occurs from reaction with the abundant  $\text{H}_3^+$  ion whenever the proton affinity of the species under consideration is greater than that of  $\text{H}_2$ . This property can be easily investigated by computational chemistry and, in this work, it has been used to assess the potential protonation of simple homo diatomics, such as  $\text{Cl}_2\text{H}^+$ ,  $\text{P}_2\text{H}^+$ , and  $\text{Si}_2\text{H}^+$ , as well as apolar species containing two equivalent CN moieties, such as diisocyanogen (CNNC) and  $(E)\text{-1,2-dicyanoethene}$ . Quantum chemistry has also been exploited to investigate the mechanisms of three protonation reactions of  $\text{H}_3^+$  with  $\text{Cl}_2$ ,  $\text{P}_2$ , and CNNC. To support laboratory measurements and astronomical observations of the resulting transient species, the rotational spectroscopic parameters were accurately computed together with their fundamental vibrational frequencies. For this purpose, we have employed CCSD(T)-based computational methodologies, which provide equilibrium structures with errors better than 0.001 Å and 0.1° for bond distances and angles, respectively. Such an accuracy is expected to lead to rotational constants predicted, in relative terms, with uncertainties better than 0.2%. Instead, the expected accuracy on vibrational frequencies is  $\sim 10\text{ cm}^{-1}$ , thus being well suited to guide band assignments.

Keywords: astrochemistry, protonation, rotational spectroscopy, apolar molecules, ISM, proxy, quantum-chemistry

## 1 INTRODUCTION

The overwhelming majority of chemical species in the interstellar medium (ISM) have been discovered via radioastronomy, which exploits their rotational signatures. However, the observation of new astronomical species comes to a setback when the species of interest are weakly polar or apolar (Yamamoto, 2017). In the former case, a possible way out is offered by the line stacking technique (Yen et al., 2016), while for apolar molecules, one has to rely on the observation of the so-called molecular proxies. These are

25 polar systems whose presence in the astronomical object under consideration can be directly related to  
26 non-observable species. Molecular proxies can be obtained in several ways, with some of them being well  
27 established in the literature.

28 A first possibility is to claim the presence of an apolar species based on the observation of its cyano-  
29 derivatives, which usually have a significant electric dipole moment. Indeed, the high abundance of the CN  
30 radical together with its highly reactive nature leads to species containing the CN moiety through formation  
31 pathways that are usually accessible even in the conditions of the ISM. A significant example is provided  
32 by the observation of benzonitrile (C<sub>6</sub>H<sub>5</sub>CN) (McGuire et al., 2018), whose detection in the ISM has been  
33 undoubtedly related to the presence of benzene in the same environment. Indeed, different experiments  
34 have demonstrated the effectiveness of the reaction between the CN radical and benzene C<sub>6</sub>H<sub>6</sub> (Lee et al.,  
35 2019; Cooke et al., 2020). Similarly, the observation of cyanonaphthalene towards TMC-1 (McGuire et al.,  
36 2021) suggests the presence of naphthalene in this cold core. Other than the CN radical, proxies can also  
37 be formed by the CCH radical. However, the observation of its derivatives is more challenging because  
38 the ethynyl group leads to molecular proxies with a smaller electric dipole moment when compared to the  
39 CN-containing counterpart (Cernicharo, J. et al., 2021; McCarthy et al., 2021).

40 Another important way to observe apolar species is to consider their protonated form. Protonation in the  
41 ISM occurs owing to the presence of H<sub>3</sub><sup>+</sup>, which in turn is obtained from the reaction between H<sub>2</sub> and H<sub>2</sub><sup>+</sup>,  
42 with the latter being formed via cosmic ray ionization (Yamamoto, 2017). The H<sub>3</sub><sup>+</sup> initiates the protonation  
43 via this general mechanism:

44 which proceeds only if the proton affinity (PA) of the generic species A is greater than that of H<sub>2</sub>. Based on  
45 the PA values reported by Yamamoto (2017), H<sub>3</sub><sup>+</sup> is the primary source of N<sub>2</sub>H<sup>+</sup> and HCO<sup>+</sup>/HOC<sup>+</sup>, but it  
46 does not lead to the formation of O<sub>2</sub>H<sup>+</sup> because O<sub>2</sub> has a smaller PA than H<sub>2</sub>.

47 In the present paper, we propose the use of protonated species as suitable proxy for the radio-observation  
48 of apolar species of astrochemical interest. To this end, their computed rotational spectra are reported  
49 here for the first time. This study will involve simple diatomic molecules, such as P<sub>2</sub>, Si<sub>2</sub>, and Cl<sub>2</sub>, a  
50 linear centrosymmetric species, i.e., CNNC, and a C<sub>2h</sub> species, the E isomer of NC–CH=CH–CN. The  
51 first three are simple diatomic molecules that can be considered as reservoirs of atomic P, Si, and Cl,  
52 respectively. This is particularly interesting because the chemistry of third-row atoms in astronomical  
53 environments is still in early stages, with only a few species containing P, Si, or Cl being detected so far  
54 (McGuire, 2022). Since both vibrational (infrared) and rotational spectra of homonuclear diatomics cannot  
55 be observed, the only way-out for their detection (if avoiding electronic spectroscopy) is offered by their  
56 protonated forms. As an example, the N<sub>2</sub>H<sup>+</sup> molecule – observed for the first time in 1974 by Turner  
57 (1974) – is considered a good tracer of N<sub>2</sub>, which is otherwise not observable at radio frequencies. For  
58 this reason, the study of the simple P<sub>2</sub>H<sup>+</sup>, Si<sub>2</sub>H<sup>+</sup>, and Cl<sub>2</sub>H<sup>+</sup> ions can potentially provide useful data to  
59 guide laboratory and/or astronomical observations. While the P<sub>2</sub> and Si<sub>2</sub> precursors might be considered  
60 somewhat exotic, Cl<sub>2</sub> is a simple species stable under Earth conditions. To assess the accuracy of our work,  
61 the N<sub>2</sub>H<sup>+</sup> and HCO<sup>+</sup> ions will be used as references to test our computational strategy.

62 Another interesting molecule is the linear species diisocyanogen (CNNC) because two isomers of its  
63 family, namely CNCN and NCCN, have already been detected in the ISM. While the former was observed  
64 directly via its rotational transitions (Agúndez et al., 2018), the presence of NCCN was inferred thanks to

65 the observation of its protonated counterpart, i.e.  $\text{NCCNH}^+$  (Agúndez et al., 2015). Thus, the computational  
66 spectroscopic characterization of  $\text{CNNCH}^+$  surely represents a preliminary step toward its astronomical  
67 detection. In this case, the well-characterized  $\text{NCCNH}^+$  species will be used as reference to understand the  
68 uncertainties associated with our methodology.

69 The last molecule considered is the (*E*) isomer of 1,2-dicyanoethene, which is the main product of  
70 the reaction between the CN radical and vinyl cyanide ( $\text{CH}_2=\text{CH}-\text{CN}$ , Marchione et al. (2022)) also  
71 known as acrylonitrile. While the (*Z*) isomer of 1,2-dicyanoethene, being a polar molecule, might be  
72 detected directly, without the use of any molecular proxy, the (*E*) form lacks of a permanent electric dipole  
73 moment. Thus, we aim at providing good estimates for the rotational parameters of its counterpart, i.e.  
74 (*E*)- $\text{NC}-\text{CH}=\text{CH}-\text{CNH}^+$ .

75 This work will also report the fundamental vibrational frequencies and intensities of all the species  
76 mentioned above. This data could provide a reliable starting point for experimental measurements of their  
77 vibrational spectra as well as benchmark reference for future computations.

78 The manuscript is organized as follows. In the next section (§ 2), we detail the computational strategy  
79 adopted to describe the protonated species, with specific focus on the computation of proton affinity and  
80 formation routes as well as spectroscopic parameters. Then, the results are reported in § 3 where they  
81 are discussed together with those of chemically related species. After briefly addressing the PA values,  
82 the formation routes for the species considered are detailed, and then the computational spectroscopic  
83 characterization is considered. The last section (§ 4) will draw the main conclusions of the present study.

## 2 COMPUTATIONAL DETAILS

84 For most of the species considered in this work, experimental and computational data are missing, thus a  
85 preliminary study using density functional theory (DFT) was carried out to understand their stable form.  
86 For this purpose, the double-hybrid rev-DSD-PBEP86 functional (Santra et al., 2019), combined with the  
87 GD3BJ empirical dispersion (Grimme et al., 2011, 2010), was used in conjunction with the jun-cc-pVTZ  
88 basis set (Dunning Jr., 1989; Papajak and Truhlar, 2011). Overall, this level of theory is shortly denoted as  
89 revDSD/junTZ. Noted is that, for third-row elements, the d-augmented jun-cc-pV(T+d)Z sets have been  
90 employed (Dunning et al., 2001). The revDSD/junTZ level has been employed to derive preliminary values  
91 for equilibrium geometries, electronic energies and (harmonic) zero-point energy corrections (ZPEs).

92 For  $\text{Cl}_2\text{H}^+$ ,  $\text{P}_2\text{H}^+$ , and  $\text{Si}_2\text{H}^+$ , equilibrium structures ranging from linear to cyclic were considered and  
93 the most stable forms of each species are shown in fig. 1, where their electronic state is also reported. The  
94 same figure also provides the equilibrium structure of  $\text{CNNCH}^+$  and (*E*)- $\text{NC}-\text{CH}=\text{CH}-\text{CNH}^+$ , which  
95 were somewhat more straightforward to derive since bent structures would be very unstable. After this  
96 preliminary study, additional computations were mandatory to derive accurate spectroscopic parameters,  
97 PA estimates and formation routes.

### 98 2.1 Proton Affinity and Formation Routes

99 To understand if a protonated molecule can be formed in the ISM starting from  $\text{H}_3^+$ , the PA value of each  
100 species has to be considered in comparison with that of the  $\text{H}_2$  molecule. The PA at  $T=0$  K is computed as  
101 (McNaught et al., 1997; Marino et al., 2000):

**Figure 1.** Equilibrium structure and electronic ground state of (1)  $\text{Cl}_2\text{H}^+$ , (2)  $\text{P}_2\text{H}^+$ , (3)  $\text{Si}_2\text{H}^+$ , (4)  $\text{CNNCH}^+$ , and (5) protonated  $(E)$ -1,2-dicyanoethene.

$$\text{PA} = \Delta H_0^{\text{neutral}} - \Delta H_0^{\text{protonated}} \quad (2)$$

102 where both  $\Delta H_0$  values are obtained by combining the electronic energy obtained using the jun-Cheap  
 103 composite scheme (hereafter junChS) (Alessandrini et al., 2019) with the anharmonic ZPE. The latter  
 104 correction was computed at the ae-CCSD(T)/cc-pwCVQZ for protonated diatomics, while the cc-pwCVTZ  
 105 basis set was used for  $\text{NCCNH}^+$  and  $\text{CNNCH}^+$ . For protonated 1,2-dicyanoethene, the ZPE was evaluated  
 106 at the revDSD/junTZ level. Here, ae-CCSD(T) stands for the coupled-cluster (CC) method including a full  
 107 treatment of single and double excitations and a perturbative estimate of triples (Raghavachari et al., 1989),  
 108 with all electrons (ae) correlated. Anharmonic computations were carried out on top of the corresponding  
 109 reference geometry, on top of which junChS energy evaluations were also performed. Within the junChS  
 110 approach, the electronic energy,  $E(\text{junChS})$ , is obtained as follows (Alessandrini et al., 2019):

$$E(\text{junChS}) = E(\text{CCSD(T)/junTZ}) + \Delta E_{\text{MP2}}^{\infty} + \Delta E_{\text{MP2}}^{\text{CV}} \quad (3)$$

111 Here, the first term on the right-hand side is the fc-CCSD(T)/jun-cc-pVTZ energy (with jun-cc-pV(T+d)Z  
 112 being used for third-row elements), where fc indicates that the frozen-core approximation is used. The  
 113 second term accounts for the extrapolation to the complete basis set (CBS) limit at the MP2 level, with  
 114 MP2 denoting Møller-Plesset perturbation theory to the second order (Møller and Plesset, 1934). This  
 115 extrapolation exploits the  $n^{-3}$  formula by Helgaker et al. (1997), and requires energy computations with  
 116 two consecutive members of a hierarchical family of basis sets. In this case, the jun-cc-pV(T+d)Z and jun-  
 117 cc-pV(Q+d)Z sets were used. The third term in eq. (3) is the core-valence (CV) correction and incorporates  
 118 the effect of the correlation of inner-shell electrons, which is not included in the previous computations.  
 119 This term is computed as the difference between all-electron and frozen-core calculations, both with the  
 120 cc-pwCVTZ basis set (Peterson and Dunning Jr., 2002).

121 For three of the species considered, namely  $\text{Cl}_2\text{H}^+$ ,  $\text{P}_2\text{H}^+$ , and  $\text{CNNCH}^+$ , the formation route was also  
 122 investigated. To this end, the revDSD/junTZ level of theory was employed to locate minima (MINs) and

123 transition states (TSs) on reactive potential energy surface (PES). The correct assignment of two MINs to  
 124 the connecting TS was assured by exploiting the intrinsic reaction coordinate (IRC) analysis (Fukui, 1981),  
 125 performed at the same level of theory. To refine the electronic energy of each stationary point, the junChS  
 126 approach was employed, while the harmonic ZPE was evaluated at the revDSD/junTZ level.

## 127 2.2 Spectroscopic Characterization

128 Focusing on rotational spectroscopy, the main parameters influencing the spectrum are the rotational  
 129 constants (Barone et al., 2021). For a given inertia axis ( $\gamma = a, b, \text{ or } c$ ), in the framework of vibrational  
 130 perturbation theory to second order (VPT2) (Mills, 1972), the rotational constant of the vibrational ground  
 131 state ( $B_0^\gamma$ , corresponding to  $A_0$  for  $\gamma = a$ ,  $B_0$  for  $\gamma = b$ , and  $C_0$  for  $\gamma = c$ ), can be written as:

$$B_0^\gamma = B_e^\gamma - \sum_r \frac{d_r}{2} \alpha_r^\gamma. \quad (4)$$

132 The first term on the right-hand side of eq. (4) is the equilibrium rotational constant, which entirely  
 133 depends on the isotopic composition of the molecule and its equilibrium structure. Thus,  $B_e^\gamma$  is  
 134 straightforwardly obtained from a geometry optimization and accounts for about 99% of the value of  $B_0^\gamma$   
 135 (Puzzarini et al., 2008, 2010; Alessandrini et al., 2018). The second term on the right-hand side of eq. (4) is  
 136 the vibrational contribution to the rotational constant and it is obtained as the sum over all  $r$  vibrational  
 137 modes of the vibration-rotation interaction constants ( $\alpha_r^\gamma$ ). In eq. (4),  $d_r$  denotes the degeneracy of the  $r$ -th  
 138 vibrational mode. The vibrational correction represents a minor contribution to  $B_0^\gamma$ , but its consideration is  
 139 crucial to reach accurate computational results, comparable with experimental ones (Puzzarini et al., 2008,  
 140 2010; Alessandrini et al., 2018).

141 Since  $B_e^\gamma$  is the major contribution to  $B_0^\gamma$ , it should be computed at the highest possible level of theory  
 142 when aiming at high accuracy. For this reason, for Cl<sub>2</sub>H<sup>+</sup>, P<sub>2</sub>H<sup>+</sup>, Si<sub>2</sub>H<sup>+</sup>, and CNNCH<sup>+</sup>, the equilibrium  
 143 geometry was obtained by exploiting a composite scheme entirely based on coupled-cluster (CC) theory  
 144 (Heckert et al., 2005, 2006), which requires the minimization of the following energy gradient:

$$\frac{dE_{\text{CBS+CV+fT+fQ}}}{dx} = \frac{dE^\infty(\text{HF} - \text{SCF})}{dx} + \frac{d\Delta E^\infty(\text{CCSD(T)})}{dx} + \frac{d\Delta E(\text{CV})}{dx} + \frac{d\Delta E(\text{fT})}{dx} + \frac{d\Delta E(\text{fQ})}{dx}. \quad (5)$$

145 This composite scheme is denoted as “CBS+CV+fT+fQ” and it consists of 5 different terms:

- 146 • The extrapolation to the CBS limit, which is obtained by the sum of the HF-SCF and fc-CCSD(T)  
 147 extrapolated gradients, i.e.  $\frac{dE^\infty(\text{HF-SCF})}{dx}$  and  $\frac{d\Delta E^\infty(\text{CCSD(T)})}{dx}$ , respectively. The former is evaluated  
 148 using the three-point formula by Feller (1993) and the cc-pVT $n$ Z basis sets, with  $n=\text{T,Q,5}$ . For the  
 149 CCSD(T) correlation energy,  $\Delta E(\text{CCSD(T)})$ , gradient the  $n^{-3}$  formula (Helgaker et al., 1997) is  
 150 exploited in conjunction with the cc-pVTZ and cc-pVQZ basis sets.
- 151 • The CV contribution, which is obtained as difference between ae- and fc-CCSD(T)/cc-pwCVTZ  
 152 computations.
- 153 • The fT term, which accounts for the full treatment of triples. This is obtained as difference between  
 154 two computations carried out with the cc-pVTZ basis set, the first employing the CCSDT (Noga and  
 155 Bartlett, 1987; Scuseria and Schaefer III, 1988) method (the acronym standing for CC singles, doubles  
 156 and triples) and the second one with CCSD(T), both within the fc approximation.

157 • The fQ term, which is the contribution due to quadruple excitations. This is computed as difference  
158 between CCSDTQ (CC singles, doubles, triples and quadruples; Kállay and Gauss (2008); Kucharski  
159 and Bartlett (1991)) and CCSDT calculations, both with the cc-pVDZ basis set and within the fc  
160 approximation.

161 The CBS+CV+fT+fQ equilibrium rotational constants were then corrected for the vibrational contribution.  
162 The evaluation of vibration-rotation interaction constants requires a full cubic force field (Puzzarini et al.,  
163 2010), which was computed at the ae-CCSD(T)/cc-pwCVQZ level. For the  $\text{CNNCH}^+$  ion, a smaller basis  
164 set, cc-pwCVTZ, was instead employed. For the  $(E)\text{-NC-CH=CH-CN}^+$  species, the computational  
165 approach was slightly different because of its size. The equilibrium rotational constants were obtained  
166 from the minimization of the “CBS+CV” energy gradient, thus retaining only the first three terms on  
167 the right-hand side of eq. (5) in conjunction with the same basis sets mentioned above. In addition, the  
168 anharmonic computation required for the vibrational corrections was carried out at the revDSD/junTZ level  
169 of theory.

170 For all the species considered, the VPT2 calculations performed on the computed anharmonic force field  
171 allowed for obtaining other spectroscopic parameters, such as quartic centrifugal distortion constants and  
172 fundamental vibrational frequencies. These latter can be obtained because the computations of the cubic  
173 force constants give access, without any other additional cost, to the semi-diagonal quartic force constants.  
174 For protonated 1,2-dicyanoethene, quartic centrifugal distortion constants were computed at a different  
175 level of theory than the vibrational corrections to rotational constants, indeed considering the harmonic  
176 force field at the fc-CCSD(T)/jun-cc-pVTZ level.

177 On top of the best geometry, the electric dipole moment and the nuclear quadrupole-coupling constants  
178 (NQCCs), which are both first-order properties, were obtained. While the electric dipole moment is  
179 required to predict the type and intensity of rotational transitions, the NQCCs shape the rotational spectrum  
180 (hyperfine structure). NQC is the interaction between the quadrupole moment of a nucleus and the electric  
181 gradient at the same nucleus. This determines a splitting of the rotational energy levels, thus causing  
182 a splitting of the rotational transitions, i.e. the so-called hyperfine structure. Noted is that a nucleus is  
183 defined as quadrupolar whenever its nuclear spin is  $I > 1/2$ . The hyperfine structure can be useful for the  
184 assignment and analysis of rotational lines in the laboratory and in astronomical observations (Turner, 1974;  
185 Puzzarini et al., 2010; Melosso et al., 2021); thus, spectral simulations strongly benefit from the introduction  
186 of such interaction terms. Both NQCCs and electric dipole moment components were obtained at the  
187 ae-CCSD(T)/aug-cc-pwCVQZ level for protonated diatomics, while for  $\text{CNNCH}^+$  the aug-cc-pwCVTZ  
188 basis set was used. For protonated  $(E)\text{-1,2-dicyanoethene}$ , the fc-CCSD(T)/jun-cc-pVTZ level of theory  
189 was employed. Additionally, the vibrational corrections to the NQCCs and the electric dipole moment were  
190 also considered and obtained from the anharmonic treatment mentioned above.

191 The computational strategy outlined above was also employed to describe three molecules that are  
192 experimentally well-characterized in the literature. These are  $\text{N}_2\text{H}^+$  and  $\text{HCO}^+$ , which offer a good  
193 reference for the new protonated diatomics, and  $\text{NCCNH}^+$  for the direct comparison with  $\text{CNNCH}^+$ .

194 All DFT and MP2 computations were carried out using the Gaussian16 suite of programs (Frisch et al.,  
195 2016), while the CFour quantum-chemistry program (Stanton et al., 2016; Matthews et al., 2020) was  
196 used for all computations based on the CC theory. Concerning VPT2 calculations, its generalized version  
197 (GVPT2) (Schiff, 1955; Piccardo et al., 2015) was employed whenever using the Gaussian16 package.

### 3 RESULTS

198 The main molecule driving protonation in the ISM being H<sub>3</sub><sup>+</sup>, the first mandatory step is to investigate  
 199 whether the species considered in this work can be produced by reaction 1. The first screening is based on  
 200 PA. If PA of P<sub>2</sub>, Si<sub>2</sub>, Cl<sub>2</sub>, CNNC, and NCCHCHCN is greater than that of H<sub>2</sub>, the protonation occurs and  
 201 the reaction proceeds at the Langevin rate (Yamamoto, 2017), i.e. without a strong temperature dependence.  
 202 The data required for this comparison are reported in Table 1, which also includes the data for N<sub>2</sub>, CO, and  
 203 NCCN, whose protonated forms have already been observed in the ISM.

**Table 1.** Computed proton affinities (kJ·mol<sup>-1</sup>) for the molecules considered in this work. Electronic energies and ZPE are in Hartrees.

Process	Neutral Species		Protonated Species		
	Energy <sup>a</sup>	ZPE <sup>b</sup>	Energy <sup>a</sup>	ZPE <sup>b</sup>	PA
H <sub>2</sub> → H <sub>3</sub> <sup>+</sup>	-1.17568	0.00993	-1.34493	0.01985	418.3
N <sub>2</sub> → NNH <sup>+</sup>	-109.52407	0.00538	-109.72269	0.01604	493.5
CO → HCO <sup>+</sup>	-113.30829	0.00494	-113.54486	0.01609	591.5
P <sub>2</sub> → PPH <sup>+</sup>	-682.43110	0.00179	-682.69261	0.00816	669.9
Si <sub>2</sub> → Si <sub>2</sub> H <sup>+</sup>	-578.57543	0.00123	-578.90135	0.00685	841.0
Cl <sub>2</sub> → Cl <sub>2</sub> H <sup>+</sup>	-920.12253	0.00127	-920.33914	0.00933	547.6
NCCN → NCCNH <sup>+</sup>	-185.63331	0.01567	-185.89266	0.02642	652.7
CNNC → CNNCH <sup>+</sup>	-185.51579	0.01422	-185.80000	0.02505	717.8
NCCHCHCN → NCCHCHCNH <sup>+</sup>	-263.04052	0.04875	-263.33125	0.05935	735.5

<sup>a</sup> Electronic energy computed at the junChS level. See text. <sup>b</sup> Anharmonic ZPE corrections at the ae-CCSD(T)/pwCVQZ level of theory for diatomic species. The same method in conjunction with the cc-pwCVTZ basis set was used for NCCN and CNNC. For (E)-NCCHCHCNH<sup>+</sup> and (E)-NCCHCHCN, the ZPEs were obtained at the revDSD/junTZ level of theory.

204 Table 1 indicates a PA value of 418 kJ·mol<sup>-1</sup> for H<sub>2</sub>, in good agreement with what reported by Yamamoto  
 205 (2017) and Hunter and Lias (1998), i.e. 422.61 kJ·mol<sup>-1</sup>. A similar agreement is noted for N<sub>2</sub> and CO,  
 206 with values of 493.5 kJ·mol<sup>-1</sup> and 591.1 kJ·mol<sup>-1</sup>, respectively, to be compared with 493.8 kJ·mol<sup>-1</sup> and  
 207 594 kJ·mol<sup>-1</sup> given in Yamamoto (2017). The PA values reported in this work refer to 0 K and are more  
 208 accurate than those available in the literature. The differences noted can be ascribed to the (small) thermal  
 209 correction, the literature values referring to a temperature of 298.15 K.

210 From Table 1, it is noted that a PA value greater than that of H<sub>2</sub> has been obtained for Cl<sub>2</sub>, thus suggesting  
 211 the possible formation of Cl<sub>2</sub>H<sup>+</sup> in the ISM. A further support to this is provided by the fact that PA(Cl<sub>2</sub>) is  
 212 intermediate between PA(N<sub>2</sub>) and PA(CO), with both N<sub>2</sub>H<sup>+</sup> and HCO<sup>+</sup> detected in the ISM. In particular,  
 213 our PA(Cl<sub>2</sub>) value of 547.6 kJ·mol<sup>-1</sup> is in good agreement with that established experimentally by Cacace  
 214 et al. (1998), i.e. 548.1 ± 13 kJ·mol<sup>-1</sup>.

215 The PA value of P<sub>2</sub> is 669.9 kJ·mol<sup>-1</sup> and it is very close to that of NCCN, i.e., 652.7 kJ·mol<sup>-1</sup>, thus  
 216 confirming the plausible formation of the protonated form of P<sub>2</sub>. Finally, large PA values have been obtained  
 217 for CNNC, (E)-NCCHCHCN, and Si<sub>2</sub>. For the first two species, the PA values are 717.8 kJ·mol<sup>-1</sup> and  
 218 735.5 kJ·mol<sup>-1</sup>, respectively, which are comparable with those of molecules like H<sub>2</sub>O, H<sub>2</sub>S, and H<sub>2</sub>CO  
 219 (Yamamoto, 2017). The Si<sub>2</sub> species shows the largest PA, 841.0 kJ·mol<sup>-1</sup>, this result being likely due to its  
 220 triplet electronic ground state. Indeed, a similar value (869 kJ·mol<sup>-1</sup>) is obtained for the CCS radical in

221 the same electronic state (Yamamoto, 2017). Notably,  $\text{HCCS}^+$  as well as  $\text{H}_3\text{O}^+$  and  $\text{H}_2\text{COH}^+$  have already  
222 been observed in the ISM (Cabezas, C. et al., 2022; Wootten et al., 1991; Bacmann et al., 2016; Ohishi  
223 et al., 1996)

### 224 3.1 Formation routes

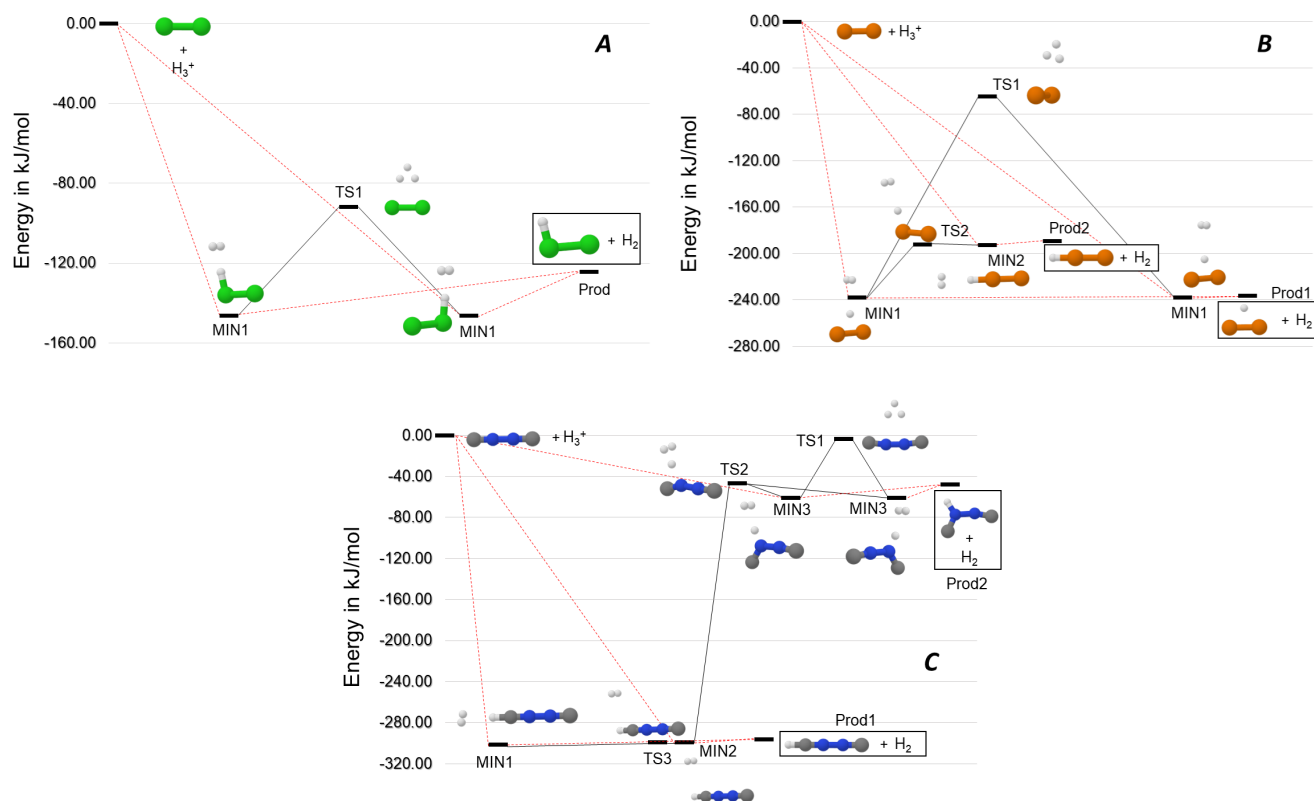

225 While the discussion above on PA values suggests that all the species under consideration could be  
226 formed in the ISM, the next step is the investigation of their formation routes. For this purpose, three  
227 test cases have been chosen:  $\text{Cl}_2\text{H}^+$ ,  $\text{P}_2\text{H}^+$ , and  $\text{NCCNH}^+$ . According to the literature (Klippenstein et al.,  
228 2010; Zhu et al., 2019), the reaction between any molecule and  $\text{H}_3^+$  is barrierless and proceeds through the  
229 formation of a stable intermediate characterized by a weak interaction between the protonated species and  
230 the  $\text{H}_2$  molecule. This also applies to the reactive PESs considered in this work, which are shown in fig. 2.  
231 While a full account on their energetics is provided in the Supporting Material (SM), in the following, only  
232 the junChS+ZPE energies will be considered for our discussion.

233 Let us start by considering the formation of  $\text{Cl}_2\text{H}^+$  from the reaction between  $\text{H}_3^+$  and  $\text{Cl}_2$  (panel A in  
234 fig. 2). The first intermediate formed, denoted as MIN1, is located at  $-143.2 \text{ kJ}\cdot\text{mol}^{-1}$  with respect to the  
235 energy of the reactants. This minimum can interconvert to its spatial equivalent structure via TS1 ( $-85.7 \text{ kJ}\cdot\text{mol}^{-1}$ )  
236 and forms  $\text{Cl}_2\text{H}^+$  and  $\text{H}_2$  without any exiting barrier. A similar reaction mechanism is also observed  
237 for  $\text{P}_2$ , panel B of fig. 2. However, two different products can be formed in this case. Starting from the  
238 reactants the open routes are: a barrierless approach to MIN1 ( $-237.7 \text{ kJ}\cdot\text{mol}^{-1}$ ) and a barrierless approach  
239 to MIN2 ( $-192.4 \text{ kJ}\cdot\text{mol}^{-1}$ ). These two intermediates are connected by the transition state TS2, located at  
240  $-191.8 \text{ kJ}\cdot\text{mol}^{-1}$ . In addition, MIN1 can also form its spatial equivalent structure through TS1. MIN1 leads  
241 to product Prod1 without any exiting barrier, with Prod1 being the most stable stationary point of the  $\text{P}_2\text{H}^+$   
242 +  $\text{H}_2$  reactive PES. Instead, MIN2 forms Prod2, i.e. the linear isomer of  $\text{P}_2\text{H}^+$ , which might be potentially  
243 present in the ISM, even though it lies  $\sim 50 \text{ kJ}\cdot\text{mol}^{-1}$  higher in energy than the cyclic form.

244 The last panel of fig. 2 (panel C) shows the reaction mechanism for the protonation of CNNC. In this case,  
245 there are three open barrierless approaches that lead to the formation of MIN1, MIN2 and MIN3. The first  
246 two intermediates are very close in energy: MIN1 lies at  $-305.5 \text{ kJ}\cdot\text{mol}^{-1}$  and MIN2 at  $-301.8 \text{ kJ}\cdot\text{mol}^{-1}$ .  
247 They can interconvert through TS3, which differs from MIN2 for the orientation of the  $\text{H}_2$  moiety with  
248 respect to the linear backbone. The motion of  $\text{H}_2$  is a large amplitude one, TS3 being indeed characterized  
249 by an imaginary frequency of only  $14 \text{ cm}^{-1}$ . Consequently, the two structures are very close in energy,  
250 i.e. they differ by  $0.1 \text{ kJ}\cdot\text{mol}^{-1}$  at both the revDSD/junTZ and junChS levels of theory augmented by  
251 corresponding ZPEs. From fig. 2, it is noted that both MIN1 and MIN2 can form – without going through  
252 any barrier – Prod1, i.e. linear  $\text{CNNCH}^+$  and  $\text{H}_2$ . TS2, lying at  $-46.4 \text{ kJ}\cdot\text{mol}^{-1}$ , represents the barrier to be  
253 overcome for distorting the linear chain and forming MIN3, which can then interconvert with its equivalent  
254 structure via TS1 or form Prod2, i.e. a bent form of  $\text{CNNCH}^+$  +  $\text{H}_2$ .

255 The three protonation reactions of fig. 2 demonstrate that  $\text{Cl}_2\text{H}^+$ ,  $\text{P}_2\text{H}^+$  and  $\text{CNNCH}^+$  can be formed in  
256 the ISM. The energetic characterization there reported is expected to have an accuracy of  $1\text{-}5 \text{ kJ}\cdot\text{mol}^{-1}$   
257 (Alessandrini et al., 2019, 2021b) and can thus be used to guide the kinetic analysis of these reactions.  
258 While there are no doubts about the isomeric form produced in the reaction between  $\text{Cl}_2$  and  $\text{H}_3^+$ , for  
259 the other two reactions, two possible products are present. However, the stability of MIN1 and the small  
260 energy difference between MIN1 and Prod1 should favor the formation of cyclic  $\text{P}_2\text{H}^+$  and linear  $\text{CNNCH}^+$ .  
261 Therefore, only these forms have been considered in the following spectroscopic characterization.

**Figure 2.** Reactive PES for: the  $\text{Cl}_2 + \text{H}_3^+$  reaction (panel A), the  $\text{P}_2 + \text{H}_3^+$  reaction (panel B), and the  $\text{CNNC} + \text{H}_3^+$  reaction (panel C). The full list of the energies is reported in the SM.

## 262 3.2 Spectroscopic Characterization

263 To enable the experimental detection of the protonated species considered in this work, a computational  
 264 spectroscopic characterization involving fundamental vibrational frequencies and rotational spectroscopy  
 265 parameters has been carried out. In the following, the results are presented according to the class of species  
 266 they belong: (i) protonated diatomics, where the experimental reference is offered by  $\text{N}_2\text{H}^+$  and  $\text{HCO}^+$ ;  
 267 (ii) the linear  $\text{CNNCH}^+$  cation compared with the  $\text{NCCNH}^+$  counterpart; (iii) the protonated form of  
 268 (*E*)-1,2-dicyanoethene. These species, with the only exception of the linear  $\text{CNNCH}^+$  molecule, are planar  
 269 asymmetric rotors. Their planarity leads to a null dipole moment component along the *c* axis ( $\mu_c = 0$ , with  
 270 *ab* thus being the molecular plane). For  $\text{P}_2\text{H}^+$  and  $\text{Si}_2\text{H}^+$ , the  $\mu_a$  component is equal to zero as well because  
 271 of symmetry reasons. For the linear rotor  $\text{CNNCH}^+$ , the only non-null dipole moment component is that  
 272 along the molecular axis, and it is simply denoted as  $\mu$ .

### 273 3.2.1 Protonated Diatomics

274 The rotational parameters of  $\text{Cl}_2\text{H}^+$ ,  $\text{P}_2\text{H}^+$ , and  $\text{Si}_2\text{H}^+$  are reported in Table 2, while those of  $\text{N}_2\text{H}^+$  and  
 275  $\text{HCO}^+$  are provided in the SM. It should be pointed out that protonated CO and  $\text{N}_2$  are linear rotor, and thus  
 276 they are characterized by a single rotational constant and one quartic centrifugal distortion term. Differently,  
 277  $\text{Cl}_2\text{H}^+$ ,  $\text{P}_2\text{H}^+$  and  $\text{Si}_2\text{H}^+$  are asymmetric rotors, very close to the prolate limit ( $\kappa = 0.999$ ). Therefore, these  
 278 species have three rotational constants and five quartic centrifugal distortion parameters.

279 The “CBS+CV+fT+fQ” level of theory augmented by vibrational corrections at the ae-CCSD(T)/cc-  
 280 pwCVQZ level of theory, provides the rotational constant for  $\text{N}_2\text{H}^+$  with an error as low as 0.01%, as shown

281 in Table S1. For HCO<sup>+</sup>, the error is slightly larger, this being 0.07%. However, both values are within the  
 282 uncertainty predicted by benchmark studies for the “CBS+CV+fT+fQ” approach (Puzzarini et al., 2008).  
 283 Even though N<sub>2</sub>H<sup>+</sup> and HCO<sup>+</sup> are linear molecules, the accuracy reached for such species should hold also  
 284 for the rotational constants of the bent Cl<sub>2</sub>H<sup>+</sup> cation and the cyclic P<sub>2</sub>H<sup>+</sup> and Si<sub>2</sub>H<sup>+</sup> species, at least when  
 285 the mean error of the three rotational constants is considered.

**Table 2.** Rotational parameters (in MHz) of Watson’s *S* reduced Hamiltonian (*I*<sup>r</sup> representation) for Cl<sub>2</sub>H<sup>+</sup>, P<sub>2</sub>H<sup>+</sup>, and Si<sub>2</sub>H<sup>+</sup>. Dipole moment components (in debyes) are also reported.

<sup>a</sup> Equilibrium rotational constants from the “CBS+CV+fT+fQ” approach. Dipole moments and NQCCs computed (CBS+CV+fT+fQ reference geometry) computed at the ae-CCSD(T)/aug-cc-pwCVQZ level. Vibrational corrections to the previous quantities and quartic centrifugal distortion constants at the ae-CCSD(T)/cc-pwCVQZ level of theory.

286 To accurately simulate rotational spectra, other parameters are required. These are the NQCCs of the  
 287 N and Cl atoms together with quartic centrifugal distortion constants for all species. As mentioned in  
 288 Computational details section, the latter parameters have been computed at the ae-CCSD(T)/cc-pwCVQZ  
 289 level of theory, while NQCCs have been obtained, on top of the “CBS+CV+fT+fQ” geometry, by computing  
 290 the electric-field gradient at the quadrupolar nuclei at the ae-CCSD(T)/aug-cc-pwCVQZ level. The NQCCs  
 291 have also been corrected for the vibrational contribution evaluated at the ae-CCSD(T)/cc-pwCVQZ level.

292 For N<sub>2</sub>H<sup>+</sup>, the experimental *D*<sub>*J*</sub> quartic centrifugal distortion constant is reproduced with a discrepancy  
 293 of about 3%, while for HCO<sup>+</sup> the error is 2%. Similar uncertainties are expected for the quartic centrifugal  
 294 distortion constants of the protonated species of Table 2. Moving to NQCCs, for N<sub>2</sub>H<sup>+</sup>, the discrepancy  
 295 with respect to experiment is on average 1% and, thus, a similar accuracy is expected for the constants of  
 296 Cl<sub>2</sub>H<sup>+</sup>, as found in other works in the literature (Cazzoli et al., 2006; Puzzarini et al., 2010).

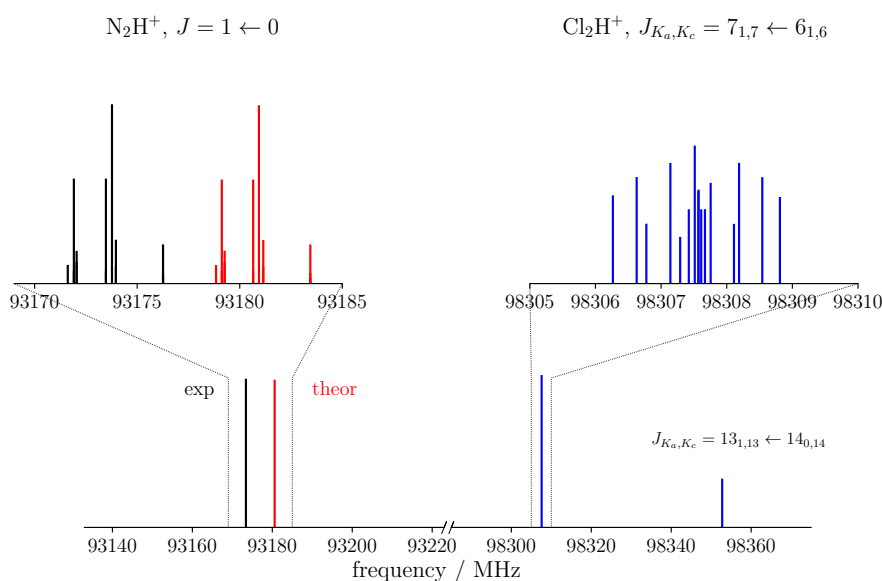

297 Finally, to simulate the rotational spectrum, the electric dipole moment components were computed at  
298 the same level of theory as NQCCs. The obtained values indicate that P<sub>2</sub>H<sup>+</sup> and Si<sub>2</sub>H<sup>+</sup> have a (very) weak  
299 *b*-type rotational spectrum, the only non-null dipole moment component ( $\mu_b$ ) being equal to 0.01 D. In the  
300 case of P<sub>2</sub>H<sup>+</sup>, the intensity of the rotational lines is also affected by spin statistics. Indeed, <sup>31</sup>P has a nuclear  
301 spin *I* of 1/2 (fermion) and the total wave function has to be anti-symmetric with respect to the exchange of  
302 the two P nuclei. The electronic and vibrational ground states being total symmetric, the overall symmetry  
303 of the total wave function is determined by the rotational and nuclear terms. Three *ortho* (symmetric) and  
304 one *para* (anti-symmetric) states arise for the nuclear wave function. Instead, the symmetry of the rotational  
305 contribution is determined by the  $K_a + K_c$  sum<sup>1</sup> because the nuclei exchange occurs by rotation around  
306 the *b* axis. As a consequence, the rotational transitions associated with odd  $K_a + K_c$  values are three times  
307 more intense than those with even  $K_a + K_c$  values.

308 The Cl<sub>2</sub>H<sup>+</sup> species has both *a*-type and *b*-type spectra, the corresponding dipole moment components  
309 being 2.28 D and 1.57 D, respectively. Thus, *a*-type transitions should have an intensity comparable to that  
310 of N<sub>2</sub>H<sup>+</sup> and HCO<sup>+</sup>, while *b*-type transitions are expected to be weaker. An example is shown in fig. 3,  
311 where the blue spectrum reports a  $\mu_a$  transition of Cl<sub>2</sub>H<sup>+</sup> at around 98307 MHz and a weaker  $\mu_b$  transition  
312 predicted at 98352 MHz. These are compared with the  $J = 1 \leftarrow 0$  transition of N<sub>2</sub>H<sup>+</sup>, for which both the  
313 theoretical simulation (this work, in red) and the experimental data (Cazzoli et al. (2012), in black) are  
314 considered. The experimental transition occurs at 93173 MHz and the theoretical simulation lies close in  
315 frequency, indeed being centered at 93181 MHz. In relative terms, this discrepancy should also apply to the  
316 simulation of Cl<sub>2</sub>H<sup>+</sup>. Conservatively, based on benchmark studies (Alessandrini et al., 2018), an uncertainty  
317 of 0.1% can be expected for each rotational constant of Cl<sub>2</sub>H<sup>+</sup>. This would locate the  $J_{K_a, K_c} = 7_{1,7} \leftarrow 6_{1,6}$   
318 transition of fig 3 in the range  $98307.6 \pm 18$  MHz ( $3\sigma$  deviation). Lastly, the two insets of fig. 3 show the  
319 hyperfine splittings based on the computed NQCCs. For N<sub>2</sub>H<sup>+</sup>, the structure reproduces very well the  
320 experimental one in terms of both intensity and shift with respect to the unperturbed frequency. The same  
321 should apply to Cl<sub>2</sub>H<sup>+</sup>.

322 For Cl<sub>2</sub>H<sup>+</sup>, P<sub>2</sub>H<sup>+</sup>, and Si<sub>2</sub>H<sup>+</sup>, vibrational frequencies have been obtained at the ae-CCSD(T)/cc-pwCVQZ  
323 level. The results are reported in Table 3, while those of N<sub>2</sub>H<sup>+</sup> and HCO<sup>+</sup> are provided in the SM,  
324 where they are also compared with the experimental counterparts. To understand the accuracy of the  
325 predictions for the protonated species addressed in this work, we start by analyzing the results for N<sub>2</sub>H<sup>+</sup>  
326 and HCO<sup>+</sup>. For the former cation, the lowest fundamental frequency is due to the bending mode. This  
327 is predicted at  $700.94 \text{ cm}^{-1}$  within the harmonic approximation and about  $9 \text{ cm}^{-1}$  lower in energy at  
328 the anharmonic level. The experiment locates this band at  $698.6353(14) \text{ cm}^{-1}$  (Foster and McKellar,  
329 1984). The other two bands of N<sub>2</sub>H<sup>+</sup> were observed at  $3233.96085 \text{ cm}^{-1}$  (Nakanaga et al., 1990) and  
330  $2257.8667(13) \text{ cm}^{-1}$  (Owrutsky et al., 1986). Both of them are well predicted by the VPT2 treatment, with  
331 an error of only  $8 \text{ cm}^{-1}$ . For HCO<sup>+</sup>, the fundamental bands are predicted (incorporating anharmonicity)  
332 to lie at  $\nu_1 = 3090.31 \text{ cm}^{-1}$ ,  $\nu_2 = 2187.67 \text{ cm}^{-1}$ , and  $\nu_3 = 830.05 \text{ cm}^{-1}$ . These are in good agreement  
333 with the experimental data, with discrepancies of about  $2 - 4 \text{ cm}^{-1}$ . In fact, the experimental observed  
334 frequencies are:  $\nu_1 = 3088.7951(31) \text{ cm}^{-1}$  (Amano, 1983),  $\nu_2 = 2183.9496(6) \text{ cm}^{-1}$  (Foster and  
335 McKellar, 1984), and  $\nu_3 = 828.2305(9) \text{ cm}^{-1}$  (Kawaguchi et al., 1985).

336 A similar accuracy is expected for the other protonated diatomics. The lowest fundamental band is  
337 observed for the stretching involving third-row atoms ( $\nu_2$  band for P<sub>2</sub>H<sup>+</sup> and Si<sub>2</sub>H<sup>+</sup>,  $\nu_3$  band for Cl<sub>2</sub>H<sup>+</sup>).

<sup>1</sup> The asymmetric rotor energy levels are labeled using (in addition to the *J* quantum number) two “pseudo” quantum numbers:  $K_a$  and  $K_c$ , which correspond to the *K* values of the two limiting prolate (referred to the *a* symmetry axis) and oblate (referred to the *c* symmetry axis) cases of the symmetric rotor, respectively.

**Figure 3.** Theoretical (red) and experimental (black)  $J = 1 \leftarrow 0$  transition of  $\text{N}_2\text{H}^+$  compared with the simulated spectrum of  $\text{Cl}_2\text{H}^+$  (blue) in the nearby frequency region. For the latter, both  $a$ -type ( $J_{K_a, K_c} = 7_{1,7} \leftarrow 6_{1,6}$ ) and  $b$ -type ( $J_{K_a, K_c} = 13_{1,13} \leftarrow 14_{0,14}$ ) transitions are visible. The two insets show the hyperfine structures due to nitrogen and chlorine nuclei for  $\text{N}_2\text{H}^+$  and  $\text{Cl}_2\text{H}^+$ , respectively.

338 This vibrational mode lies at  $518.0 \text{ cm}^{-1}$  for  $\text{Cl}_2\text{H}^+$ ,  $728.05 \text{ cm}^{-1}$  for  $\text{P}_2\text{H}^+$ , and  $459.89 \text{ cm}^{-1}$  for  $\text{Si}_2\text{H}^+$ .  
 339 The  $\nu_3$  band for  $\text{P}_2\text{H}^+$  and  $\text{Si}_2\text{H}^+$ , and the  $\nu_2$  band for  $\text{Cl}_2\text{H}^+$  correspond to the asymmetric stretching  
 340 involving the H atom, which is predicted at  $949.02 \text{ cm}^{-1}$ ,  $971.54 \text{ cm}^{-1}$ , and  $858.1 \text{ cm}^{-1}$  for  $\text{Si}_2\text{H}^+$ ,  $\text{P}_2\text{H}^+$ ,  
 341 and  $\text{Cl}_2\text{H}^+$ , respectively. The fundamental frequencies for symmetric stretching ( $\nu_1$ ) are, in the same order  
 342 as before,  $1435.82 \text{ cm}^{-1}$ ,  $1659.00 \text{ cm}^{-1}$ , and  $2619.23 \text{ cm}^{-1}$ . For the  $\text{Cl}_2\text{H}^+$  species, the most intense band  
 343 is  $\nu_1$ , while for  $\text{P}_2\text{H}^+$  and  $\text{Si}_2\text{H}^+$  it is  $\nu_3$ . In conclusion, in view of their accuracy – which is conservatively  
 344 expected to be better than  $10 \text{ cm}^{-1}$  – the data obtained in this work can allow the investigation of the  
 345 vibrational spectrum of these species as well as the ro-vibrational ones <sup>2</sup>.

### 346 3.2.2 CNNCH<sup>+</sup> and NCCNH<sup>+</sup>

347 The rotational parameters of CNNCH<sup>+</sup> are compared with those of NCCNH<sup>+</sup> in Table 4. The error  
 348 associated with our computational strategy can be derived by considering the experimental values of  
 349 NCCNH<sup>+</sup> (Gottlieb et al., 2000). For  $B_0$  of NCCNH<sup>+</sup>, the discrepancy between experiment and theory is  
 350 about 4 MHz, which means 0.09% in relative terms; thus, the value of the rotational constant of CNNCH<sup>+</sup>  
 351 lies within the interval  $5225.59 \text{ MHz} \pm 4.7 \text{ MHz}$ . For  $D_J$  of NCCNH<sup>+</sup>, the deviation of the computed  
 352 value ( $0.480 \times 10^{-3} \text{ MHz}$ ) from experiment is 9.3% and the same confidence range is expected to apply  
 353 to CNNCH<sup>+</sup>. Moving to NQCCs, in both molecules, we have two nitrogen atoms which are denoted as  
 354 the outer N and the inner N; while such denotation is rather straightforward for NCCNH<sup>+</sup>, in the case of  
 355 CNNCH<sup>+</sup>, the outer N is the furthest from H, i.e. N2 in fig. 1. In NCCNH<sup>+</sup>, the NQCC of the outer N is  
 356 well reproduced, the error being 0.2%, while a discrepancy of about 12% is noted for the inner NQCC, the  
 357 experimental value being 0.250 MHz and the computed one 0.221 MHz. However, it has to be noted that  
 358 the absolute discrepancy is nearly the same:  $\sim 50 \text{ kHz}$  for  $\chi(\text{outer})$  and  $\sim 30 \text{ kHz}$  for  $\chi(\text{inner})$ . Therefore,  
 359 the hyperfine splittings are well reproduced as shown in the left inset in fig. 4, where the experimental

<sup>2</sup> For those interested in the prediction of the rotational constants of vibrational excited states, the required  $\alpha_r^2$  values are available in Table S2

**Table 3.** Harmonic and anharmonic vibrational frequencies (cm<sup>-1</sup>) for Cl<sub>2</sub>H<sup>+</sup>, P<sub>2</sub>H<sup>+</sup>, and Si<sub>2</sub>H<sup>+</sup>. Anharmonic intensities in km·mol<sup>-1</sup>. All quantities are at the ae-CCSD(T)/cc-pwCVQZ level of theory.

Cl <sub>2</sub> H <sup>+</sup>			
Mode <sup>a</sup>	Harm. Freq.	Frequency	Intensity
$\nu_1$ A'	2740.60	2619.23	234.4
$\nu_2$ A'	880.69	858.10	19.0
$\nu_3$ A'	525.24	518.05	13.4
P <sub>2</sub> H <sup>+</sup>			
	Harm. Freq.	Frequency	Intensity
$\nu_1$ A <sub>1</sub>	1793.54	1659.00	433.8
$\nu_2$ A <sub>1</sub>	737.32	728.05	0.71
$\nu_3$ B <sub>2</sub>	1095.77	971.54	1376.9
Si <sub>2</sub> H <sup>+</sup>			
	Harm. Freq.	Frequency	Intensity
$\nu_1$ A <sub>1</sub>	1518.28	1435.82	1120.2
$\nu_2$ A <sub>1</sub>	468.18	459.89	10.2
$\nu_3$ B <sub>2</sub>	1063.83	949.02	1675.0

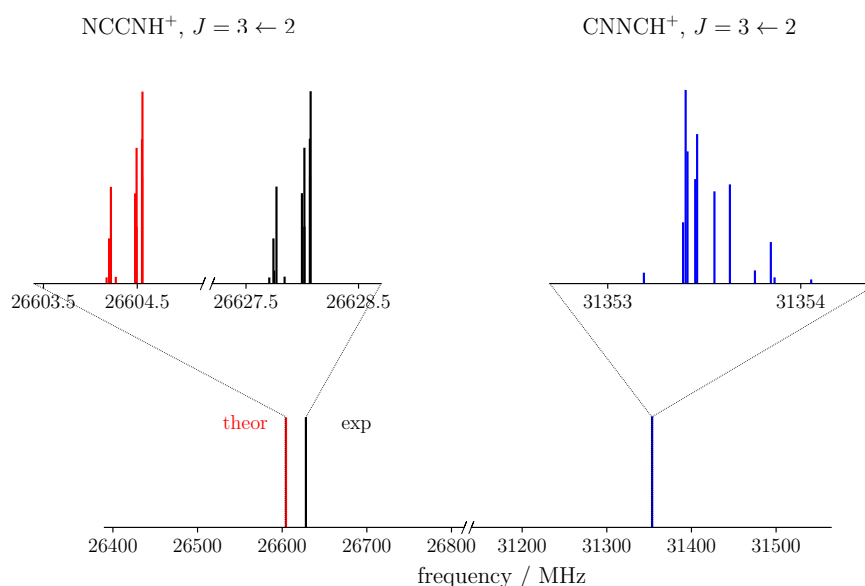

<sup>a</sup> The symmetry of the normal mode is given in parentheses.

360 and theoretical hyperfine structures of the  $J = 3 \leftarrow 2$  transition of NCCNH<sup>+</sup> are depicted. Focusing on  
 361 the unperturbed transition, the experimental frequency of NCCNH<sup>+</sup> is 24 MHz lower than the simulated  
 362 one. This deviation can be considered as the uncertainty affecting the  $J = 3 \leftarrow 2$  transition of CNNCH<sup>+</sup>,  
 363 which is shown in fig. 4 together with its hyperfine structure. Concerning the latter, an analogous accuracy  
 364 to that observed for NCCNH<sup>+</sup> is expected. Indeed, in absolute terms, the uncertainty affecting NQCCs  
 365 should be of the order of 50 kHz. Since the dipole moment of CNNCH<sup>+</sup> is large (about 6 D) and only 0.4 D  
 366 smaller than that of NCCNH<sup>+</sup>, the detection of this new protonated form is reasonable and future works  
 367 will benefit from the present data.

368 Table 4 also reports the fundamental frequencies and intensities of the vibrational modes for both  
 369 NCCNH<sup>+</sup> and CNNCH<sup>+</sup>. In this case, no experimental reference is available in the literature, but  
 370 vibrational frequencies computed at the ae-CCSD(T)/cc-pwCVTZ level are sufficiently accurate to guide  
 371 the assignment of the (ro-)vibrational spectrum for both species.

### 372 3.2.3 NCCHCHCNH<sup>+</sup>

373 The last molecule considered in this work is the *E* isomer of NCCHCHCNH<sup>+</sup>. According to the computed  
 374 electric dipole moment components, *a*-type transitions are the most prominent features of the rotational  
 375 spectrum because the associated dipole component is as large as 10.1 D. Based on the literature on this topic  
 376 (Puzzarini et al., 2008), in relative terms, the uncertainty affecting the equilibrium “CBS+CV” rotational  
 377 constants is expected to be 0.6%, which drastically reduces to about 0.1% when vibrational corrections  
 378 are incorporated. Actually, this uncertainty can be as small as 0.05%, as demonstrated, for example, by  
 379 Melosso et al. (2022); Alessandrini et al. (2021a). For an accurate simulation of the rotational spectrum of

**Figure 4.** Theoretical (red) and experimental (black)  $J = 3 \leftarrow 2$  transition of NCCNH<sup>+</sup> compared with the simulation of the same transition of CNNCH<sup>+</sup> (blue). The insets show in detail the corresponding hyperfine structures.

**Table 4.** Rotational parameters and fundamental vibrational frequencies of CNNCH<sup>+</sup> and NCCNH<sup>+</sup>.

<sup>a</sup> Values in MHz if not otherwise stated. Equilibrium rotational constants at the “CBS+CV” level of theory augmented by vibrational corrections at the revDSD/junTZ level. Quartic centrifugal distortion constants at the fc-CCSD(T)/junTZ level. Dipole moments (in debyes) and NQCCs computed at the same level of theory but on top of the “CBS+CV” geometry and vibrationally corrected at the revDSD/junTZ level. For further details see text. Watson’s *S* reduction in *I*<sup>\*</sup> representation is used. <sup>b</sup> The symmetry of the normal mode is given in parentheses. Vibrational frequencies and intensity computed at the revDSD/junTZ level of theory using GVPT2.

380 this species, the NQCCs of both nitrogen atoms have been computed, on top of the “CBS+CV” geometry,  
 381 at the fc-CCSD(T)/jun-cc-pVTZ level. Quartic centrifugal distortion constants have been obtained from  
 382 a harmonic force field at the same level of theory. All these data, collected in Table 5, can guide future  
 383 experimental measurements as well as astronomical search of this molecule in view of its large dipole  
 384 moment (in particular that associated with *a*-type transitions) and the small uncertainties affecting our  
 385 spectroscopic parameters. Notably, the observation of this species in the ISM would indirectly confirm  
 386 the feasibility of the reaction between the CN radical and vinyl cyanide, as suggested in Marchione et al.  
 387 (2022).

388 In Table 5, the vibrational fundamental frequencies of (*E*)-NCCHCHCNH<sup>+</sup> are reported. It is noted that  
 389 the strongest band is the one associated with the stretching of the terminal H atom. The weakest band  
 390 has an intensity of 0.6 km·mol<sup>-1</sup> and it is the out-of-plane bending of the CN and CNH terminal groups.

391 According to the literature on this topic (Barone et al., 2015), double-hybrid functionals should reproduce  
392 the experimental fundamental frequencies with a mean error of about 10.4 cm<sup>-1</sup>.

## 4 CONCLUSIONS

393 In the ISM conditions, protonation can occur easily thanks to the abundance of H<sub>3</sub><sup>+</sup>. For this reason,  
394 protonated forms of “invisible” (to rotational spectroscopy and thus to radioastronomy) apolar species  
395 are considered tracers of the latter and can be used to derive an estimate of their abundance. In this work,  
396 the presence of five new apolar species in the ISM has been suggested based on the investigation of the  
397 corresponding protonated forms: P<sub>2</sub>H<sup>+</sup>, Cl<sub>2</sub>H<sup>+</sup>, Si<sub>2</sub>H<sup>+</sup>, CNNCH<sup>+</sup>, and (*E*)-NCCHCHCNH<sup>+</sup>. These can  
398 be considered good proxies of P<sub>2</sub>, Cl<sub>2</sub>, Si<sub>2</sub>, CNNC, and (*E*)-NCCHCHCN, respectively. The most stable  
399 forms of these species have been preliminary investigated at the revDSD/junTZ level of theory. This  
400 pointed out that Cl<sub>2</sub>H<sup>+</sup> has a bent structure, while P<sub>2</sub>H<sup>+</sup> (in contrast with N<sub>2</sub>H<sup>+</sup> which is linear) and Si<sub>2</sub>H<sup>+</sup>  
401 have a cyclic structure. CNNCH<sup>+</sup> is linear in analogy to the NCCNH<sup>+</sup> isomer, which has been already  
402 characterized and detected in the ISM. Finally, a planar structure has been found for (*E*)-NCCHCHCNH<sup>+</sup>.

403 State-of-the-art computational methodologies have been used to assess the PA values of Cl<sub>2</sub>, P<sub>2</sub>, Si<sub>2</sub>,  
404 CNNC, and (*E*)-NCCHCHCN to be compared with that of H<sub>2</sub>. Indeed, a PA greater than that of H<sub>2</sub> implies  
405 that protonation due to H<sub>3</sub><sup>+</sup> is favored. This is the case for all the species considered in this study, and  
406 the computed PA values have been found in good agreement with experimental and previous theoretical  
407 estimates available in the literature. To give an example, the PA value of Cl<sub>2</sub>H<sup>+</sup> is in good agreement with  
408 the experimental counterpart reported by Cacace et al. (1998), the difference being only 0.5 kJ·mol<sup>-1</sup>.

409 To provide more details on the protonation mechanisms, the formation routes leading to Cl<sub>2</sub>H<sup>+</sup>, P<sub>2</sub>H<sup>+</sup>, and  
410 CNNCH<sup>+</sup> have been explored. The junChS+ZPE energies, evaluated on top of revDSD/junTZ geometries,  
411 pointed out the presence of simple reaction paths starting from the corresponding apolar species and H<sub>3</sub><sup>+</sup>.  
412 All these mechanisms are dominated by a barrierless step from reactants to adducts, but also from these  
413 latter to products. In all the three cases, the minimum energy path leads to the most stable protonated forms,  
414 namely bent Cl<sub>2</sub>H<sup>+</sup>, cyclic P<sub>2</sub>H<sup>+</sup>, and linear CNNCH<sup>+</sup>. The first two formation routes are similar to those  
415 producing N<sub>2</sub>H<sup>+</sup> and HCO<sup>+</sup>; therefore, it can be safely assumed that a similar mechanism leads to Si<sub>2</sub>H<sup>+</sup>.  
416 We also expect that the formation of (*E*)-NCCHCHCNH<sup>+</sup> presents similarity with that of CNNCH<sup>+</sup>.

417 Since the investigated protonated species are potentially present in the ISM, an accurate computational  
418 spectroscopic characterization has also been carried out. For protonated diatomics, the rotational constants  
419 are expected to reproduce the experimental counterparts with an error of 0.1%, or even smaller as in the  
420 case of HCO<sup>+</sup> and N<sub>2</sub>H<sup>+</sup>. For CNNCH<sup>+</sup>, and (*E*)-NCCHCHCNH<sup>+</sup>, because of the reduction in the level of  
421 theory employed, a larger uncertainty has been obtained, but still on the order of 0.1%. For all the species  
422 investigated, a full set of rotational parameters, also including quartic centrifugal distortion constants and  
423 NQCCs, has been obtained and used to estimate low-*J* rotational transitions. To give an example, the  
424  $J_{K_a, K_c} = 7_{1,7} \leftarrow 6_{1,6}$  rotational transition of Cl<sub>2</sub>H<sup>+</sup> is expected to lie in the range 98307.6 ± 18 MHz.  
425 For CNNCH<sup>+</sup>, the  $J = 3 \leftarrow 2$  rotational transition is predicted to be centered at around 30353.5 MHz  
426 with an uncertainty of about 24 MHz. The spectroscopic characterization of (*E*)-NCCHCHCNH<sup>+</sup> is of  
427 particular interest because it results from protonation of the *E* isomer of 1,2-dicyanoethene, which in turn  
428 is the main product of the reaction between the CN radical and acrylonitrile (Marchione et al., 2022). This  
429 reaction is of great astrochemical relevance, but the only possible option for detecting (*E*)-NCCHCHCN  
430 is via its protonated proxy. This work reports – for the first time – the rotational constants of this species  
431 and points out that protonation leads to a large dipole moment of about 10 D, which further suggests the

432 detectability of (E)-NCCHCHCNH<sup>+</sup>. Therefore, our simulations will be useful to support and complement  
433 experimental measurements as well as to guide tentative detections or assignments.

434 For all the aforementioned molecules, the fundamental vibrational frequencies have accurately obtained  
435 by exploiting a methodology that incorporates the effects of anharmonicity. Therefore, the expected  
436 accuracy of our predictions is 10 cm<sup>-1</sup> or even better, which is largely sufficient for the assignment of  
437 experimental infrared bands.

## CONFLICT OF INTEREST STATEMENT

438 The authors declare that the research was conducted in the absence of any commercial or financial  
439 relationships that could be construed as a potential conflict of interest.

## AUTHOR CONTRIBUTIONS

440 SA worked on conceptualization of the work as well as investigation. SA, LB and MM carried out the  
441 formal analysis and wrote a first draft of the manuscript. CP reviewed the manuscript and provided the  
442 funding. Final editing was carried out by CP, LB, MM and SA.

## FUNDING

443 This work has been supported by MIUR (PRIN Grant Number 202082CE3T) and by the University of  
444 Bologna (RFO funds). The COST Action CA21101 “COSY - Confined molecular systems: from a new  
445 generation of materials to the stars” is also acknowledged. This work was supported by the Open Access  
446 Publishing Fund of the Scuola Normale Superiore.

## ACKNOWLEDGEMENTS

447 The SMART@SNS Laboratory (<http://smart.sns.it>) is acknowledged for providing high-  
448 performance computing facilities.

## SUPPLEMENTAL DATA

449 Supplementary Material collects the rotational parameters and vibrational frequencies of N<sub>2</sub>H<sup>+</sup> and HCO<sup>+</sup>  
450 and their comparison with experiment. For these, also vibration-rotation interaction constants are provided  
451 together with those of Cl<sub>2</sub>H<sup>+</sup>, P<sub>2</sub>H<sup>+</sup>, and Si<sub>2</sub>H<sup>+</sup>. The optimized structural parameters at different level of  
452 theory are reported for all the molecules of this work. In the last section, the energy values of the stationary  
453 points involved in the formation routes of fig. 2 are given.

## DATA AVAILABILITY STATEMENT

454 The original contributions presented in the study are included in the article/supplementary material, further  
455 inquiries can be directed to the corresponding author.
