### **Cell Adhesion on Nanometer Scale Protein Patterns with Micrometer Scale Spacings**

*D. Vurmaz<sup>1</sup>, G. Oyman<sup>1</sup>, D. Pesen Okvur<sup>1</sup>; <sup>1</sup>Izmir Institute of Technology, Izmir, Turkey*

Surface patterning techniques are proving to be tremendously useful for cell biology applications. Electron beam lithography (EBL) is a high resolution, flexible direct patterning method used in semiconductor industry. We have previously developed an EBL based patterning approach which directly uses proteins as EBL resists on silicon surfaces. However, silicon is not transparent and thus not suitable for many light microscopy techniques. On the other hand, indium tin oxide coated glass (ITO-glass) is suitable for light microscopy due to its transparent nature; it is also conductive and can thus be used for EBL. Our results show that nanometer scale patterns of the cell adhesion promoting protein fibronectin (FN) can be fabricated on ITO-glass surfaces. We show that using lines in the design and choosing micrometer scale step sizes, protein nanopatterns can be fabricated with the added advantage of significantly reduced exposure times (from days to minutes). We determine that a minimum dose of 50 pAs/cm is required for pattern formation and FN nanodot radius increases linearly from  $118 \pm 5$  nm to  $326 \pm 9$  nm as dose increases from 212 to 1000 pAs/cm. In addition, we test the effect of micrometer scale spacing between and size of protein nanopatterns on cell adhesion. We show that cells respond to protein nanopatterns on ITO-glass by forming pattern specific focal adhesions. While cells do not form focal adhesions on FN nanodots with radius of 100 nm, they do so on FN nanodots with radii of 200 and 400 nm. Furthermore, number and maturation of focal adhesions is inversely correlated with spacing between nanodots namely two, four and eight microns.

**Tracking cytoplasmic flow during development and regeneration of *Stentor coeruleus***

J. Sheung<sup>1,2</sup>, B. Prevo<sup>1</sup>, P. Gross<sup>1</sup>, M. Slabodonick<sup>1,3</sup>, W. F. Marshall<sup>1,3</sup>; <sup>1</sup>Physiology Course, Marine Biological Laboratory, Woods Hole, MA, <sup>2</sup>Physics, University of Illinois, Urbana-Champaign, IL, <sup>3</sup>Biochemistry, UCSF, San Francisco, CA

The mechanisms that determine the shape of cells remain largely unknown. The giant ciliate *Stentor* has a complex structure that can regenerate after perturbations. *Stentor* morphogenesis faces many of the same problems as development of multicellular embryos, raising the question of whether gradients of diffusible morphogens may play a role in spatial patterning. The times-scale required to establish such a gradient, and the sensitivity of this gradient to external input and its stability in space and time impose contradictory constraints on the rheological properties of the cytoplasm, with the former requiring the fluidity typical of a low Reynold's number material and the later requiring the viscosity typical of a high Reynold's number material. *Stentor coeruleus*, one of the largest known unicellular ciliates measuring in at millimeters in length, is capable of complete regeneration of its asymmetric and highly complex structure from a cell fragment over minutes as long as one of its nuclei remains intact. Its ability to do so implies that it has found a way around the conundrum, and the molecular mechanism by which this is done is not well understood. In a series of experiments conducted during the Physiology Course at the Marine Biological Laboratory, we studied the cytoplasmic streaming of *Stentor* treated with various drugs targeting the cytoskeleton including AMP-PNP, paclitaxel, blebbistatin, and cytochalasin D, and compared with the wild-type. Using Particle Image Velocimetry (PIV) techniques implemented in MatLAB, we extracted local flow vectors over time inside *Stentors* immobilized in 4% methylcellulose and visualized by DIC microscopy. The flow in the main body of the animal is circumferential in the dorsal-ventral plane and can travel across the cell in minutes, whereas the flow in the tail is highly linear. None of the drug treatments lead to statistically significant changes in the flow patterns, flow velocities, and length scales of flow persistence across both time and space. Preliminary data on real-time cytoplasmic flow of *Stentor* right after a clean cut divided the cell into two halves show that the cytoplasmic flow changes immediately, not only preventing the cytoplasm from leaking out of the gap in the membrane, but also actively flowing back towards the center of the cell.

**Functional interplay between cell cycle and cell phenotypes.**

W-C. Chen<sup>1,2</sup>, P-H. Wu<sup>2</sup>, J. M. Phillip<sup>1</sup>, S. B. Khatau<sup>1</sup>, J. Choi<sup>1</sup>, M. R. Dallas<sup>1</sup>, K. Konstantopoulos<sup>1</sup>, S. X. Sun<sup>3</sup>, J. S. Lee<sup>4</sup>, D. Hodzic<sup>5</sup>, D. Wirtz<sup>1</sup>; <sup>1</sup>Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, <sup>2</sup>Johns Hopkins Physical Science - Oncology Center, Baltimore, MD, <sup>3</sup>Mechanical Engineering, Johns Hopkins University, Baltimore, MD, <sup>4</sup>Center for Strategic Scientific Initiatives, National Cancer Institute, Bethesda, MD, <sup>5</sup>Ophthalmology, Washington University School of Medicine, St. Louis, MO

Cell cycle distribution of adherent cells is typically assessed using flow cytometry, which precludes the measurements of cell phenotypes and their cycle phase in the same environment. Here we use a microscopy system to simultaneously and quantitatively analyze the cell-cycle phase of thousands of cells and their associated cell properties. This assay demonstrates that population-averaged cell phenotypes can be written as a linear combination of cell-cycle fractions and phase-dependent phenotypes. By perturbing cell cycle through forced cell synchronization and inhibition of cell-cycle regulators or changing nuclear morphology by depletion of structural proteins, our results reveal that cell cycle regulators Cdk4/6 and structural proteins Nesprins and Lamin A/C significantly interfere with each other's *prima facie* functions. This study introduces a high-throughput method to simultaneously measure cell cycle and

phenotypes at single-cell resolution and highlights the functional interplay between cell cycle and cell phenotypes.

**Thermorheology of living cells.**

*T. R. Kiessling<sup>1</sup>, A. W. Fritsch<sup>1</sup>, R. Stange<sup>1</sup>, J. A. Käs<sup>1</sup>; <sup>1</sup>Institute for Experimental Physics I, University of Leipzig, Leipzig, Germany*

Within reasonable temperature ranges, many biological functions are known to undergo modulations, like myosin motor activity, CO<sub>2</sub> uptake of cultured cells or sex determination of several species. As mechanical properties of living cells are considered to play a key role for plenty of cell functions - ranging from stem cell differentiation to cancer progression - it is surprising that only little is known on how their rheology is affected by temperature. This might be due to the fact that a variation in temperature triggers complex regulatory processes and alterations of the molecular architecture of cells. Rheological studies done so far have in common that temperature was varied exclusively on long timescales where the physical response of cellular matter is overlaid by complex biological alterations. Using an Optical Stretcher, we utilize laser induced heating to vary temperature on a millisecond timescale, while simultaneously probing the mechanical response of cells to optical force. In contrast to temperature variations on long timescales, milliseconds are probably too short for cells to react on a regulatory level. Surprisingly, we find that time-temperature superposition - a simple scaling concept frequently used in polymer physics - sufficiently describes the observed shift of creep compliance of whole living MCF10A breast epithelial cells upon temperature changes. From the found scaling factors, we derive the activation energy for the viscous flow to be on the order of 80kJ/mol, while it is not necessary to make any assumption about a specific viscoelastic model. Furthermore, we compare effects of short time temperature variations to those induced by temperature changes on long time scales and conclude that differences arise from cellular adaptation to temperature. Short time temperature variation is a powerful approach to explore pure physical responses and to separate them from those caused by biological adaptation. This could help to bridge the gap between the rheology of living matter and polymer physics. Furthermore, the revealed strong temperature dependence of the mechanical properties of cells has important implications for other studies on cells and cell mechanics.

**Insights into cytoplasmic rheology gained from modeling cellular blebbing.**

*W. Strychalski<sup>1</sup>, R. D. Guy<sup>1</sup>; <sup>1</sup>Mathematics, University of California, Davis, CA*

Blebbing occurs when the cytoskeleton detaches from the cell membrane, resulting in the pressure-driven flow of cytosol towards the area of detachment and the local expansion of the cell membrane. Recent experiments involving blebbing cells have led to conflicting hypotheses regarding the timescale of intracellular pressure propagation. The interpretation of one set of experiments supports a poroelastic cytoplasmic model which leads to slow pressure equilibration when compared to the timescale of bleb expansion. A different study concluded that pressure equilibrates faster than the timescale of bleb expansion. To address this, a dynamic computational model of the cell was developed that includes mechanics of and the interactions between the intracellular fluid, the actin cortex, the cell membrane, and the cytoskeleton. Results show the relative importance of cytoskeletal elasticity and drag in bleb expansion dynamics. Our results also show that a poroelastic model of the cytoplasm can explain experimental data and support the hypothesis that pressure equilibrates relatively fast.

**Interaction between Lung Cancer Cell and Myofibroblast Mediated by Cyclic Tensile Strain.**

C-H. Lee<sup>1,2</sup>, J-W. Huang<sup>3</sup>, H-J. Pan<sup>1</sup>, W-Y. Yao<sup>2</sup>, Y-W. Tsao<sup>1</sup>, C-W. Wu<sup>3</sup>, W-Y. Liao<sup>4</sup>, Y-C. Tung<sup>1</sup>; <sup>1</sup>Research Center for Applied Sciences, Academia Sinica, Taipei, Taiwan, <sup>2</sup>Institute of Biophotonics, National Yang-Ming University, Taipei, Taiwan, <sup>3</sup>Department of Mechanical and Mechatronic Engineering, National Taiwan Ocean University, Keelung, Taiwan, <sup>4</sup>Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan

Myofibroblasts (MFs) play important roles in the development and metastasis of tumors by exchanging major growth factors with the cancer cells. It is also well known that the phenotype of MFs is subject to the stimulations of mechanical tension. Therefore, it is intriguing to understand how mechanical tension is involved in cancer metastasis by mediating the activities of MFs. This topic is of special importance for lung cancers because cells near the lung keep experiencing cyclic tensile strain (CTS) along with breath. However, to quantify the degree of mechanical strain on the MF and to measure the migration ability of cancer cells in vivo are both difficult.

In this work we used a two-layer microfluidic cell-culture chip to introduce CTS on MFs, and characterized the migration speed of lung cancer cells under the influence of the conditioned medium of MF without and with the CTS. A 0.1-mm-thick PDMS film between the top and bottom layers of this culture chip was used as the stretchable substrate for the MF and the valves controlling the flows of the media. For better cell adhesion, we coated the surface of culture chambers with fibronectin. With an injected liquid volume of 50  $\mu$ l into the chamber under the PDMS film, the strain on this film was nearly 10%.

The cell lines used in this work were human lung cancer cells (CL1-0) and lung fibroblasts (MRC-5). Cells in the chip were cultured in Leibovitz L15 medium. Before the experiments, the MRC-5 cells were activated to be MF by 10 ng/ml transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1). The activation was confirmed by measuring the  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA), a major marker for MFs, in fixed cells. We measured that the expression level of  $\alpha$ -SMA in the MRC-5 cells was increased for 80% by TGF- $\beta$ 1.

We employed 0.27 Hz, 5-10% CTS on the MFs for 6 hours and let the conditioned medium of the MFs flow to the chamber of cancer cells. The migration speed was calculated from the displacements of cell centroids in the 6 hours. We found that the conditioned medium of MFs effectively increased the cancer cell motility, while the CTS significantly reduced the ability of MFs to enhance the migration speed of cancer cells. In the cell culture chip we also verified that the effect of CTS on the MF could be compensated by interleukin-1 $\beta$ . This result suggests that mechanical stimulations are involved in cancer metastasis through the modification of the phenotype of MF.

1753

**How growth cone leading edge dynamics alters with substrate adhesion.**

M. Knorr<sup>1</sup>, M. Ilse<sup>1</sup>, T. Claudepierre<sup>2</sup>, J. A. Käs<sup>1</sup>; <sup>1</sup>Institut für Experimentelle Physik 1, Universität Leipzig, Leipzig, Germany, <sup>2</sup>Klinik und Poliklinik für Augenheilkunde, Universitätsklinikum Leipzig, Leipzig, Germany

While growth cones move on two-dimensional substrates their leading edge alternates between rapid phases of protrusion and retraction. Actin polymerization underneath the plasma

membrane, that switches stochastically between On and Off states and a steady retrograde actin flow were found to be the driving forces of leading edge fluctuations. According to the adhesion clutch hypothesis a growth cone can only move forward if increased adhesion slows down retrograde flow and thus faster polymerization leads to net protrusion. What is still missing in this picture is how the stochastic nature of the leading edge contributes to growth cone advancement and how these dynamics are coupled to the substrate. Therefore, we measured the actin dynamics of retinal ganglion cell growth cones on substrates with specific (Laminin 1) and unspecific binding (poly-D-lysine) and compared retrograde flow velocity, protrusion and retraction speed of actin polymerization as well as stochastic switching times between protrusion and retraction events. We find that retrograde flow and retraction velocities are much faster for growth cones on poly-D-lysine, but protrusion velocity is similar for poly-D-lysine and Laminin. Analysis of stochastic switching show that alterations between protrusion and retraction events happen much faster on poly-D-lysine than on Laminin. These findings may lead to a deeper understanding on how the stochastic nature of growth cone actin dynamic can be classified in terms of growth cone motility.

**Precise assembly of multiscale and multicomponent 3D tissues.**

*M. Todhunter<sup>1</sup>, N. Jee<sup>1</sup>, J. S. Liu<sup>1</sup>, J. T. Farlow<sup>1</sup>, A. Cerchiari<sup>1</sup>, A. K. Paulson<sup>1</sup>, Z. J. Gartner<sup>1</sup>;  
<sup>1</sup>Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA*

The spatial arrangement of multiple cell types in three dimensions contributes to the functional properties of human tissues. To better understand how the arrangement of cells in a tissue affect the tissue's function, we have developed a bottom-up strategy for building components of the human mammary gland that are suitable for 3D in vitro culture and live cell imaging. The method provides 10  $\mu\text{m}$  resolution for the positioning of individual cells in the x and y directions and across distances greater than 1 cm. Using this approach, we are probing the role of microenvironment in driving the self-organization of luminal and myoepithelial cells in the human mammary epithelium, testing the capacity of epithelial tissues to buffer for cell-to-cell variability in growth rates during morphogenesis, and assessing how the spatial distribution of activated signaling nodes such as Ras affect multicellular behaviors that contribute to the form and function of a tissue.

1755

#### Regulation of the actin-activated MgATPase activity of *Acanthamoeba* myosin II by phosphorylation of serine 639 in motor domain loop 2.

X. Liu<sup>1</sup>, D-Y. Lee<sup>1</sup>, S. Cai<sup>1</sup>, M-S. Hong<sup>1</sup>, S. Shu<sup>1</sup>, R. L. Levine<sup>1</sup>, E. D. Korn<sup>1</sup>; <sup>1</sup>NHLBI, Bethesda, MD

*Acanthamoeba* myosin II (AMII) is a typical Class II myosin with a pair of identical 1509-residue heavy chains and two pairs of light chains. The C-terminal non-helical tailpiece that begins with Pro1483 contains 27 residues with a pattern of four continuous repeats of XXSXR. Previous studies identified that at least three of these serines were phosphorylated *in vivo* and *in vitro* and phosphorylation correlated with almost complete inactivation of actin-activated MgATPase activity. Several lines of evidence suggested that filamentous forms of AMII were required for the full activity. To understand the fundamental mechanisms we re-investigated these interesting issues by using recombinant AMII expressed in SF-9 cells. Here we show that two non-filamentous forms of AMII, heavy meromyosin and myosin subfragment, are very active and down-regulated by phosphorylation like full-length AMII. By mass spectroscopy, we show that Ser639 in loop 2 of the motor domain, in addition to the four serines in the non-helical tailpiece but no other residues, is phosphorylated by a partially purified kinase *in vitro* and Ser639 is also phosphorylated in inactive endogenous myosin isolated from the amoebae. Mutation of Ser639 to Ala in both subfragment 1 and full-length myosin does not affect actin-activated MgATPase. Phosphorylation of the serines in the non-helical tailpiece or their mutation to Glu or Asp does not affect the activity of S639A mutants. Conversely, S639D mutants of both subfragment 1 and full-length myosin are inactive irrespective of the phosphorylation state of the serines in the non-helical tailpiece. To our knowledge, *Acanthamoeba* myosin II is the first example of regulation of myosin actin-activated MgATPase activity by phosphorylation of loop 2. We further demonstrate by electron microscopy that phosphorylation of the serines in the non-helical tailpiece or their mutation to Glu alters the lateral association of AMII dimers in tetramers and octomers irrespective of mutation or phosphorylation of Ser639.

1756

#### *Dictyostelium* MHCK D exhibits lamellipodial localization in chemotaxing cells and is required for normal slug migration.

G. Anderson<sup>1</sup>, E. Lehman<sup>1</sup>, P. A. Steimle<sup>1</sup>; <sup>1</sup>Biology, University of North Carolina at Greensboro, Greensboro, NC

Contraction-dependent processes such as cytokinesis and cell migration rely on the proper assembly and localization of myosin II bipolar filaments. In *Dictyostelium* cells, as well as in mammalian cells, myosin II filament disassembly can be driven by phosphorylation of the myosin II heavy chain (MHC) "tail". MHC phosphorylation in *Dictyostelium* is catalyzed by at least three kinases (MHCK-A, -B, and -C) that share homologous alpha-kinase catalytic and WD-repeat domains. In the current study, we examined the cellular and biochemical characteristics of another *Dictyostelium* alpha kinase, MHCK-D, that possesses the same domain organization as the other MHCKs; and thus is predicted to function in a similar manner. We report here that over-expression of MHCK-D slows suspension growth, with cells becoming large and multinucleated over time; a phenotype consistent with a role for MHCK-D in driving myosin II filament disassembly. Moreover, *in vitro* kinase experiments revealed that MHCK-D

phosphorylates MHC to a stoichiometry of ~0.6 mol/mol MHC and in manner that leads to myosin II filament disassembly. RT-PCR analysis of expression revealed that MHCK-D, unlike the other MHCKs, is expressed only during *Dictyostelium* multicellular development (peak expression at ~16h). We also found that in live *Dictyostelium* cells GFP-tagged MHCK D exhibits robust and persistent localization to the leading edges of cellular extensions. By contrast, a truncation of MHCK-D lacking the WD-repeat domain localizes mainly to the cytoplasm, suggesting that the WD-repeat domain is involved in the targeting the kinase to cellular protrusions. Comparisons of *Dictyostelium* slug phototaxis between wild-type and *mhkD*-null cells revealed that the absence of MHCK-D leads to increased slug migration. Taken together, our results demonstrate that MHCK-D is a bone fide myosin II heavy chain kinase in *Dictyostelium* that is likely to function in myosin II filament turnover at the leading edges of migrating cells, and that MHCK-D plays a critical role in facilitating the highly complex process of multicellular slug migration.

1757

### **UCS protein Rng3p stabilizes myosin-II motor activity to initiate actomyosin ring assembly in fission yeast.**

B. C. Stark<sup>1</sup>, V. Sirotkin<sup>2</sup>, M. Lord<sup>1</sup>; <sup>1</sup>Molecular Physiology & Biophysics, University of Vermont, Burlington, VT, <sup>2</sup>Cell & Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

UCS proteins have been proposed to operate as co-chaperones that function with Hsp90 during the de novo folding of myosin-II motors. We show that the fission yeast UCS protein, Rng3p, is recruited to pre-assembled actomyosin ring structures and promotes ring assembly. Isolation of Myo2p in the absence of Rng3p function demonstrated that it is not required for Myo2p folding or actin binding but is essential for its ATPase activity and actin filament motility. A mutant form of Myo2p, hypersensitive to reduced Rng3p function (Myo2-E1p), binds actin filaments yet lacks motor activity and exhibits conformational instability. Rng3p is specific to Myo2p, however we could artificially target Rng3p to myosin-I patches using a point mutant that destabilizes the motor. We propose a novel role for UCS proteins in myosin stabilization and activation that responds to the accumulation of a critical concentration of motors. We predict this role is independent of de novo folding involving Hsp90 .

1758

### **Genetic Replacement of Nonmuscle Myosin (NM) IIA with NM IIC1-GFP In Vivo.**

Y. Zhang<sup>1</sup>, X. Ma<sup>1</sup>, R. S. Adelstein<sup>1</sup>; <sup>1</sup>LMC, NHLBI, NIH, Bethesda, MD

The purpose of this study is to learn whether NM IIC1 can functionally replace NM IIA, during mouse development. Alternative splicing of pre-mRNA encoding NMHC IIC generates several isoforms. An alternative exon encoding 8 amino acids can be incorporated near the ATP binding site at amino acid 227 to form NM IIC1. A second alternative exon encoding 41 amino acids can be incorporated near the actin binding site at amino acid 636 to form NM IIC2. Because NM IIC1 is the most abundant form of NM IIC expressed in a variety of tissues such as liver, kidney, testes, brain, and lung, we chose NM IIC1 to replace NM IIA in vivo. Previous work has shown that ablation of NM IIA results in lethality in mice at E6.5, prior to gastrulation, due to abnormalities in the visceral endoderm (Conti et al. JBC 279:41263, 2004). To replace NMHC IIA with NMHC IIC1 in the mouse, homologous recombination was used to ablate NMHC IIA by inserting the cDNA encoding NMHC IIC1-GFP into the first coding exon of the Myh9 gene to produce A<sup>C<sup>-</sup>GFP</sup>/A<sup>+</sup> mice. We have obtained heterozygous mice without apparent abnormalities however, the breeding of heterozygous mutant mice does not produce live homozygous A<sup>C<sup>-</sup>GFP</sup>/A<sup>C<sup>-</sup>GFP</sup> mice. Homozygous embryos die at approximately E10.5 after gastrulation, showing

that NM IIC1-GFP, by restoring a normal visceral endoderm, can support gastrulation. At both E9.5 and E10.5,  $A^{C^*-GFP/A^{C^*-GFP}}$  embryos are markedly smaller than wild-type littermates and are developmentally delayed. Cell proliferation is decreased while large numbers of apoptotic cells are found in homozygous embryos at these stages, indicating that the cause of embryonic lethality is related to cell death. Explants from the E9.5 embryos were cultured and MEF cell migration from the explants was recorded by time lapse microscopy. Compared to wild-type MEFs  $A^{C^*-GFP/A^{C^*-GFP}}$  MEFs display an increased speed of outgrowth. Furthermore the  $A^{C^*-GFP/A^{C^*-GFP}}$  MEFs are polarized, containing both larger ruffling lamellipodia and longer filopodia. Immunostaining shows that NM IIC1-GFP can be incorporated into stress fibers in  $A^{C^*-GFP/A^{C^*-GFP}}$  MEFs. However these stress fibers were fewer and less well-organized compared with wild-type cells. Focal adhesions in  $A^{C^*-GFP/A^{C^*-GFP}}$  MEFs are also fewer in number and smaller in size. These results indicate that although NM IIC1, which is not normally expressed in mice until E11, can restore a normal visceral endoderm at E6.5 it can't replace NM II-A's function in focal adhesion formation and maturation.

1759

### **Myosin IIA regulates the cellular architecture of podocyte.**

*H. Kurihara<sup>1</sup>, T. Sakai<sup>1</sup>; <sup>1</sup>Department of Anatomy, Juntendo University School of Medicine, Tokyo, Japan*

Podocytes are characterized by a large cell body and numerous foot processes. Cell body and primary processes contain microtubules and intermediate filaments, while foot processes have only actin filaments. Cytoskeletal organization in podocyte is a key factor for maintaining its cell shape. Especially, actin cytoskeleton may play a crucial role in the regulation of foot process structure, because the reorganization of actin-binding proteins causes the effacement or retraction of foot processes. Point mutations in MYH9, the gene encoding nonmuscle myosin heavy chain II-A (NMHCII-A), develop progressive glomerulosclerosis. However, the roles of myosin IIA in kidney are not elucidated. Our preliminary study showed that podocytes specifically express myosin IIA, but not myosin IIB in glomerulus. Immunoelectron microscopy of myosin IIA resulted that myosin IIA is distributed in the cytoplasm of cell body and primary processes. Specialized localization is seen on the actin arc shown at the boundary between cell body and foot processes. The signals for myosin IIA were dramatically decreased in PAN nephrotic kidney, in which the morphological changes of podocytes including the effacement of foot processes were seen. In addition, myosin IIA was dephosphorylated under the nephrotic condition. We next examined the role of a cytoskeletal motor protein, myosin IIA in cell process formation by using immortalized rat podocyte cell lines which we have originally established. These cell lines express all of cytoskeletal proteins seen in vivo podocyte including alpha-actinin 4, vimentin and nestin intermediate filaments. Cytochalasin D treatment induces the rearrangement of vimentin and nestin intermediate filaments and cell process formation through the membrane retraction. Cell processes induced by cytochalasin D treatment contain bundled intermediate filaments never seen in the resting cells. Myosin IIA is located at the cell margin with actin filaments in resting cells, but the main signals for myosin IIA are colocalized with vimentin filaments after stimulation. Myosin IIA is also seen at the base between neighboring cell processes with actin filaments, suggesting that the membrane retraction is achieved by the mechanical force of actomyosin. Treatment of blebbistatin, myosin II inhibitor reduced the morphological change of cultured podocytes induced by cytochalasin D. Myosin IIA silencing using siRNA is associated with significantly reduced cell process formation and inhibition of intermediate filament bundling. In conclusion, myosin IIA is expressed in podocyte and could play an important role in maintaining the structural integrity of podocytes.

1760

**Role of Nonmuscle Myosin IIB in Cancer Cell Invasion through 3-Dimensional Matrix.**

*D. G. Thomas<sup>1</sup>, A. Rape<sup>2</sup>, Y-L. Wang<sup>2</sup>, H. Baskaran<sup>3</sup>, T. Egelhoff<sup>1</sup>; <sup>1</sup>Cell Biology, Cleveland Clinic Lerner Research Institute, Cleveland, OH, <sup>2</sup>Biomedical Engineering, Carnegie Mellon, Pittsburgh, PA, <sup>3</sup>Biomedical Engineering, CWRU, Cleveland, OH*

Tumor metastasis is a complex process that involves the migration of a tumor cell from the primary tumor to distant organs. A major component to cellular migration is the motor protein nonmuscle myosin II (NMII). NMII is expressed in mammalian cells to regulate cellular structure and cytoskeletal dynamics. The three nonmuscle isoforms (IIA, IIB, and IIC) are expressed in tissue and cell type specific patterns. Treatment of the murine mammary gland epithelial cell line, NMuMG, by transforming growth factor  $\beta$ -1 (TGF $\beta$ 1) induces an epithelial to mesenchymal change in morphology. During this transition, NMIIB is dramatically upregulated at both mRNA transcript and protein levels. This observation led our group to investigate if NMIIB is required for the invasion of tumor cells through a dense 3D collagen matrix.

We used a macrophage-stimulated migration assay, where the tumor cells enter a paracrine loop with macrophages to enhance the upward migration through a three-dimensional collagen gel. NMIIB knockdown in human breast carcinoma cells (MDA-MB 231) reduced tumor cell invasion by 85% compared to control. Similarly, the murine mammary tumor cell line (4T1) exhibited a 47% reduction in invasion in NMIIB knockdown cells compared to control.

To better understand the mechanism of which NMIIB knockdown inhibits migration, we are examining the contribution NMIIB plays in both the generation of traction stress to the extracellular environment as well as other aspects of cellular organelle organization and polarity. Knockdown of NMIIB in 4T1 cells, reduced the average traction stress of a cell 86% compared to scramble control ( $p < 0.05$ ). Knockdown of NMIIA, an abundant isoform in 4T1 cells failed to reduce the traction stress. Also, we are generating a collection of fluorescent protein-tagged organelle and nuclear markers to assess the role of NMIIB in cytoskeletal organization and cell polarity during 2D and 3D migration.

These data suggest that NMIIB plays an important role in tumor metastasis and invasion as by regulating a cell's interaction with its extracellular environment. Further studies are being pursued to identify mechanisms and possible therapeutic targets.

1761

**C2 insert containing isoform of Nonmuscle Myosin II-C is necessary for neuritogenesis of Neuro-2a cells.**

*S. Saha<sup>1</sup>, S. K. Dey<sup>1</sup>, A. Biswas<sup>2</sup>, P. Das<sup>1</sup>, M. R. Das<sup>1</sup>, S. S. Jana<sup>1</sup>; <sup>1</sup>Department of Biological Chemistry, IACS, Kolkata, India, <sup>2</sup>Infectious Disease & Immunology Division, IICB, Kolkata, India*

Nonmuscle myosin IIs (NM IIs) are ubiquitously expressed throughout the entire mammalian organism and play distinct roles in cell division, adhesion, and migration. Three isoforms of NM II: namely II-A, II-B and II-C are found in vertebrates. Recently, it has been shown that the heavy chain of NM II-C undergoes alternative splicing at loop1 and loop2 of the head region, and gives rise to four possible isoforms: NM II-C0, -C1, -C2, -C1C2. C2 insert containing isoforms NM II-C2 and NM II-C1C2, are specifically expressed in mouse and human brain, and their ATPase and in vitro motility activities are independent of myosin light chain phosphorylation. However, the functional role of these alternatively spliced isoforms is unknown. Here, we report for the first time that the expression of the C2 insert containing isoform, NM II-C1C2 is inducible in Neuro-2a cells during differentiation both at mRNA and protein levels. Immunoblot and RT-PCR analysis reveal that expression of NM II-C1C2 peaks between days 3-

6 of differentiation. Localization of NM II-C2 and -C1C2 in Neuro-2a cells suggest that C2 insert containing isoforms are localized in the cytosol and along the neurites, specifically at adherence point to substratum. Inhibition of endogenous NM II-C1C2 using siRNA decreases the neurite length by 43% compared with control cells treated with nonspecific siRNA. Time lapse image analysis reveals that neurites of C2-siRNA treated cells have a net negative change in neurite length per minute, leading to reduction of overall neurite length. During the neuritogenesis, NM II-C1C2 can interact and colocalize with  $\beta$ 1-integrin in neurites as assessed by immunoprecipitation and immunofluorescence studies. Altogether, these studies indicate that NM II-C2 may be involved in stabilizing neurites by maintaining their stable structure at adhesion sites

1762

**Myosin II isoforms self-organize characteristic contractile units in actomyosin bundles.**

*T. Thoresen<sup>1</sup>, M. Gardel<sup>1</sup>; <sup>1</sup>Institute for Biophysical Dynamics, University of Chicago, Chicago, IL*

Diverse myosin II isoforms regulate contractility of actomyosin bundles in disparate physiological processes by variations in both motor mechanochemistry and the extent to which motors are clustered into thick filaments. While the role of mechanochemistry is well appreciated, the extent to which thick filament size regulates actomyosin contractility is unknown. Here we studied the contractility of minimal actomyosin bundles formed in vitro by mixtures of F-actin and thick filaments of non-muscle, smooth and skeletal muscle myosin isoforms with varied thick filament size. The diverse myosin II isoforms guide the self organization of distinct contractile units within in vitro bundles with measured shortening rates similar to those of in vivo myofibrils and stress fibers. The frequency of self-organized contractile units along the bundle is proportional to the thick filament size, resulting in a bundle shortening rate that is proportional to thick filament size. These experiments provide insight into the regulation of smooth muscle contractility where thick filament size is dynamically regulated. We develop a model that describes our data, providing a framework in which to understand how diverse myosin II isoforms regulate the contractile behaviors of actomyosin bundles found in muscle and non-muscle cells.

**F-actin Buckling Coordinates Contractility and Severing in a Biomimetic Actomyosin Cortex.**

*M. P. Murrell<sup>1</sup>, M. Gardel<sup>1</sup>; <sup>1</sup>Institute for Biophysical Dynamics, University of Chicago, Chicago, IL*

Myosin II motors drive contractility of the cortical actin network, enabling shape change and cytoplasmic flows underlying diverse physiological processes ranging from cell division and migration to tissue morphogenesis. Yet, despite its importance, the mechanisms that describe contractility and the generation of mechanical forces within the cortex are not well understood. Here we recapitulate contractility in vitro, through the development of a minimal model of the cell actomyosin cortex by coupling a two-dimensional, cross-linked F-actin network decorated by myosin thick filaments to a model cell membrane. Myosin motors generate both compressive and tensile stresses on F-actin and consequently, induce large bending fluctuations. Over a large range of conditions, we show the extent of network contraction corresponds exactly to the extent of individual F-actin shortening via buckling. This demonstrates an essential role of buckling in facilitating local compression to enable mesoscale network contraction of up to 80% strain. Portions of F-actin with a radius of curvature  $\sim$ 300 nm are prone to severing and thus, compressive stresses mechanically coordinate contractility with F-actin severing, the initial step

of F-actin turnover. Finally, the F-actin curvature acquired by myosin-induced stresses can be further constrained by adhesion of the network to a membrane, accelerating filament severing but inhibiting the long-range transmission of the stresses necessary for network contractility. Thus, the extent of membrane adhesion can regulate the coupling between network contraction and F-actin severing. These data demonstrate the essential role of the non-linear response of F-actin to compressive stresses in potentiating both myosin-mediated contractility and filament severing. This may serve as a general mechanism to mechanically coordinate contractility and cortical dynamics across diverse actomyosin assemblies in smooth muscle and non-muscle cells.

#### **Tension-sensing by myosin motors as a function of duty-ratio and network stiffness**

*J. B. Alberts<sup>1</sup>, S. Stam<sup>2</sup>, M. L. Gardel<sup>2</sup>, E. M. Munro<sup>3</sup>; <sup>1</sup>Biology, University of Washington, Friday Harbor, WA, <sup>2</sup>Physics, University of Chicago, Chicago, IL, <sup>3</sup>Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL*

Motor proteins are critical to cells in processes such as cellular contractility, motility, cell division, and intracellular transportation and compartmentalization. Thus detailed simulations of these processes require motor representations that can be “benchmarked” to encapsulate key features of the biochemical and mechanical motor characteristics. Here we explore the feasibility of a simple two-spring motor model: we assign a measured crossbridge stiffness, powerstroke conformation change, and biochemical transition rates such that each individual *in silico* motor is a close abstraction (in these key features) of the real thing. We gain assurance in our model by mimicking experimental assays that measure the ability of myosin heads to translate actin filaments, both as a function of myosin density and load on the filament. Finally, we assemble these individual myosin motors into minifilaments to explore the fundamental units of actomyosin contraction. We discover that different isoforms of myosin—which may differ from each other mainly in duty-ratio—can serve to amplify or distribute load. This “tension-sensing” (or lack thereof) may be an important driver of the geometry and organization of contractile structures.

#### **Defining myosin relay domain interactions in muscle by mutation suppression.**

*S. I. Bernstein<sup>1</sup>, W. A. Kronert<sup>1</sup>, G. C. Melkani<sup>1</sup>, A. Melkani<sup>1</sup>; <sup>1</sup>Biology, San Diego State University, San Diego, CA*

The relay domain of myosin is proposed to be a key communicator element that interacts a) within the main body of the motor to sense the nucleotide state and b) with the converter domain to drive the power stroke and muscle contraction. We tested specific residues involved in these proposed interactions by engineering mutations at sites modeled to contact the relay domain and then making putative compensatory mutations within the relay domain. The mutant myosins were expressed transgenically in *Drosophila* indirect flight muscles, which allow assessment of myosin function *in vitro* and *in vivo*. We mutated residue R714 near the SH1-SH2 helix in the main body of myosin. We found that R714E myosin ATPase is reduced by ~80% and that no *in vitro* motility is detected. R714E organisms show myofibril assembly defects that are exacerbated with age and these organisms cannot fly. Putative compensatory mutation E499R in the relay domain improves ATPase activity so that there is only ~35% reduction compared to wild type. Further, R714E/E499R myosin moves actin filaments at ~30% of wild-type velocity. Normal myofibril assembly is restored and myofibrils are more stable, but no flight ability is present. We next studied mutation R759E in the converter domain. It depresses myosin ATPase activity, *in vitro* motility and flight ability. Although myofibrils

assemble normally, they degenerate as flies age. We inserted lysine mutations at putative interacting relay domain loop residues I508, N509 or D511 in an attempt to suppress the R759E mutant phenotypes. N509K dramatically rescues muscle structure and function, with significant increases in ATPase rates and in vitro motility. In contrast, D511K has no effects on R759E myosin and muscle, whereas the I508K/R759E double mutant myosin has no ATPase activity or in vitro motility. Overall our compensatory mutation approach shows that residue R714 in the main body of the myosin motor interacts with residue E499 of the relay domain and that relay residue N509 interacts with converter domain residue R759. These interactions are critical for normal ATPase activity, in vitro motility, myofibril assembly and/or stability and flight muscle function. Thus the specific residue contacts identified permit the myosin relay domain to communicate information between the nucleotide binding pocket and the converter domain and are essential for progress through the mechanochemical cycle that powers muscle contraction.

## Dynein

1766

### A 3.3-Å structure of the dynein motor domain.

*E. S. Gleave<sup>1</sup>, H. Schmidt<sup>1</sup>, A. P. Carter<sup>1</sup>; <sup>1</sup>MRC Laboratory of Molecular Biology, Cambridge, UK*

Dyneins are minus end directed microtubule motors which transport many intracellular cargos, are necessary for mitosis and allow the beating of cilia and flagella.

Dyneins are large multi subunit complexes with molecular weights in the megadalton (MDa) range. The heavy chain of dynein contains a 300 kDa motor domain, which is present in all members of the dynein family. The motor domain is comprised of a ring of six " ATPases Associated with diverse cellular Activities " (AAA+) domains. Hydrolysis of ATP at the AAA+ domains causes the relocation of the linker domain to generate the force which is required for the movement of dynein. It is not known how the linker interacts with the ring during the ATP hydrolysis cycle. We use X-ray crystallography and subsequent biochemical experiments to gain insight into this mechanochemical cycle.

We determined a 3.3-Å crystal structure of the *Saccharomyces cerevisiae* cytoplasmic dynein motor domain, crystallized without nucleotide. In this state the linker interacts with a conserved site on AAA5, which mutagenesis experiments show is functionally necessary. Nucleotide soaking experiments show that the main ATP hydrolysis site (AAA1) is in a low-nucleotide affinity state and gives insight to the nucleotide interactions of three other sites (AAA2, AAA3 and AAA4).

### How Dynein and Microtubules Rotate the Nucleus.

*J. Wu<sup>1</sup>, R. B. Dickinson<sup>1</sup>, K. C. Lee, T. P. Lele<sup>1</sup>; <sup>1</sup>Chemical Engineering, University of Florida, Gainesville, FL*

In living cells, a fluctuating torque is exerted on the nuclear surface but the origin of the torque is unclear. In this study, we found that the nuclear rotation angle is directionally persistent on a time scale of tens of minutes, but rotationally diffusive on longer time scales. Rotation required the activity of the microtubule motor dynein. We formulated a model based on microtubules undergoing dynamic instability, with tensional forces between a stationary centrosome and the nuclear surface mediated by dynein. Model simulations suggest that the persistence in rotation angle is due to the transient asymmetric configuration of microtubules exerting a net torque in

one direction until the configuration is again randomized by dynamic instability. The model predicts that the rotational magnitude must depend on the distance between the nucleus and the centrosome. To test this prediction, rotation was quantified in patterned cells in which the cell's centrosome was close to the projected nuclear centroid. Consistent with the prediction, the angular displacement was found to decrease in these cells relative to unpatterned cells. This work provides the first mechanistic explanation for how nuclear dynein interactions with discrete microtubules emanating from a stationary centrosome cause rotational torque on the nucleus.

**Effects of Molecular Motors on Microtubule Mechanics.**

J. Wu<sup>1</sup>, N. Shekhar<sup>1</sup>, G. Misra<sup>1</sup>, R. J. Russell<sup>1</sup>, A. J. Ladd<sup>1</sup>, R. B. Dickinson<sup>1</sup>, T. P. Lele<sup>1</sup>;  
<sup>1</sup>Chemical Engineering, University of Florida, Gainesville, FL

In order to determine forces on intracellular microtubules, we measured shape changes of individual microtubules following laser severing in bovine capillary endothelial (BCE) cells. Surprisingly, regions near newly created minus ends increased in curvature following severing, while regions near new microtubule plus ends depolymerized without any observable change in shape. With dynein inhibited, regions near severed minus ends straightened rapidly following severing. These observations suggest that dynein exerts a pulling force on the microtubule which buckles the newly created minus end. Moreover, the lack of any observable straightening suggests that dynein prevents lateral motion of microtubules. To explain these results, we developed a model for intracellular microtubule mechanics which predicts the enhanced buckling at the minus end of a severed microtubule. Our results show that microtubule shapes reflect a dynamic force balance, in which dynein motor and friction forces dominate elastic forces arising from bending moments. A centrosomal array of microtubules subjected to dynein pulling forces and resisted by dynein friction is predicted to center on the experimentally observed timescale, with or without the pushing forces derived from microtubule buckling at the cell periphery.

**Structural basis for microtubule binding and release by dynein.**

W. B. Redwine<sup>1</sup>, R. Hernandez-Lopez<sup>1</sup>, S. Zou<sup>2</sup>, B. Goodman<sup>2</sup>, J. Huang<sup>2</sup>, S. L. Reck-Peterson<sup>2</sup>, A. E. Leschziner<sup>1</sup>; <sup>1</sup>Molecular and Cellular Biology, Harvard University, Cambridge, MA, <sup>2</sup>Cell Biology, Harvard Medical School, Boston, MA

Cytoplasmic dynein is a large molecular motor responsible for nearly all minus-end-directed microtubule-based transport in cells. Movement by all motors involves coordinating cycles of track binding and release with cycles of force-generating nucleotide hydrolysis. For the well-studied myosin and kinesin motors, track binding and nucleotide binding occur within close proximity; in contrast, these sites are separated by 25 nm in dynein. A major question in the field is how coordination between these distant sites is achieved. We have obtained a sub-nanometer-resolution structure of dynein's microtubule-binding domain bound to microtubules by cryo-electron microscopy and used molecular dynamics to arrive at a pseudoatomic model of

the interaction. We have identified the structural rearrangements within the microtubule-binding domain that communicate microtubule binding to the rest of the motor as well as specific interactions used by dynein to tune its affinity for the microtubule. We used single molecule motility experiments to probe the functional role of these interactions, and provide evidence that cytoplasmic dynein has been selected for sub-maximal processivity. The importance of a finely tuned motor is supported by our finding that dynein-powered nuclear oscillations in yeast are altered in strains expressing highly processive mutant motors.

1770

### Characterization of dynein by single-molecule investigations in vivo.

V. Ananthanarayanan<sup>1</sup>, M. Schattat<sup>1</sup>, S. Vogel<sup>1</sup>, A. Krull<sup>1</sup>, N. Pavin<sup>1,2</sup>, I. Tolic-Norrelykke<sup>1</sup>; <sup>1</sup>Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, <sup>2</sup>Department of Physics, University of Zagreb, Zagreb, Croatia

Cytoplasmic dynein is a motor protein that exerts force on microtubules and in doing so, drives a myriad of intracellular activities including mitotic spindle positioning and chromosome movements in meiotic prophase. To generate these forces, dynein needs to be anchored, with the anchoring sites being typically located at the cell cortex. The key question is: By what mechanism do single dyneins accumulate at sites where they can generate large collective forces? Here, we directly observe single dyneins in fission yeast, which allowed us to identify the main steps of the dynein binding process: (i) from the cytoplasm to the microtubule, and (ii) from the microtubule to the cortical anchors Mcp5. We uncovered that dyneins on the microtubule move, surprisingly, either in a diffusive or a directed manner, with the switch from diffusion to directed movement occurring upon binding of dynein to the cortex. This was further confirmed by abolishing the cortical-binding ability of the anchor (Mcp5-PH $\Delta$ ). We were thus able to force dynein on the microtubule bound to Mcp5-PH $\Delta$  to switch to directed movement, providing further evidence to the idea that dynein is 'activated' upon binding to its anchor. This dual behavior of dynein on the microtubule, together with the two steps of binding, constitute the mechanism by which dyneins find cortical anchors in order to generate large-scale movements in the cell.

1771

### Cytoplasmic Dynein Uses Its Two Motor Domains To Crosslink And Slide Anti-parallel Microtubules.

M. E. Tanenbaum<sup>1</sup>, R. D. Vale<sup>1</sup>, R. J. McKenney<sup>1</sup>; <sup>1</sup>Cellular and Molecular Pharmacology, UCSF, San Francisco, CA

Cytoplasmic dynein is the predominant minus-end directed microtubule motor protein in cells. Dynein performs a myriad of functions in addition to canonical transport of vesicular cargo, including the organization of microtubules within the mitotic spindle. How dynein performs such non-canonical functions is unknown. Here we demonstrate using *in vitro* and *in vivo* assays that dynein utilizes its two motor domains to crosslink and slide anti-parallel microtubules. *In vitro*, both native dynein purified from brain tissue, as well as a minimal GST-dimerized construct lacking the tail domain and accessory subunits are capable of crosslinking microtubules, suggesting the motor domains alone are sufficient for this activity. Addition of ATP causes sliding of overlapped anti-parallel microtubules, demonstrating that dynein can slide microtubules independently of any other factors. Single molecule imaging reveals that individual dynein motors encountering an anti-parallel microtubule overlap often pause for prolonged periods of time and frequently reverse direction, suggesting that the two motor domains can bind both microtubules in the overlap simultaneously. *In vivo*, dynein produces an inward force in the mitotic spindle that antagonizes the kinesin-5-dependent outward sliding

force. We show using RNAi-rescue experiments that a minimal, tailless dynein dimer is sufficient for this activity of dynein, indicating that sliding of anti-parallel microtubules within the spindle can be driven by the action of the dynein motor domains alone. Our results identify an unexpected new mode of dynein driven motion and shed light on the mechanisms cells use to organize the microtubule network.

1772

### **Cytoplasmic Dynein Steps Through Uncoordinated Action of its Two Heads.**

M. DeWitt<sup>1</sup>, A. Y. Chang<sup>1</sup>, P. Combs<sup>1</sup>, A. Yildiz<sup>2</sup>; <sup>1</sup>University of California, Berkeley, Berkeley, CA, <sup>2</sup>Physics, University of California, Berkeley, Berkeley, CA

Cytoplasmic dynein is a homodimeric AAA+ motor that transports a multitude of cargos towards the microtubule minus end. How the two catalytic head domains interact and move relative to each other during processive movement remains poorly understood. We have tracked the relative positions of both heads with nanometer precision and directly observed that the heads move independently along the microtubule. The heads remain widely separated and the stepping behavior of the heads varies as a function of interhead separation. Consistent with a lack of tight coordination, only one active head is sufficient for processive movement and the active head drags its inactive partner head forward. These results show that dynein is the first dimeric motor that moves processively without interhead coordination, a mechanism fundamentally distinct from the hand-over-hand mechanism of kinesin and myosin.

1773

### **Testing the tug-of-war model of bidirectional transport by measuring molecular motor forces *in vivo*.**

C. Leidel<sup>1</sup>, R. A. Longoria<sup>1</sup>, F. Marquez Gutierrez<sup>1</sup>, G. T. Shubeita<sup>1</sup>; <sup>1</sup>Center for Nonlinear Dynamics and Department of Physics, Institute for Cellular and Molecular Biology, The University of Texas at Austin, Austin, TX

Molecular motor proteins are responsible for force generation in myriad cellular processes. Much of our understanding of how motors function has benefited from force measurements and manipulation at the single molecule level *in vitro*. We report on novel optical trapping methodology capable of precise *in vivo* stall-force measurements of *individual* endogenous cargoes hauled by molecular motors in their native environment. We present unprecedented stall force histograms of motor-driven lipid droplets in *Drosophila* embryos. Force measurements show that equal numbers of kinesin-1 and cytoplasmic dynein haul each cargo in opposite directions. Critically, by measuring cargo dynamics in the optical trap, we find that there is memory: it is more likely for a cargo to resume motion in the same direction -rather than reverse direction- after the motors transporting it detach from the microtubule due to the trap force. This suggests that only motors of one polarity are active on the cargo at any instant in time and is not consistent with the tug-of-war models of bidirectional transport where both polarity motors can bind the microtubules at all times. We further use the optical trap to measure, *in vivo*, the detachment rates from microtubules of kinesin-1 and dynein-driven lipid droplets. Unlike what is commonly assumed, we find that dynein's but not kinesin's detachment time *in vivo* increases with opposing load. This suggests that dynein's interaction with microtubules behaves like a catch bond and further argues in favor of a regulatory model for bidirectional transport.

1774

**Dynein from *C. reinhardtii* translocates microtubules from conspecific axonemal tubulin faster than from porcine brain tubulin.**

J. Alper<sup>1</sup>, M. Tovar<sup>1</sup>, F. Decker<sup>1</sup>, J. Howard<sup>1</sup>; <sup>1</sup>Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

Eukaryotic cilia are motile organelles whose regular beating propels cells through fluids and moves fluids past cells. They contain a highly conserved structure, the axoneme, consisting of a "9 + 2" array of nine microtubule doublets surrounding a central pair of singlet microtubules, dynein motor proteins, and accessory proteins. How the microtubules, motors, and accessory proteins give rise to the periodic beat is not known. However, recent studies have suggested that the mechanochemical properties of dynein may be sufficient to achieve coordination. Because the action of dynein requires it to interact with microtubules, it is likely that its mechanochemical cycle is dependent on specific dynein-tubulin interactions. It is known that axonemal microtubules are enriched in certain tubulin isotypes and post-translational modifications over non-axonemal microtubules. We asked if the mechanochemical and biophysical properties of axonemal dynein depend on the source of the microtubules.

We compared the gliding motility of microtubules polymerized from tubulin purified from *Chlamydomonas* axonemes and porcine brains over surfaces coated with *Chlamydomonas* axonemal dynein. We found that the translocation speed of microtubules polymerized from *Chlamydomonas* tubulin was 1.6 times faster than porcine brain microtubules. We also found that the saturating mean gliding velocity was reached with shorter *Chlamydomonas* microtubules than with porcine microtubules. These results show that the source of tubulin does affect the biophysical properties of motor proteins. Modeling these results further suggested that tubulin source affected dynein-microtubule affinity and the kinetics of its powerstroke.

These preferences may be attributable to differences in primary structure or post-translational modification of the tubulin. We further investigated some of the commonly occurring post-translational modifications in our gliding assays. The results additionally are suggestive of the roles these modifications may play in axonemal motility.

1775

**The Minimal Requirements for Dynein Processivity and a Force-Dependent Gating Mechanism.**

F. B. Cleary<sup>1</sup>, T. Bilyard<sup>2</sup>, D. D. Chan<sup>2</sup>, V. Belyy<sup>1</sup>, A. Y. Chang<sup>2</sup>, A. Yildiz<sup>2</sup>; <sup>1</sup>Biophysics, University of California, Berkeley, Berkeley, CA, <sup>2</sup>Physics, University of California, Berkeley, Berkeley, CA

Cytoplasmic dynein drives minus-end directed motility along microtubules. In contrast to other cytoskeletal motors, the detailed mechanism of dynein processivity and force generation remains unclear. By engineering the mechanical, catalytic, and geometric properties of the dynein motor domain we show that neither a rigid linkage between monomers nor dimerization between N-terminal tail domains is essential for processive movement. Instead, dynein processivity minimally requires the linker domain of one active monomer to be attached to an inert microtubule tether retaining only the dynein microtubule binding domain. The release of a dynein monomer from the microtubule can be mediated either by nucleotide binding or external load. Using optical trapping we find that nucleotide dependent microtubule release is inhibited when force is applied to the linker domain. Force dependent release is strongly asymmetric, with faster release towards the minus-end. On the basis of these measurements, we develop a model that describes the basis of dynein processivity, directionality and force generation.

1776

**A novel function for Dynein in the plus-end transport of a localized mRNA.**

P. Sanghavi<sup>1</sup>, S. Laxani<sup>1</sup>, G. B. Gonsalvez<sup>1</sup>; <sup>1</sup>Cellular Biology and Anatomy, Georgia Health Sciences University, Augusta, GA

The proper functioning of most eukaryotic cells requires the establishment and maintenance of polarity. The *Drosophila* oocyte uses mRNA localization to establish polarity and hence is an excellent model to study these processes. In particular, *bicoid* mRNA localizes to the anterior margin of the oocyte, *gurken* mRNA localizes to the dorsal-anterior corner, and *oskar* mRNA localizes to the posterior pole. The spatial restriction of these mRNAs and subsequent protein products is essential for patterning the embryo. The localization of all three mRNAs requires intact microtubules, and presumably, microtubule-based motor proteins. For instance, loss-of-function mutants in Kinesin heavy chain (Khc), the motor subunit of Kinesin-1, results in *oskar* mRNA delocalization. Furthermore, the vast majority of *oskar* mRNP particles are non-motile in *khc* mutants. However, a small percentage of *oskar* particles display active and directional motility in *khc* nulls. These results suggest that although Khc is essential for *oskar* mRNA localization, another motor might also participate in the transport step. Consistent with this notion, published results indicate that Dynein heavy chain (Dhc), the motor subunit of the Dynein complex, co-localizes with Khc and *oskar* mRNA at the posterior pole. Additionally, we found that the targeted mis-localization of *oskar* mRNA to the center of the oocyte resulted in a similar re-distribution of Dhc and Khc. We therefore hypothesized that Dynein and Kinesin are present in a complex with *oskar* mRNA and that both motors are required for its efficient transport. In order to test this hypothesis, we specifically depleted Dhc in the germline using shRNA mediated knock-down. This strategy enabled us to bypass the requirement for Dynein in oocyte specification, a limitation that had previously restricted the analysis of Dynein function in mRNA localization. Germline-specific depletion of Dhc severely compromised the localization of *oskar* mRNA. In addition to *oskar* mRNA, the posterior localization of Khc was also affected. Based on these results, we conclude that the plus-end directed transport of *oskar* mRNA by Khc requires Dynein. Our results provide the first evidence that *oskar* mRNA localization requires the concerted activities of opposite polarity motors.

1777

**Linking dynein mutations to crystal structures and cell phenotypes.**

S. Sivagurunathan<sup>1</sup>, R. Schnittker<sup>1</sup>, S. Nandin<sup>2</sup>, M. D. Plamann<sup>1</sup>, S. J. King<sup>2</sup>; <sup>1</sup>University of Missouri-Kansas City, Kansas City, MO, <sup>2</sup>University of Central Florida, Orlando, FL

Even with recent advances in the dynein heavy chain (DHC) crystal structure, the complex organization of the DHC has made it difficult to understand the dynein mechanochemical cycle. To further probe dynein structure/function relationships, we utilized forward and reverse genetics in the ascomycete fungus *Neurospora crassa*. *N. crassa* has a haploid genome and dynein is not an essential gene, making genetic studies straightforward to perform. Using a forward genetic screen we isolated over 30 spontaneous missense mutations spanning almost all the domains of the DHC gene. In addition, we reverse engineered mammalian neurodegenerative mutations into the DHC. The effect of DHC mutations on dynein localization was probed by replacing the native dynein intermediate chain (DIC) with a fluorescently tagged DIC. Live-cell imaging studies on strains carrying DHC mutations revealed the presence of at least six major classes of dynein localization phenotypes. Endomembrane cargo transport is altered to different extents in the different classes of DHC mutant strains. To further understand the mechanisms by which the mutations affect dynein function, mutations located distantly from

the enzyme active site were chosen for in vitro characterization. Studies on purified dynein from these strains revealed novel mechanisms of dynein regulation. We identify several interesting correlations between the location of individual mutations within the dynein structure and the specific cellular defects observed in vivo. The linkage between defects in particular areas of the DHC 3D structure with cellular mislocalization phenotypes indicate that the individual DHC mutations entrap the motor at particular stages of the dynein mechanochemical and intracellular transport cycles.

1778

**The Dynein Inhibitor Ciliobrevin D Does Not Inhibit T Cell Microcluster Movement.**

*J. Yi<sup>1</sup>, K. Shan<sup>1</sup>, X. Wu<sup>1</sup>, T. Kapoor<sup>2</sup>, J. K. Chen<sup>3</sup>, J. Hammer<sup>1</sup>; <sup>1</sup>NHLBI, NIH, Bethesda, MD, <sup>2</sup>Laboratory of Chemistry and Cell Biology, Rockefeller University, New York, NY, <sup>3</sup>Department of Chemical and Systems Biology, Stanford University School of Medicine, Stanford, CA*

The contact area between a T cell and an antigen presenting cell (APC) is organized into a bull's eye arrangement of segregated concentric regions, collectively known as the immunological synapse (IS). The IS serves as the structural basis of signaling and secretion between the T cell and APC. The center area of the IS, termed the central supra-molecular activation cluster (cSMAC), is marked by the accumulation of T cell receptor (TCR) microclusters (MCs). We recently showed that the centripetal movement of TCR MCs to the cSMAC is driven entirely by a combination of actin polymerization driven actin retrograde flow in the dSMAC (lamellipodial actin network) and actomyosin II driven actin arc contraction in the pSMAC (lamellar actin network). Saito and colleagues have, however, reported that the microtubule dependent transport of TCR MCs driven by cytoplasmic dynein contributes significantly to the centripetal movement of TCR MCs. Recently, a very effective membrane-permeable small molecule inhibitor of cytoplasmic dynein called Ciliobrevin was described. Here we show that the kinetics of centripetal TCR MCs movement are normal in Ciliobrevin-treated cells, suggesting that their movement is indeed largely, if not entirely, driven by actin-dependent mechanisms. Finally, we show that Ciliobrevin D is cytotoxic to Jurkat T cells when the cells are imaged with blue light, such as when imaging GFP-chimeras, but not when imaging with green light and higher wavelengths, representing a cautionary tale for other investigators interested in using Ciliobrevin to inhibit dynein in living cells.

1779

**Dynein Phosphorylation Involved in Adenovirus Attack and Host Defense.**

*J. Scherer<sup>1</sup>, R. Vallee<sup>1</sup>; <sup>1</sup>Columbia University, New York, NY*

Viruses have evolved to successfully exploit physiological host cell processes for efficient infection. Critical entry barriers for DNA viruses and retroviruses are the plasma membrane and the dense cytoplasm, which limits virions to sub-diffusional motility and attenuates nuclear targeting. Human adenovirus 5 (Ad5) binds to cell surface receptors (CAR and integrins), activating PKA and other protein kinases, and then enters the host cell by endocytosis. Following endosomal escape, Ad5 requires dynein-mediated transport to reach the nuclear envelope (NE) and complete the infectious cycle. Ad5 recruits dynein through a direct interaction between its hexon subunit and the dynein IC and LIC1 subunits. We recently found PKA phosphorylation of LIC1 to be essential for this interaction and for virus transport to the nucleus. However, why host activation of PKA should serve to enhance virus transport is unclear. To test for protective cellular effects of PKA phosphorylation, we tested for changes in microtubule organization and the behavior of a range of vesicular structures, including mitochondria, the Golgi apparatus, multi-vesicular bodies, early endosomes, and lysosomes/late

endosomes (lyso/LEs). We observe dramatic specific dispersal of lyso/LEs within 15-30 min of infection using lysotracker, GFP-Rab7, and GFP-NPC1 as markers, but no effect on microtubules or other vesicular organelles. Lyso/LE dispersal is blocked by RILP overexpression, and by pharmacological PKA or integrin inhibition. We identify a single, novel PKA site in LIC1, which is required for both Ad5 transport to the nucleus and lyso/LE dispersal as judged by use of phosphomutant and phosphomimetic LIC1 constructs. These results suggest a novel host defense mechanism involving centripetal lyso/LE transport to intercept incoming virus. Ad5 may, in turn, have evolved a compensatory mechanism for enhanced transport to the NE. Our results also identify what seems to be an important PKA target involved in regulating bidirectional organelle transport, a result with important implications for a general understanding of transport regulation.  
 Supp. by NIH GM47434 and GM102347.

1780

### **Force up-regulation in dynein driven lipid droplets of cos1 cells.**

*B. Janakaloti Narayanareddy<sup>1</sup>, P. Anand<sup>1</sup>, S. P. Gross<sup>1</sup>; <sup>1</sup>Dev & Cell Biology, UC Irvine, Irvine, CA*

Most intracellular organelle transport is along the microtubules and is carried out by a combination of kinesin variants and dynein. A key question in transport regulation is how the system deals with various impediments to motion, to avoid or minimize subsequent potential traffic jams. The force adaptation—evident within ten seconds, complete within thirty—improved the ability of LDs to escape the trap between three and four-fold. To date, there has been no suggestion that cargos can sense or respond to opposition to motion. However, at a larger scale there is a well-known biological precedent called the Starling's law<sup>1</sup>. It is about the adaptive behavior that the heart undergoes where the more the heart is stretched, the stronger the cardiac muscle contracts. The adaptation could involve the activation and inactivation of motors wherein 'inactive' motors could be rapidly turned on, as needed, if signaling controlled the reactivation process. For kinesin, such inactivation/reactivation could occur via a newly discovered tail-independent pathway<sup>2</sup>, by head-tail binding<sup>3</sup>, or by cofactors that directly inhibit the motor domain. For dynein, in vitro evidence shows the motor is inactive when bound only to NudE, and this inhibition is reversed when also bound to Lis1<sup>4</sup>. During the development of a new system to measure forces powering lipid droplets in cells, we were surprised to find that there was not a well-defined stalling force. That is, when we attempted to stall moving cargos, the majority stopped initially, but most escaped from the optical trap on subsequent attempts. We will be presenting the data showing that droplet force production adapts to overcome obstacles to advancement.

### Heterologously Expressed BicD2 is Sufficient to Drive Apical Interkinetic Nuclear Migration in Developing Rat Brain.

D. Hu<sup>1</sup>, A. Baffet<sup>1</sup>, T. Nayak<sup>1</sup>, V. Doye<sup>2</sup>, A. Akhmanova<sup>3</sup>, R. Vallee<sup>1</sup>; <sup>1</sup>Columbia Univ., New York City, NY, <sup>2</sup>Inst Jacques Monod, CNRS, Univ. Paris Diderot, Paris, France, <sup>3</sup>Utrecht Univ., Utrecht, Netherlands

Radial glial progenitor cells (RGPCs) are precursors for the majority of neurons in the developing neocortex. The RGPCs undergo bidirectional cell cycle-dependent nuclear oscillations known as interkinetic nuclear migration (INM). Defects in INM contribute to brain developmental disorders, but the purpose and mechanism of this behavior remain under investigation. Our previous work revealed that KIF1A mediates basal nuclear migration during G1 whereas cytoplasmic dynein mediates apical nuclear migration during G2 (Tsai et al. Nat. Neurosci. 2010, 13:1463-71). Mitosis then occurs exclusively at the ventricular surface of the developing brain. These results provide a mechanism to account for alternating basal and apical nuclear transport. How cell cycle regulation of this behavior is controlled, however, remains largely mysterious. We have found that factors responsible for G2-specific recruitment of dynein to the HeLa cell nuclear envelope - BicD2, Nup133, and CENP-F - are required for apical nuclear migration in embryonic rat brain (Nayak et al., *MBoC*. 22 [abstr. 47] 2011). In utero electroporation of shRNAs for these factors arrested this process and further revealed that BicD2 is required earlier during G2 than Nup133 and CENP-F. These results support our hypothesis that dynein acts from the nuclear envelope during apical migration, which we have now further confirmed by immunohistochemical colocalization of dynein and BicD2 to the nuclear rim of RGPCs in situ. To test further the relative roles of BicD2 vs. Nup133-CENP-F in apical migration, we constitutively targeted BicD2 to the NE using a BicD2-KASH fusion protein. Nuclei of transfected RGPCs dramatically accumulated at the ventricular surface of the brain, suggesting that BicD2 can be sufficient for dynein recruitment to the nuclear envelope and apical migration. Expression of BicD2 alone rescued the late apical nuclear migration arrest we observe in RGPCs subjected to Nup133 RNAi. Our results indicate that a pool of nuclear envelope-associated cytoplasmic dynein drives apical INM, and that G2-dependent dynein recruitment to this site is not only necessary, but also sufficient to control G2 INM. Supp. by NIH HD40182.

### Molecular adaptations in dynein for generation of large forces inside cells.

A. Rai<sup>1</sup>, A. Rai<sup>1</sup>, A. J. Ramaiya<sup>1</sup>, R. Jha<sup>1</sup>, R. Mallik<sup>1</sup>; <sup>1</sup>Biological Sci, Tata Institute of Fundamental Research, Mumbai, India

The unit generator of force inside living cells is often a motor protein that exerts a tiny force of 1-10 piconewtons. However, many processes in cells require much larger forces and must therefore rely on motors working in a team. How collective force is generated by such teams of motors is fundamentally important, but has evaded understanding. To investigate this, we develop a new model system for optical trapping directly inside living cells that overcomes certain caveats and technical hurdles with earlier in vivo force measurements. This allows us to measure the function of endogenous cellular motor-assemblies with a precision comparable to in vitro bead assays.

We make the paradoxical observation that weak dynein motors team up to generate very large forces whereas stronger kinesins fail as a team. We show that dynein's improved teamwork arises from this motor's unique ability to vary stepsize in response to load, i.e. to shift gears (Mallik et al, Nature 2004). Each dynein motor in a team speeds up or slows down, depending

on the load it experiences. Dyneins therefore bunch closer together when hauling load, and consequently share load better to work efficiently as a team. We provide multiple independent lines of experimental evidence to support this hypothesis, and bring out precise mechanistic details of this process.

These results connect single-molecule properties of motors to their biologically relevant cellular functions, and suggest that nature has designed different motor proteins to adapt them for specific functions. More specifically, our work shows why dynein, the only known geared motor, needs a gear inside cells.

**Regulated inhibition of dynein motility along astral microtubules ensures unidirectional spindle movement along the polarized cell axis.**

*S. M. Markus<sup>1</sup>, K. A. Kalutkiewicz<sup>1</sup>, W-L. Lee<sup>1</sup>; <sup>1</sup>Biology, University of Massachusetts Amherst, Amherst, MA*

Cytoplasmic dynein and kinesin transport a multitude of cargos toward the opposite microtubule ends in the cell. Whether and how these motors are differentially regulated along microtubules are poorly understood. In yeast, we have proposed a regulated-offloading model to explain how dynein powers the transport of the nucleus into the mother-bud neck via microtubule sliding along the cell cortex: the dynein regulator She1 limits dynein offloading by gating the recruitment of dynactin to the astral microtubule plus end, a prerequisite for offloading to the cortex. However, whether She1 subsequently affects cortically anchored dynein activity during microtubule sliding is unclear. Using single-molecule motility assays, we show that She1 strongly inhibits dynein movement along microtubules, acting directly on the motor domain in a manner independent of dynactin. She1 has no effect on the motility of either Kip2, a kinesin that utilizes the same microtubule track as dynein, or human kinesin-1, demonstrating its specificity for the dynein motor. At single-molecule resolution, She1 binds tightly to and exhibits diffusional behavior along microtubules. Diffusive She1 collides with and pauses motile dynein motors, prolonging their attachment to the microtubule. Furthermore, Aurora B/Ipl1 directly phosphorylates She1 and this modification appears to enhance the diffusive behavior of She1 along microtubules and its potency against dynein. In cells, She1 dampens productive microtubule-cortex interactions specifically in the mother compartment, thereby polarizing spindle movements toward the bud cell. Our data reveal how inhibitory microtubule-associated proteins selectively regulate motor activity to achieve unidirectional cargo transport, and demonstrate a direct link between cell cycle machinery and dynein pathway activity.

1784

**Cortical dynein is critical for proper spindle positioning in human cells.**

*S. Kotak<sup>1</sup>, P. Gönczy<sup>1</sup>; <sup>1</sup>Swiss institute for experimental cancer research/EPFL, Lausanne, Switzerland*

Correct placement of the mitotic spindle is a fundamental process for defining cell division axis. Studies in several cellular systems revealed that cytoplasmic dynein together with evolutionarily conserved cortically anchored ternary complex (LIN-5/GPR-1/2/G $\alpha$  in *C. elegans* and NuMA/LGN/G $\alpha$  in human cells) is required for spindle positioning, but their relationship is not completely understood. By analyzing fixed specimens on fibronectin-coated coverslips and conducting live imaging experiments, we uncover that balance levels of ternary complex components are critical for dynein-dependent spindle positioning in non-polarized HeLa cells and *C. elegans* embryos. Intriguingly, by employing mutant versions of G $\alpha$  lacking myristoylation

signal, we establish that dynein is needed at the cortex to direct spindle positioning. Importantly, we identified a region within NuMA that mediates its interaction with dynein motor complex. By targeting this region to the plasma membrane, we demonstrate that the mere presence of dynein at that location is sufficient to direct spindle oscillations independent of ternary complex in HeLa cells. Overall, our findings support a model in which the balanced proportion of ternary complex serves to anchor dynein at the plasma membrane to direct spindle positioning.

### Attenuation of Dynein-Mediated Spindle Elongation Ensures Proper Force Generation During Anaphase.

K. A. Kalutkiewicz<sup>\*1</sup>, S. M. Markus<sup>\*1</sup>, W-L. Lee<sup>1</sup>; <sup>1</sup>Biology, University of Massachusetts Amherst, Amherst, MA

The segregation of sister chromatids during anaphase ensures that each resulting daughter cell possesses one set of chromosomes. This process is mediated by the mitotic spindle, which consists of microtubules, microtubule-associated proteins (MAPs), and molecular motors. It is currently unclear how these motors and MAPs generate an appropriate output of force to separate the spindle poles and thus achieve accurate chromosome segregation. Here, we use live-cell imaging to show that budding yeast deficient for She1 (*she1Δ*), a well-characterized inhibitor of dynein pathway function, exhibit significantly faster pole separation than wild-type cells. Combining *she1Δ* with mutations in either of the two kinesin-5 motors (*kip1Δ* or *cin8Δ*) did not restore the rate of pole separation to wild-type levels, suggesting that neither of these motors is responsible for the fast anaphase phenotype. Consistent with this hypothesis, we find that recombinant She1 has no effect on the *in vitro* motility of Cin8-3GFP. However, we found that *she1Δ* cells that were also deleted for the dynein heavy chain (*she1Δ dyn1Δ*) exhibited anaphase kinetics that were in fact restored to wild-type levels, suggesting that dynein is responsible for the fast anaphase phenotype. We also find that loss of dynein alone (*dyn1Δ*) has no effect on anaphase kinetics, indicating that dynein may normally be prohibited from participating in this process in wild-type cells. To determine whether hyperactivity of dynein can account for this phenotype independent of She1 dysfunction, we enhanced dynein function by overexpressing Pac1/LIS1, which increases the frequency and the level of dynein at the cell cortex. We found that overexpressing Pac1 in wild-type cells phenocopied the fast pole separation observed in *she1Δ* cells. Previous studies suggest that *she1Δ* cells exhibit a chromosome segregation defect, which may be a consequence of the rapid spindle elongation observed here. Thus, our data suggest that cortical dynein can contribute to anaphase forces, but its activity is prevented by regulated cortical targeting and She1-mediated inhibition to effectively attain an appropriate rate of spindle elongation. (\*These authors contributed equally to this work)

### Motor Neuron Disease-Associated Mutations in p150<sup>Glued</sup> Disrupt the Initiation of Retrograde Axonal Transport.

J. Machamer<sup>1</sup>, S. Collins<sup>1</sup>, Y. Yang<sup>1</sup>, A. Kolodkin<sup>2</sup>, T. E. Lloyd<sup>1</sup>; <sup>1</sup>Neurology and Neuroscience, Johns Hopkins University, Baltimore, MD, <sup>2</sup>Neuroscience and HHMI, Johns Hopkins University, Baltimore, MD

Increasing evidence suggests that defects in axonal transport may be a primary cause of neurodegenerative diseases. p150<sup>Glued</sup> is the major subunit of dynactin, a complex that functions with dynein in minus-end-directed microtubule transport. Different mutations within the p150 CAP-Gly microtubule-binding domain cause distinct autosomal dominant neurodegenerative syndromes, termed Hereditary

Motor Neuropathy 7B (HMN7B) and Perry Syndrome. HMN7B-associated mutations introduced into *Drosophila Glued* using homologous recombination generate a partial loss-of-function allele ( $G^{G38S}$ ) with impaired neurotransmitter release at the neuromuscular junction (NMJ) and adult-onset locomotor dysfunction. Interestingly,  $G^{G38S}$  animals accumulate endosomes within swollen terminal boutons of the NMJ, and this phenotype is due to a neuron autonomous loss of *Glued* function. Surprisingly, the anterograde motor kinesin and retrograde motor dynein colocalize on these expanded terminal endosomes, and genetic interactions studies show that kinesin and p150 function synergistically at the NMJ. Live imaging analysis of vesicle transport along axons and at the NMJ suggests that this phenotype is not due to a generalized defect in axonal transport, but rather a specific defect of dynactin in coordinating initiation of retrograde transport at microtubule plus ends of the distal-most NMJ boutons, called terminal boutons. Together, these data suggest that the presynaptic retractions that occur early in motor neuron degenerative diseases begin with an inability to initiate retrograde axonal transport at terminal boutons. We are currently investigating: (1) How p150 affects synaptic vesicle cycling and neurotransmitter release, (2) How HMN7B and Perry mutations differentially affect p150 function in axons and synapse, and (3) Modifiers of HMN7B-mediated axonal degeneration.

**Dynactin contributes to formation of a septin barrier in the midbody and is required for timely abscission.**

*T.-Y. Yeh<sup>1</sup>, T. A. Schroer<sup>1</sup>; <sup>1</sup>Biology, Johns Hopkins University, Baltimore, MD*

Dynactin is a critical component of the cytoplasmic dynein motor that acts as a cargo adaptor and processivity enhancer. We showed previously that dynactin's "pointed end complex" subunits, p27 and p25, help target dynactin to early and recycling endosomes. Cells depleted of p27 and p25 show no obvious structural defects in their mitotic spindles and complete karyokinesis normally, but they do exhibit profound delays in cytokinetic abscission. Dynactin is not essential for MKLP-1 or Aurora B kinase targeting to the central spindle or midbody. However, microtubule growth patterns and the localization of the microtubule cross-linker, PRC1, in the cytokinetic bridge are affected in cells depleted of dynactin subunits. Our data suggest that dynein/dynactin based events are required for assembly of a physical barrier in the midbody region that is necessary for timely abscission. In keeping with this, we found septin accumulation in the midbody to be significantly reduced in cells depleted of dynactin subunits. These results are consistent with a model in which septin is carried into the cytokinetic bridge via dynein/dynactin-based movement of recycling endosomes.

1788

**Probing the subunit interactions in the dynactin shoulder/sidearm.**

*S. A. Ketcham<sup>1</sup>, T. A. Schroer<sup>1</sup>; <sup>1</sup>CMDB, Johns Hopkins University, Baltimore, MD*

Dynactin is a multi-subunit complex that acts as a cargo adaptor and processivity enhancer for the microtubule-based motors cytoplasmic dynein and kinesin-2. Biochemical analysis of the dynactin complex indicates that it is composed of three sub-structures: the shoulder/sidearm, the Arp1 minifilament and the pointed end complex. The shoulder/sidearm, which consists of p150<sup>Glued</sup>, dynamitin and p24, binds to cytoplasmic dynein via the p150<sup>Glued</sup> subunit. We aim to understand the protein-protein interactions within dynactin's shoulder/sidearm, as well as how the shoulder/sidearm anchors to the Arp1 minifilament. To this end, we have taken advantage of the insolubility of bacterially expressed p24 to probe the interactions among the shoulder/sidearm subunits. In the presence of either dynamitin or p150<sup>Glued</sup>, p24 can be renatured by step-wise dialysis out of denaturant, whereas it is insoluble on its own under the same conditions. Using a series of fragments containing its predicted  $\alpha$ -helical domains, we

have been able to refine the portions of p24 necessary for complex formation. AA 1-67 of p24 form a complex with AA 127-1048 of p150<sup>Glued</sup>. AA 114-178 of p24 interacts with both the N-terminal and C-terminal halves of dynamitin, suggesting it binds both parts of the molecule. AA 33-67 of p24 interacts with just the C-terminal half of dynamitin (AA 213-406). Taken together, these results indicate that the extreme N-terminus of p24 binds p150<sup>Glued</sup> and the C-terminus of p24 interacts with dynamitin.

1789

### **Production of recombinant cytoplasmic dynein complexes.**

*M. A. Schlager<sup>1</sup>, A. G. Diamant<sup>1</sup>, A. P. Carter<sup>1</sup>; <sup>1</sup>MRC-LMB, Cambridge, UK*

Movement is one of the defining characteristics of life at the cellular level. Cytoplasmic dynein is one of the motors that power this movement. It carries a wide range of cargos and plays a crucial role during cell division. The largest component of the dynein motor complex is the dynein heavy chain, which consists of a head and a tail domain. The head contains the motor domain, which powers movement utilizing the energy from ATP hydrolysis. Although the dynein motor domain generates the force needed for movement, it depends heavily on the tail domain to function as a processive motor that can transport cargo. The heavy chain tail serves as a scaffold for a number of additional dynein subunits. The intermediate chain and light intermediate chain bind directly to the heavy chain tail, whereas light chains bind to the intermediate chain. Together these accessory chains and the heavy chain make up the dynein tail complex that provides the site of cargo and adaptor protein interaction. Unlike other motors, only one cytoplasmic dynein exists, which suggests that it has unique mechanisms for controlling cargo specificity. In budding yeast (*Saccharomyces cerevisiae*) dynein is not essential, which has allowed us to engineer yeast strains that express tagged dynein complexes at very high levels. Furthermore we use fed batch fermentation to grow large quantities of these strains allowing us to scale up protein production. Our preliminary data indicate that we are able to produce large quantities of complete dynein complexes as well as separate dynein tail complexes obtained by truncating the heavy chain gene. We have been able to confirm the functionality of the full length complexes using single molecule TIRF microscopy assays. Furthermore, we have confirmed that the dynein tail complexes are well behaved and complete using both mass spectrometry and gel filtration analysis. Taken together, the tools that we have developed to date will help us to uncover the mechanisms underlying of dynein's cargo specificity.

1790

### **Polymerase Chain Reaction Procedures for the detection of Human T-Cell Leukemia Virus Type 1.**

*T. E. Garcia<sup>1</sup>, D. Gibson<sup>1</sup>; <sup>1</sup>Biology, University of Texas of the Permian Basin, Odessa, TX*

Human T-Cell Leukemia Virus Type 1 (HTLV-1) affects an estimated 10-20 million people worldwide. It is believed to be the causative agent of adult t-cell leukemia (ATL) and HTLV-1 associated myelopathy/tropical spastic paraparesis (HAM/TSP). To initiate a successful infection, HTLV-1 must bind to the cell, penetrate into the cytosol, deposit its genome into the host cell cytoplasm and progress to the nucleus in order to replicate. Previous studies have shown that HTLV-1 infection is dependent upon interactions between the virus and host cell cytoskeleton. Researchers have illustrated that HTLV-1 intracellular movement is dependent upon microtubules. Our laboratory has found evidence that HTLV-1 interacts with a microtubule-based motor protein called cytoplasmic dynein. Therefore, we have formulated the hypothesis that cytoplasmic dynein is required for HTLV-1 replication. To investigate this, we will use

polymerase chain reaction (PCR) method. Initially, we purified an HTLV-1 DNA plasmid called delta X-M. This plasmid contains two of the three HTLV-1 viral genes. To determine if delta X-M was purified we performed restriction enzyme digest with Bam H1. Gel analysis indicated the presence of two expected band sizes of 4315 and 6633 base pairs. Next, we performed PCR using the purified delta X-M plasmid. Gel electrophoresis analysis demonstrated that a region of HTLV-1 Pol gene was amplified. Collectively, the results support the notion that PCR is an effective method to study HTLV-1 replication. Currently, we are employing siRNA technique to knock-out cytoplasmic dynein. This approach will help us determine whether cytoplasmic dynein plays a significant role in HTLV-1 replication process.

### **Actin and Actin-Associated Proteins III**

1791

#### **Formin INF2 localizes to focal adhesions and is critical for coordination of adhesion and contraction.**

*C. T. Skau<sup>1</sup>, C. M. Waterman<sup>1</sup>; <sup>1</sup>National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, MD*

Focal adhesions (FAs) are mechanosensitive complexes that form the physical and signaling link between the extracellular matrix and the actin cytoskeleton and are critical to driving cell migration. During migration, FAs form at the cell leading edge then undergo force-dependent maturation during which they elaborate a dorsal stress fiber to allow integration of force transmission across the cell. The formin family of actin nucleators is thought to be critical to FA maturation and formation of dorsal stress fibers. A proteomic analysis of FAs from our lab revealed two formin family members as FA components. We investigated the role of one of these, the formin INF2, in assembly and maturation of FAs and their associated stress fibers in mouse embryonic fibroblasts. We found that green fluorescent protein-tagged INF2 associated with FAs, partially co-localizing with known adhesion proteins including paxillin, VASP, and vinculin. INF2 localized to the rear of paxillin-marked FAs, partially co-localizing with the growing stress fiber. We utilized siRNA-mediated knockdown of INF2 to determine its role in FA and stress fiber formation and dynamics. Knockdown of INF2 had no effect on localization of paxillin, vinculin and VASP to FA, however had major effects on FA morphology. Compared to control, in cells with reduced INF2, FAs were smaller, more numerous, and failed to elongate, indicative of a possible maturation defect. Examination of the actin cytoskeleton in cells with reduced INF2 showed that although both stress fibers and dorsal arcs were present, INF2 knockdown cells contained fewer dorsal stress fibers, and actin bundles in both stress fibers and arcs were wavy and disorganized. To determine the requirement for INF2 in cell migration, we tracked migration of individual cells. INF2 knockdown cells also exhibited migration defects migrate displaying an abnormal "jumping" motility. These results suggest that INF2 participates in coordinating adhesion and contraction during cell migration by integrating FA maturation and stress fiber formation.

1792

**Single actin filament imaging studies of the *Drosophila* formin Cappuccino.**

C. L. Vizcarra<sup>1</sup>, M. E. Quinlan<sup>1,2</sup>; <sup>1</sup>Department of Chemistry & Biochemistry, University of California Los Angeles, Los Angeles, CA, <sup>2</sup>Molecular Biology Institute, University of California Los Angeles, Los Angeles, CA

The *Drosophila* formin Cappuccino (Capu) is essential for body axis establishment in the fly oocyte. When Capu is mutated, a diffuse cytoplasmic actin mesh is absent during mid-oogenesis, a condition that is correlated with premature cytoplasmic streaming and a loss of cell polarity. Capu has two mammalian homologues, Fmn1 and Fmn2, the latter of which is essential for construction of a cytoplasmic actin network in the mouse oocyte. Since the first *in vitro* studies of formin/actin interactions, a common theme has emerged: while formins build F-actin through highly conserved domains, there is a great deal of diversity in activities across the seven families of mammalian formins. These activities include processive elongation; filament nucleation, capping, and severing; intra- and inter-molecular regulation; microtubule binding; and F-actin bundling. We are interested in understanding the biochemical details of Capu family formins in order to better understand the nature of the actin-based structures that they build *in vivo*. Toward that end, we have used total internal reflection microscopy to study the effects of Capu-CT (including the FH1 and FH2 domains through the C-terminus) on actin filament growth. Similar to other formins, Capu and Chickadee (Chic, *Drosophila* profilin) accelerate the rate of filament elongation three- to four-fold over the rate of actin alone. This rate acceleration is only observed with Chic and not seen when Capu is mixed with human or yeast profilins. In the absence of Chic, Capu does not change the rate of filament growth. The C-terminal tail (~30 aa) of Capu has been identified as a crucial region for actin filament nucleation, regulation by the WH2-based nucleator Spire, microtubule association, and autoinhibition. We find that it also plays a role in filament elongation. When the tail of Capu-CT is truncated, the elongation rate of filaments from Chic-actin is unchanged, but the processivity of Capu-CT is compromised. We are currently using mutagenesis and chimeric formin constructs to understand the nature of the interaction between the tail and the elongating filament.

1793

**Cell-free analysis of the curious regulation of actin dynamics by the formin INF2.**

A. L. Hatch<sup>1</sup>, H. N. Higgs<sup>1</sup>; <sup>1</sup>Biochemistry, Geisel School of Medicine at Dartmouth, Hanover, NH

INF2 is a formin protein that catalyzes both the polymerization and depolymerization of actin filaments. In cells, INF2 localizes in a splice variant-dependent manner to either the endoplasmic reticulum (ER) or the cytoplasm, and regulates mitochondrial or Golgi dynamics, respectively. Mutations in INF2's Diaphanous Inhibitory Domain (DID), a key auto-inhibitory region for other formins, have been identified in two diseases: a kidney disorder called Focal Segmental Glomerulosclerosis (FSGS) and the neuronal disease Charcot Marie Tooth Disease (CMTD). The placement of these mutations suggests regulatory abnormalities in these diseases. My project targets the unusual regulation of INF2. In cells, INF2 is largely inactive for actin assembly, and this regulation depends upon auto-inhibitory interaction of DID with the C-terminal Diaphanous Auto-regulatory Domain (DAD). When purified INF2 is tested, however, the DID/DAD interaction does not inhibit actin polymerization. These results suggest that the DID-DAD interaction is important for INF2 regulation, but requires additional factors for robust inhibition. We term this regulation "facilitated auto-inhibition". To identify factors acting in facilitated auto-inhibition, I have developed a cell-free assay that monitors INF2-mediated actin polymerization activity on ER membranes. Alone, these membranes have a low ability to polymerize actin, but are strongly activated by a poly-clonal antibody against the DID. Addition of an antibody against the FH2 domain of INF2 abolishes polymerization, suggesting the

polymerization is INF2 dependent. I use this system to test the relevance of protein and non-protein co-factors in INF2 facilitated auto-inhibition.

1794

**Involvement of formins in myosin-X driven filopodia formation.**

*N. O. Alieva<sup>1</sup>, M. Natarajan<sup>1</sup>, X. Yuan<sup>1</sup>, A. D. Bershadsky<sup>1,2</sup>; <sup>1</sup>Mechanobiology Institute, National University of Singapore, Singapore, Singapore, <sup>2</sup>Weizmann Institute of Science, Rehovot, Israel*

Filopodia are dynamic cellular protrusions composed of actin filament bundles. They have been found to be important in many cellular activities including cell migration, neuronal growth cones dynamics, cell-cell junction formation and others. Unconventional myosin-X (Myo10) is a powerful inducer of filopodia formation and elongation once it undergoes over-expression (Berg & Cheney, 2002, Nature Cell Biology 4, 246). Live-cell imaging shows that Myo10 is present at the filopodia tip as a bright puncta and remains there as the filopodia extend and retract. The exact mechanism, by which Myo10 induces filopodia formation and elongation remains unclear. Formins are a family of actin nucleators, which also promote the elongation of actin filaments. A few members of the formin family have been found in filopodia, though the exact role they play in filopodia dynamics remains controversial. Here we present that Myo10 induced filopodia formation is highly dependent on formins. We found at least two formins, Dia1 and Dia2, were present in filopodia of HeLa cells with over-expression of myosin 10. SMIFH2, a small molecule inhibitor of formin homology 2 domains, dramatically decreased the number and length of Myo10 induced filopodia and in higher doses lead to the disappearance of Myo10 from the filopodia tip. Applying low doses of SMIFH2 caused changes in the dynamics of Myo10 enriched puncta at the filopodia tip. We observed numerous Myo10 positive patches being pinched out of the myosin 10 puncta at the filopodia tip and moving rearward towards the cell body at rates corresponding to the retrograde flow of actin in filopodia. Forward motion of Myo10 puncta observed in control conditions was completely blocked by SMIFH2. Furthermore, we demonstrate that the morphological phenotype observed after SMIFH2 exposure is consistent with the phenotype observed after specific short-hairpin (sh) RNA-mediated down regulation of human Dia2 gene. Ectopic expression of mouse Dia2, which is insensitive to human shRNA knockdown, rescued the Myo10 induced filopodia formation similar to the control phenotype. We hypothesize that Myo10 functions in concert with formins in filopodia formation and maintenance.

1795

**Mechanistic Studies of *Drosophila* Spir, a WH2-Nucleator.**

*A. S. Rasson<sup>1</sup>, S. Pham<sup>1</sup>, J. Bois<sup>1</sup>, M. Quinlan<sup>1</sup>; <sup>1</sup>Chemistry and Biochemistry, UCLA, Los Angeles, CA*

In the past few decades research has shed light on how nucleators contribute to the initiation of actin polymerization. Specifically we have learned a great deal about the Arp2/3 complex and formins, but there is still little understood about the third and newest class, WH2-nucleators. Beyond the fact that they use multiple actin-monomer-binding-WH2 domains to initiate actin filament assembly, a common theme is that an extra motif or domain is needed. To better understand the mechanism of WH2-nucleators we are using *Drosophila* Spire (Spir), as a model. We found that two WH2 domains connected by a specific linker motif, called linker-3, are sufficient for nucleation. Spir has a WH2 cluster consisting of four WH2 domains that are ~20 amino acids long, tethered together by short linker regions, the last one being linker-3. We took a reductionist approach to studying how Spir nucleates actin filaments by first examining the affect of each individual WH2 domain on actin. We observed large differences in affinity for actin monomers (30 nM - 1 μM), as well as distinct effects on spontaneous actin polymerization. To

our surprise, the amount each WH2 domain inhibited spontaneous actin polymerization did not correlate with the affinity of the WH2 domains for actin monomers. Next, we worked with more complex constructs trying to incorporate what we have learned. The latter half of Spir's WH2 cluster (C3D) has roughly half the nucleation activity as the full cluster. We will refer to this as wildtype activity. We have created chimeras, consisting of different WH2 domains connected by linker-3 to identify how domain-order affects nucleation activity. Briefly, placing the third WH2 domain of Spir (WH2C) N-terminal to linker-3 produced the strongest nucleators, similar to the wildtype construct. In fact, a construct with reversed order (D3C) had no nucleation activity. Finally, we found that only two point mutations were sufficient to convert a moderate strength nucleator (W3D) to wildtype activity levels. Continuing this work will help us refine our model of the mechanism of WH2-nucleators, which play important roles in various processes such as oogenesis and neuronal development.

1796

### **Interactions between microtubules and the *Drosophila* formin Cappuccino.**

E. Roth-Johnson<sup>1</sup>, M. Quinlan<sup>2,3</sup>; <sup>1</sup>Molecular Biology Interdepartmental PhD Program, University of California, Los Angeles, CA, <sup>2</sup>Department of Chemistry & Biochemistry, University of California, Los Angeles, CA, <sup>3</sup>Molecular Biology Institute, University of California, Los Angeles, CA

Formin family actin nucleators are potential coordinators of the actin and microtubule cytoskeletons; in addition to nucleating actin filaments, all formins tested to date can bind and/or bundle microtubules *in vitro*. To gain a more detailed mechanistic understanding of formin-microtubule interactions and formin-mediated actin-microtubule crosstalk, we studied microtubule binding by Cappuccino (Capu), a formin involved in regulating actin and microtubule organization during *Drosophila* oogenesis. We found that the C-terminal half of Capu (CapuCT, containing the FH1, FH2, and tail domains) binds taxol-stabilized microtubules with submicromolar affinity. Removal of the ~30 aa C-terminal tail dramatically reduces CapuCT's ability to bind microtubules. This sequence is sufficient for microtubule binding, albeit with micromolar affinity, suggesting that both the tail and upstream regions in CapuCT are required for high-affinity binding. Interestingly, the microtubule binding stoichiometry of the tail is approximately twofold higher than that of CapuCT, and both constructs exhibit reduced binding stoichiometry to microtubules at higher ionic strengths. Attempting to further map a microtubule-binding motif within the tail domain, we found that CapuCT-microtubule binding decreased approximately linearly as the tail was successively truncated. Furthermore, no single point mutation within the tail had a marked effect on microtubule binding. Together, these results suggest that microtubule binding by the tail domain is mediated by nonspecific charge-based interactions. To investigate the role of Capu in coordinating the actin and microtubule cytoskeletons, we next asked whether microtubules affect CapuCT's actin polymerization activity: indeed, they potently inhibit CapuCT's actin polymerization activity *in vitro*. We then mutated two conserved actin binding residues in CapuCT's FH2 domain (I706A and K856A) and tested the ability of these mutants to bind microtubules. While the I706A mutation had minimal effects on CapuCT-microtubule binding, the K856A mutation increased microtubule binding stoichiometry approximately twofold to a stoichiometry similar to that of the tail. Together, these findings fit our model that specific residues within FH2 are important for microtubule binding, perhaps orienting the formin dimer on the microtubule lattice, while the highly charged tail confers avidity through non-specific ionic interactions. Loss of FH2 domain binding may reveal additional microtubule-tail binding sites, thereby increasing binding stoichiometry. Microtubules could inhibit CapuCT's actin polymerization activity by preventing actin from binding to the FH2 and tail domains, which are both necessary for robust actin nucleation activity.

**The formin FMNL3 induces filopodia that act in cell-cell adhesion.***T. J. Gauvin<sup>1</sup>, H. N. Higgs<sup>1</sup>; <sup>1</sup>Biochemistry, Geisel School of Medicine at Dartmouth, Hanover, NH*

FMNL3 is a vertebrate formin that bundles actin filaments *in vitro*, in addition to the common formin activities of enhancing actin nucleation and allowing extended actin filament elongation. Constitutively active FMNL3 constructs produce abundant filopodia when over-expressed in multiple cell types. In the current work, we show that the role of endogenous FMNL3 is to produce filopodia, since siRNA-mediated FMNL3 suppression results in a 2-fold filopodial decrease in U2OS cells. FMNL3-induced filopodia enrich at new cell-cell contacts. FMNL3 suppression results in cell-cell adhesion defects in U2OS cells moving as a sheet, with a 3-fold increase in the occurrence of gaps between cells and in the lifetime of these gaps. Given the effect of FMNL3 on cell-cell adhesion, we investigated its localization and dynamics during the process in more detail. By immunofluorescence microscopy, endogenous FMNL3 localizes to filopodial tips and also to diffraction-limited (<300 nm) cytoplasmic puncta. Two lines of evidence suggest these puncta are microtubule-associated. First, the puncta are dispersed by nocodazole (microtubule depolymerization) but not Latrunculin B (actin depolymerization). Second, the puncta appear to align along microtubules in fixed cell images. Upon cell-cell contact, FMNL3 rapidly enriches at the nascent contact site, with decreased enrichment as the contact matures. Active Cdc42 or Rac1 (but not RhoA or RhoC) also induce FMNL3 translocation to the leading edge. To monitor FMNL3 dynamics, we developed an internal GFP-fusion construct, since both N- and C-termini serve important functions that are disrupted by tagging. Live-cell microscopy confirms that the intracellular FMNL3 puncta are associated with microtubules, and also shows that they are capable of rapid translocation along these microtubules. At the cell surface, FMNL3-labeled filopodia are highly dynamic, with lifetimes < 30 sec. Upon cell-cell contact, filopodia stabilize dramatically as the tips adhere to the neighboring cell. Based on these results, we propose a model whereby FMNL3 is sequestered on cytoplasmic vesicles that are microtubule-tethered. During cell migration, these vesicles are delivered to the leading edge, where FMNL3 is activated by Cdc42 to promote filopodial growth. Upon cell-cell contact, these filopodia stabilize, allowing cadherin-mediated adhesion.

1798

**Arp2/3-dependent mechanism of filopodium formation by FMNL3: cellular and biochemical evidence for convergent elongation.***E. G. Heimsath, Jr. <sup>1</sup>, H. N. Higgs<sup>1</sup>; <sup>1</sup>Biochemistry, Geisel School of Medicine at Dartmouth, Hanover, NH*

Filopodia are finger-like cellular protrusions involved in a myriad of processes, including chemosensing, cell migration, and cell adhesion. These structures are made up of bundled actin filaments oriented with their barbed ends toward the distal tip. To assemble filopodia, the activities of at least four components are needed: an actin nucleator, a factor that enables filament elongation in the presence of capping proteins, a filament bundling factor, and a factor that tethers filaments to the plasma membrane. In principle, the formin FMNL3 conducts all four of these activities, since N-terminal myristoylation localizes it to the plasma membrane, it can bundle actin filaments, as well as perform the common formin activities of increasing nucleation and preventing capping protein-mediated termination of elongation. Constitutively active constructs of FMNL3 induce potent filopodial assembly in multiple cell types. Curiously, however, FMNL3 constructs that are poor nucleators (but retain elongation and bundling activities) are equally capable of filopodia assembly. These results prompted us to probe the mechanism of FMNL3-mediated filopodial assembly in more detail.

Two general models have been proposed for filopodial assembly. In the “Tip Nucleation” model, a formin (or other nucleator) concentrates at the plasma membrane, nucleates actin filaments de novo, and then maintains elongation, causing protrusion and deformation of the membrane. Subsequent recruitment of the bundling protein fascin results in filopodial maturation. In the “Convergent Elongation” model, filopodia originate from an Arp2/3-derived lamellipodial dendritic network of branched filaments. In this Arp2/3-dependent mechanism, a membrane-bound formin (or other elongator) outcompetes capping protein for pre-existing filament barbed ends, facilitating synchronized elongation. Subsequent filopodial convergence occurs through fascin-mediated bundling.

Our data support a convergent elongation model for FMNL3-mediated filopodial assembly. Through Arp2/3 inhibition studies using the small molecule CK666 or shRNA-mediated suppression, we demonstrate in Jurkat pre-B leukemic cells that FMNL3-mediated filopodial assembly requires Arp2/3 complex. Using TIRF microscopy and a purified protein system including actin, profilin, capping protein, Arp2/3 complex, and fascin, we show that both nucleation-competent and nucleation-compromised FMNL3 constructs support bundling of Arp2/3 complex-mediated dendritic networks. Arp2/3 complex and FMNL3 are the key factors in this system, the former to nucleate filaments and the latter to allow elongation. Fascin enhances filament bundling, however is not sufficient to form filopodia either biochemically or in cells. We propose that FMNL3’s bundling activity facilitates initial convergence of Arp2/3 complex-initiated filaments, followed by bundle stabilization by fascin. Further experiments with VASP test its potential role in this process. We will relate these studies to cellular studies in our laboratory linking FMNL3-generated filopodia to cell-cell adhesion.

#### **Autoregulation of the formin Cappuccino in the absence of canonical autoinhibitory domains.**

*B. Bor*<sup>1</sup>, *C. L. Vizcarra*<sup>2</sup>, *M. L. Phillips*<sup>2</sup>, *M. E. Quinlan*<sup>2</sup>; <sup>1</sup>*Molecular Biology Interdepartmental Program, University of California Los Angeles, University of California, Los Angeles, Los Angeles, CA,* <sup>2</sup>*Chemistry and Biochemistry, University of California, Los Angeles, Los Angeles, CA*

Formins are a conserved family of proteins known to enhance actin polymerization. Five of the seven groups of metazoan formins are regulated by autoinhibitory interactions between the C-terminal diaphanous autoregulatory domain (DAD) and the N-terminal diaphanous inhibitory domain (DID). Based on the lack of DID/DAD sequence homology the formin family of formins was not predicted to be autoregulated. Previously published data for the *Drosophila* formin Cappuccino (Capu) is consistent with this prediction (Rosales-Nieves et al., NCB 2006). However, the mammalian ortholog of Capu, Formin-1, is autoinhibited (Kobielak et al., NCB 2004). We, therefore, re-examined Capu and found that it is, in fact, autoinhibited. Pyrene actin polymerization assays and TIRF single filament assays show that the N-terminal half of Capu (Capu-NT) potently inhibits nucleation and binding to the barbed end of elongating filaments by the C-terminal half of Capu (Capu-CT). Furthermore, Capu-NT was able to dissociate barbed end bound Capu-CT from actin filaments. We mapped the interacting regions. Within Capu-NT we identified residues 80-222 as the Capu Inhibitory Domain (CID). Hydrodynamic analysis indicates that Capu-NT is a dimer, similar to the N-termini of other formins. A dimerization domain is within residues 222-321. These data combined with circular dichroism suggest that the CID is structurally distinct from previously described DID domains. Within Capu-CT, the Capu-tail, C-terminal to the FH2 domain, was necessary to bind CID. Interestingly, the Capu-tail

also binds to the Spir-KIND domain (Pechlivanis et al., JBC 2009; Vizcarra et al., PNAS 2011). None of the single Capu-tail point mutations sufficient to abolish the Capu-tail/Spir-KIND interaction affect the Capu-tail/CID interaction, suggesting that Spir-KIND and CID bind to Capu-tail differently. Future work will be aimed at understanding how Capu autoinhibition fits with known regulatory interactions with Spir.

**The formin INF2 severs actin filaments through a fundamentally different mechanism from cofilin: relating biochemical function to cellular activity.**

*P. S. Gurel<sup>1</sup>, H. N. Higgs<sup>1</sup>; <sup>1</sup>Biochemistry, Geisel School of Medicine at Dartmouth College, Hanover, NH*

Formins are a class of proteins that accelerate actin nucleation, then influence filament elongation rate by remaining at the barbed end. INF2 is a biochemically unique mammalian formin in that it accelerates both actin polymerization and depolymerization. Importantly, mutations in INF2 lead to the kidney disease focal and segmental glomerulosclerosis (FSGS) and the neurological disorder Charcot-Marie Tooth Disease (CMTD). I am elucidating the molecular mechanism of INF2's unique depolymerization activity, using TIRF microscopy and other biochemical assays of actin dynamics. Prior work in our lab has shown that depolymerization requires both the FH2 and WH2/DAD sequences, and occurs in two steps: a) a severing step, which requires phosphate release from the actin subunits; and b) a depolymerization step, which requires the WH2/DAD. My work reveals the following mechanistic features of INF2-mediated severing/depolymerization. First, rapid severing occurs throughout the length of the filament and not progressively from the barbed end. This suggests that INF2 binds filament sides prior to severing and accelerates phosphate release of filaments since it is capable of severing filament segments less than 50s after monomer addition. Second, INF2 can bind filament sides that are both phosphate-bound and phosphate-free, but with different stoichiometries. Additionally, INF2 can alter filament flexibility in the phosphate-free state. These results suggest that phosphate release causes a conformational change to filament-bound INF2, allowing severing. Lastly, INF2 bound at the barbed end causes catastrophic disassembly of short filaments. Based on these results, I postulate that both filament side binding and barbed end binding by the FH2 domain changes filament architecture, which promotes severing and changes monomer dynamics at filament ends. I postulate further that the WH2/DAD enhances severing by insertional binding between actin subunits in the filament. These results contrast in several aspects with the severing mechanism employed by cofilin. This mechanistic investigation of INF2 severing/depolymerization activity gives insight on recent cellular results from our lab, which reveal a role for INF2-mediated actin dynamics in fission of both Golgi and mitochondria.

**Functional analysis of the N-terminal extension of troponin I muscle contraction and organization in *C. elegans* striated muscle.**

*D. E. Barnes<sup>1,2</sup>, K. Ono<sup>1</sup>, S. Ono<sup>1,2</sup>; <sup>1</sup>Pathology, Emory University, Atlanta, GA, <sup>2</sup>Cell Biology, Emory University, Atlanta, GA*

Troponin is a complex of three proteins [troponin I (TNI), troponin T (TNT), and troponin C (TNC)], which functions as an actin-linked calcium switch for muscle contraction. Calcium binding to TNC induces a large conformation change of TNI; TNT mediates the structural change to the tropomyosin-actin complex. However, the precise mechanism of the troponin regulation is not completely understood. TNI is at the core of the troponin complex, and its

elongated structure allows interaction with multiple molecules including TNC, TNT, and actin. The central region of TNI plays a major role in inhibition of actin-myosin interaction in the absence of calcium and is conserved among TNI proteins from different species. However, in invertebrate TNI proteins, N-terminal extensions of variable lengths are present, but their function remains unclear. Vertebrate cardiac TNI also has an N-terminal extension that modulates contractility in a PKA-phosphorylation dependent manner, while vertebrate skeletal TNI lacks an N-terminal extension. To better understand the function of the N-terminal extension of TNI, we used the nematode *Caenorhabditis elegans* as a model system. The body wall muscle of *C. elegans* is obliquely striated muscle and uses troponin as a major actin-linked regulatory system for muscle contraction. *C. elegans* has four TNI genes, and all TNI isoforms have N-terminal extension of ~30 amino acids. Among them, *unc-27* plays a major role in contractile regulation in the body wall muscle. *unc-27(e155)* is a putative null allele, and *unc-27(e155)* homozygotes showed impaired contractility and disorganization of sarcomeric actin filaments. Transgenic expression of GFP-tagged wild-type UNC-27 protein rescued both muscle contractility and sarcomeric actin organization. In contrast, GFP-UNC-27 lacking the N-terminal 29 amino acids failed to rescue the contractility defect but was able to rescue sarcomeric actin organization. Disorganized sarcomeric actin filaments in *unc-27* mutants are most likely caused by excessive and uncontrolled actin-myosin interaction, in the absence of TNI. Therefore, our results suggest that UNC-27 lacking the N-terminal extension inhibits actin-myosin interaction, thereby rescuing the actin organization, but fails to release the inhibitory state. Thus, in *C. elegans* muscle, the N-terminal extension of TNI appears to play an essential role in regulating muscle contractility.

### **A troponin-T mutation initiates cardiac and skeletal myopathy due to impaired thin filament regulation in *Drosophila melanogaster*.**

M. C. Viswanathan<sup>1</sup>, S. Haigh<sup>2</sup>, J. C. Sparrow<sup>2</sup>, W. Lehman<sup>3</sup>, A. Cammarato<sup>1</sup>; <sup>1</sup>The Johns Hopkins University School of Medicine, Baltimore, MD, <sup>2</sup>Biology, University of York, York, United Kingdom, <sup>3</sup>Physiology and Biophysics, Boston University School of Medicine, Boston, MA

Muscle contraction results from an orchestrated series of molecular events that permit transient interactions between myosin containing thick filaments and actin containing thin filaments. The high affinity of myosin for actin suggests that without regulation, muscle would remain in a continuous state of contraction. Contractile regulation of striated muscle is predominately achieved by Ca<sup>2+</sup>-dependent activity of the thin filament troponin-tropomyosin complex. Lesions in various subunits of the complex cause dysregulation of force production and myopathy. For example, at least 5 point mutations in a span of 10 amino acids (from positions 130 – 139) in human cardiac troponin T (cTnT) are associated with distinct cardiomyopathic responses. We have examined the consequences of an amino acid substitution at the end of this well-conserved region of TnT on different muscle types from *Drosophila melanogaster* up101 mutants. Fly hearts were surgically exposed. Cardiac performance and morphology were assessed using direct immersion DIC optics, high speed video imaging and motion analysis. Relative to control, up101 hearts displayed a phenotype reminiscent of human restrictive cardiomyopathy. Diastolic and systolic dimensions and percent fractional shortening were significantly reduced. Furthermore systolic intervals were significantly prolonged. This suggests thin filament dysregulation, excessive periods of force production and diastolic dysfunction. To characterize the molecular phenotype and fundamental cause of cardiac remodeling we isolated thin filaments from fly indirect flight muscles (IFM). The constitutively expressed mutation results in flightlessness due to severe IFM hypercontraction and destruction within hours of adulthood. Electron microscopy and three-dimensional reconstruction of IFM thin filaments revealed Ca<sup>2+</sup>-dependent tropomyosin strand movement, typical of control filaments,

was not a general feature of the TnT mutants. The vast majority of Ca<sup>2+</sup>-free mutant thin filaments exhibited tropomyosin associated with the inner domain of successive actin monomers, distal to known myosin binding sites, and are unlikely to sterically prevent contraction. We are currently performing in vivo genetic interaction screens to identify second site mutations critical for interplay among the mutant troponin-tropomyosin complex and actin. We aim to elucidate genetic modifiers and to suppress the myopathic phenotypes to better understand thin filament-mediated contractile regulation in health and in disease.

1803

#### Insights into post-translational modification of Profilin-1.

W. J. Veon<sup>1</sup>, S. Shroff<sup>1</sup>, P. Roy<sup>1,2</sup>; <sup>1</sup>Bioengineering, University of Pittsburgh, Pittsburgh, PA, <sup>2</sup>Pathology, University of Pittsburgh, Pittsburgh, PA

Profilin-1 (Pfn1) is a small actin-monomer binding protein that plays an essential role in actin cytoskeletal control in cells. In addition to actin, Pfn1 also interacts with phosphoinositides and a myriad of proteins bearing poly-L-proline motifs. The mechanisms by which ligand associations of Pfn1 are regulated are not well understood. We postulated that ligand interactions of Pfn1 are fine-tuned by post-translational modifications. By two-dimensional (2D) gel electrophoresis analyses of HEK293 cell lysate, we have identified up to 5 different charged forms of Pfn1 in vivo. Among these, the most stoichiometrically abundant form of Pfn1 appears to be in a phosphorylated state. Mutagenesis studies further revealed that the major in vivo phosphorylation site is not the previously speculated S137 residue in its C-terminal polyproline motif-binding region. These data demonstrate that the bulk of cellular Pfn1 exists in phosphorylated state. (This study is supported by a grant from the National Cancer Institute of NIH 2R01CA108607-06 to PR).

#### GSK3 Phosphorylates the Actin-Regulating Protein CAP1 (adenylyl Cyclase-Associated Protein 1).

G-L. Zhou<sup>1,2</sup>, H. Huhe<sup>1</sup>, P. Ghai<sup>1</sup>, J. Field<sup>2</sup>; <sup>1</sup>Department of Biological Sciences and Arkansas Biosciences Institute, Arkansas State University, State University, AR, <sup>2</sup>Department of Pharmacology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

**Background:** The actin cytoskeleton is crucial for many important cellular functions such as cell morphogenesis, cytokinesis, cell polarity and motility. Understanding how cells signal to the actin cytoskeleton may also shed light on the interplay between signals leading to morphological and proliferative transformation in cancer. For example, cofilin is an example that links cell signaling to the actin cytoskeleton because it is phosphorylated by LIM kinase to control actin dynamics. CAP (adenylyl Cyclase-Associated Protein) is a conserved key actin-regulating protein that functions with cofilin to regulate actin dynamics through two independent mechanisms. We have recently identified mammalian CAPs as phospho-proteins, and we aimed to unravel mechanisms of regulation of CAP1 by phosphorylation.

**Methods and Results:** We identified 9 phosphorylation sites on mouse CAP1 through a proteomics approach. Results from stable expression of point mutants that mimic both phosphorylated and dephosphorylated residues in NIH3T3 cells suggest that Ser36 and Ser307/Ser309 are regulatory sites since expression of the phosphomimetic mutants led to distinct actin cytoskeleton phenotypes. We developed phospho-specific antibodies against the Ser36 and Ser307/Ser309 sites, and found that inhibitors of GSK3 (Glycogen Synthase Kinase 3) reduces phosphorylation at the Ser307/Ser 309 sites. Kinase assays using synthetic peptides

narrowed the site to Ser309; Thr314 appears to serve as the priming site (motif: S/TxxxxS/T). Furthermore, whereas in untreated cells CAP1 partially localizes to cell peripherals, treatment with GSK3 inhibitor caused CAP1 to lose this localization and the cells lost cell polarity as well. We also screened physiological stimuli that may regulate CAP1 phosphorylation, and found that Ser309 phosphorylation is reduced in cells undergoing dynamic actin rearrangement, in contrast the phosphorylation is elevated in quiescent cells and cells cultured in suspension. GSK3 has been shown to play roles in cell migration and polarity, and our studies suggest that CAP1 may mediate some GSK3 signals.

1805

**Mutation of the Tlr1999 GAF domain from the cyanobacterium *Thermosynechococcus elongatus* to obtain red-fluorescence for possible use in cellular tagging.**

V. Metea<sup>1</sup>, A. Breen<sup>1</sup>, A. Carter<sup>1</sup>, J. Darnton<sup>1</sup>, S. Kwong<sup>1</sup>, B. Vaccaro<sup>1</sup>, C. Lagarias<sup>2</sup>, N. Rockwell<sup>2</sup>, S. Spiller<sup>1</sup>; <sup>1</sup>Biology, Mills College, Oakland, CA, <sup>2</sup>Molecular and Cellular Biology, UC Davis, Davis, CA

Fluorescent tagging is a very effective method to label proteins. GFP (green fluorescent protein) is the most widely used fluorescent tag, but as it is green fluorescent, the tags cannot be visualized beyond a certain depth into cells or tissues. Red fluorescent light travels farther, thus scientists can observe a wider range and depth by microscopy of tissue. There are red fluorescent tags currently available on the market, but we are engineering a shorter amino acid sequence to lessen the possibility of interference with other processes in living cells. The Spiller Lab is working with the Class II GAF domains of five distinct cyanobacteriochrome genes from the *T. elongatus* genome and has found that when mutated, these genes no longer perform blue/green photoconversion and instead they fluoresce near infrared light. Analysis of Tlr1999 cyanobacteriochrome in particular appears promising in its ability to fluoresce efficiently. It is in our interest to shorten the amino acid sequence of the tags, so a 176 amino acid truncation of the GAF region is being investigated for the behavior of its unmutated form to allow for investigation of the properties of its mutated form. The mutated form of Tlr1999 contains a point mutation of cysteine to aspartate performed to prevent photoreversibility (ensuring light absorption and then fluorescence in the longer wavelength red spectrum). Our ultimate goal is to bioengineer a small, red fluorescent tag (SmuRF) that can be used to visualize the lymphocyte cytoskeleton interacting with green fluorescent labeled HIV. Visualizing the details of the HIV infection process with advanced microscopy techniques may allow researchers to obtain insight and progress towards a cure.

1806

**Mutant alpha-crystallin inhibits lens growth by perturbing lens cell-cell alignment and cell elongation.**

W. Stopka<sup>1</sup>, C. Cheng<sup>2</sup>, X. Gong<sup>1,2</sup>; <sup>1</sup>UCB/UCSF Graduate Program in Bioengineering, UC Berkeley, Berkeley, CA, <sup>2</sup>Vision Science and Optometry, UC Berkeley, Berkeley, CA

The mechanism for how the  $\alpha$ A-Y118D crystallin mutant causes a unique postnatal lens growth defect remains unknown. We hypothesized three possible explanations for the postnatal growth defect in mutant  $\alpha$ A-Y118D lenses: 1) increased epithelial cell apoptosis, 2) decreased epithelial cell proliferation, or 3) failed fiber cell elongation. Results showed that  $\alpha$ A-Y118D lenses exhibited no increase in normal levels of lens epithelial cell apoptosis. BrdU labeling revealed no difference in epithelial cell mitotic index between P7 wild-type (WT) and mutant lenses. In contrast, by P21, mutant lens epithelial cells had about half the normal mitotic index compared to WT lens epithelial cells. The decrease in mitotic index in mutant lenses suggests that the  $\alpha$ A-

Y118D mutant protein affects epithelial cell proliferation. Imaging of GFP-positive whole lenses displayed perturbed fiber cell-cell alignment and aberrant or delayed fiber cell elongation in  $\alpha$ A-Y118D mutant lenses from mice older than three weeks. To further investigate the mechanism for how  $\alpha$ A-Y118D mutant crystallin protein might cause these cellular defects, we determined the protein distributions of WT  $\alpha$ A,  $\alpha$ A-Y118D mutant, WT  $\alpha$ B in cultured primary epithelial cells isolated from WT and  $\alpha$ A-Y118D mutant lenses. Co-labeling with cytoskeletal proteins, we found that WT  $\alpha$ A and  $\alpha$ B crystallin proteins are associated with F-actin filaments in WT cultured lens epithelial cells. In contrast, in the cultured  $\alpha$ A-Y118D mutant lens epithelial cells, WT  $\alpha$ B remains associated with F-actin while  $\alpha$ A-Y118D shows no association with F-actin. Thus,  $\alpha$ A-Y118D probably affects F-actin in some way to perturb fiber cell-cell alignment and fiber cell elongation in mutant lenses.

1807

**The GAF only domain TePixJ from Cyanobacteriochrome of *Thermosynechococcus elongatus* BP-1 transfected into mammalian cells for enhanced in vivo microscopy in the near-infrared spectrum.**

*R. F. Meza-Acevedo<sup>1</sup>, T. Ou<sup>1</sup>, D. Thompson<sup>2</sup>, D. B. Salantes<sup>1</sup>, E. Charbonneau<sup>1</sup>, B. Vaccaro<sup>1</sup>, J. Darnton<sup>1</sup>, S. Lane-Njuguna<sup>1</sup>, A. Breen<sup>1</sup>, N. Rockwell<sup>2</sup>, J. C. Lagarias<sup>2</sup>, S. Spiller<sup>1</sup>; <sup>1</sup>Biology, Mills College, Oakland, CA, <sup>2</sup>UC Davis, Sacramento, CA*

Cyanobacteriochromes are widely occurring photoreceptors in photosynthetic bacteria that respond to all wavelengths of the visible spectrum. The diversity of two cyteines photocycles of cyanobacteriochromes has been recently demonstrated. *Thermosynechococcus elongatus* BP-1, a thermophilic cyanobacterium, have several cyanobacteriochromes whose ability to fluoresce far-red light after a single mutation to the second cysteine in their GAF domain. In this study we engineered a short, near-infrared fluorescent protein from isolated GAF domain of TePixJ (TII0569) in class II cyanobacteriochromes, incorporating phycocyanobilin as the chromophore. The fluorescent protein has excitation and emission maxima of 647 and 660 nm, respectively, a quantum yield of 0.081, and consists of 174 amino acids, which is much smaller than previously characterized Infrared Fluorescent Proteins. To examine its function in fusion proteins, we constructed a plasmid using an actin vector as a model and transfected mammalian cells for in vivo imaging. Visualization of transfected lymphocyte cells suggests promising success of labeling the actin cytoskeleton with near-infrared fluorescence. Future goal of our project is to construct plasmids using a tubulin vector and other actin vectors as models, and use the red-labeled lymphocyte cells to study virus infection processes, in collaboration with partners at the Center for Biophotonics Science and Technology (CBST-UC Davis) and UC Davis Department of Biochemistry.

1808

**Cooperative G-actin binding regulates shuttling of the RPEL protein Phactr1 to control PP1 activity and actomyosin assembly.**

*M. Wiazlak<sup>1</sup>, S. Mouilleron<sup>2</sup>, J. Diring<sup>1</sup>, J. Abella<sup>3</sup>, M. Way<sup>3</sup>, N. Q. McDonald<sup>2</sup>, R. Treisman<sup>1</sup>; <sup>1</sup>London Research Institute, Transcription Laboratory, Cancer Research UK, London, United Kingdom, <sup>2</sup>London Research Institute, Structural Biology Laboratory, Cancer Research UK, London, United Kingdom, <sup>3</sup>London Research Institute, Cell Motility Laboratory, Cancer Research UK, London, United Kingdom*

Actin-binding proteins play crucial roles in the regulation of actin dynamics and assembly of F-actin structures involved in cell migration, adhesion and metastasis. We previously established that G-actin binding controls the subcellular localization and activity of the MRTF family of

transcription co-activators. The regulatory RPEL domain of MRTFs contains three copies of the G-actin binding RPEL motif. Signal-induced depletion of the G-actin pool reduces G-actin-RPEL interaction, causing nuclear accumulation and activation of MRTFs. In contrast, the Phactr family of novel PP1-binding proteins each contain four RPEL motifs, but whether G-actin can control their function and how they regulate PP1 activity is unclear. In this study we analyze the role of actin-Phactr interaction in control of Phactr localization and interaction with PP1.

Activation of Rho-actin signaling in fibroblasts induces nuclear accumulation of Phactr1, but not other family members. Actin binding by the three C-terminal RPEL motifs is required for Phactr1 cytoplasmic localisation in resting cells and its nuclear accumulation is importin  $\alpha$ - $\beta$ -dependent. Moreover, G-actin and importin  $\alpha$ - $\beta$  compete to bind NLSs associated with the N- and C-terminal RPEL motifs and all four motifs are required for the inhibition of Phactr1 nuclear accumulation by elevated G-actin.

We report the structure of a Phactr1 G-actin•RPEL domain complex with three G-actins around the crank-shaped RPEL domain forming a closed helical assembly. Their spatial relationship is similar to our previously described pentavalent MRTF-A G-actin•RPEL domain complex, suggesting conserved cooperative interactions between actin•RPEL units organize the RPEL domain. We identified novel contacts with neighbouring actins and show that secondary contact residues of the N-terminal RPEL motif are required for actin-mediated inhibition of Phactr1 nuclear import. This strongly suggests that those contacts govern formation of multivalent actin•RPEL assemblies.

We show that G-actin and PP1 bind competitively to the Phactr1 C-terminal region. Expression of Phactr1 C-terminal RPEL mutants that cannot bind G-actin induces actomyosin foci, which occur in a PP1-dependent manner. Finally, in CHL-1 metastatic melanoma cells, Phactr1 exhibits actin-regulated subcellular localization and is required for stress fibre assembly, motility and invasiveness. These data reveal a novel role for Phactr1 in actomyosin assembly and suggest that Phactr1 G-actin sensing allows its coordination with F-actin availability.

1809

#### **Probing the functional roles of caldesmon using phosphomimetic peptides.**

*R. Huang<sup>1</sup>, T. Kitazawa<sup>1</sup>, Q. Jiang<sup>1</sup>, T. Jain<sup>1</sup>, C-L. A. Wang<sup>1</sup>; <sup>1</sup>Boston Biomedical Research Institute, Watertown, MA*

The interaction between the actin-binding protein caldesmon (CaD) and actin is regulated by Erk- and Pak-mediated phosphorylation at sites in the C-terminal region where the major actin-binding sites reside. To probe the roles of CaD and its phosphorylation in vivo, we have designed three phosphomimetic peptides: ErkA, corresponding to the CaD sequence flanking the Erk-phosphorylation sites with the two Ser residues replaced by Ala; PakA, corresponding to the CaD sequence flanking the Pak-phosphorylation sites with the two Ser residues replaced by Ala; and ErkD, same as ErkA except that the Ser residues are replaced by Asp. All peptides were labeled with FITC and coupled to a Tat-tag at the N-termini. Overnight incubation of these CaD peptides with tissues or cells attained high loading efficiency as evidenced by the incorporation of the FITC fluorescence. We have performed force measurements on intact rat mesenteric arteries incubated with CaD peptides to see how the contractile properties are perturbed. Tension was measured with phenylephrine stimulation. For ErkA/PakA-loaded tissues, the same force level was obtained as the control (buffer alone), but the relaxation was slower. For the tissue incubated with ErkD peptide, the kinetics was more similar to the control. The observed effect of the peptides (ErkA+PakA) was reminiscent of the results with smooth muscle CaD-null tissues, suggesting that, as shown by the in vitro experiments, filament-bound

smooth muscle CaD is displaced by ErkA/PakA, but not by ErkD. In another experiment peptide-loaded human metastatic breast cancer cells MDA-MB231 were tested in nude mice through subcutaneous injection. It was found that ErkA and PakA effectively suppressed tumor development. How these peptides interfered with tumor growth awaits further investigation, but these pilot experiments demonstrated the feasibility and usefulness of synthetic decoy peptides in the studies of CaD's functions. Supported by a grant from NIH (HL92252).

### **Toxoplasma gondii Actin Assembles via Isodesmic Polymerization**

K. Skillman<sup>1</sup>, C. Ma<sup>1</sup>, K. Diraviyam<sup>2</sup>, D. Fremont<sup>3</sup>, J. Cooper<sup>4</sup>, L. Sibley<sup>1</sup>, D. Sept<sup>2</sup>;

<sup>1</sup>Molecular Microbiology, Washington University School of Medicine, St. Louis, MO, <sup>2</sup>Biomedical Engineering, University of Michigan, Ann Arbor, MI, <sup>3</sup>Pathology and Immunology, Washington University School of Medicine, St. Louis, MO, <sup>4</sup>Cell Biology and Physiology, Washington University School of Medicine, St. Louis, MO

The protozoan parasite *Toxoplasma gondii* relies on actin polymerization for motility and host cell invasion. Despite this strict requirement for actin filaments, *T. gondii* actin (TgACTI) remains largely unpolymerized *in vivo* and recombinant TgACTI only forms short filaments *in vitro*. TgACTI has several amino acid substitutions when compared with muscle actin, and our previous work showed that these changes significantly diminish the lateral contacts and interactions within the actin filament. The net result is that the two strands of the filament assemble with less cooperativity and not surprisingly this has significant effects on the polymerization kinetics. Here we show that the highly unusual characteristics of TgACTI result from isodesmic polymerization rather than the nucleation-elongation kinetics of conventional eukaryotic actins. TgACTI polymerization kinetics lack a lag phase and critical concentration, and all of the results from dynamic light scattering, dilution induced depolymerization, and sedimentation can be fit using a single pair of kinetic rate constants. These findings expand the repertoire of how actin functions in cell motility and offer clues about the evolution of self-assembling, stabilized protein polymers.

## **Regulation of Actin Dynamics II**

### **Drosophila nurse cell dumping reveals a novel interaction between prostaglandin signaling and Fascin.**

C. M. Groen<sup>1</sup>, A. Spracklen<sup>1</sup>, T. Fagan<sup>1</sup>, T. Tootle<sup>1</sup>; <sup>1</sup>Anatomy and Cell Biology, University of Iowa, Carver College of Medicine, Iowa City, IA

Prostaglandins (PGs), lipid signals produced downstream of cyclooxygenase (COX) enzymes, are known to regulate actin cytoskeletal dynamics. However, the mechanisms by which PGs mediate this remain unknown. *Drosophila* nurse cell dumping, an important process in oogenesis, provides a model for studying how PG signaling affects actin remodeling. This process requires active remodeling of the actin cytoskeleton to allow the nurse cells to squeeze their cytoplasmic contents into the growing oocyte. Using this model, we have previously shown that PGs are required for actin remodeling during nurse cell dumping, and that Pxt is the *Drosophila* COX-like enzyme. A screen utilizing our *in vitro* follicle maturation assay (Spracklen, Meyer, and Tootle, unpublished data) identified the actin bundling protein Fascin (Singed in *Drosophila*) as a putative downstream target of PG signaling. Fascin has previously been shown to be required for actin filament bundle formation during oogenesis and nurse cell

dumping. Here, we show that fascin and pxt mutants display similar actin remodeling defects in nurse cells. Reduced Fascin levels enhance the nurse cell dumping, and thus actin remodeling, defects of both COX inhibition and reduced Pxt levels. Reduced Fascin levels synergize with reduced Pxt levels to affect actin filament bundle formation, cortical actin structure, and membrane integrity in nurse cells. Additionally, over-expression of Fascin in the germline suppresses the effects of COX inhibition and loss of Pxt. Importantly, Fascin levels, both mRNA and protein, are not affected by alterations in PG signaling. These data indicate that Fascin activity is a downstream target of PG signaling in nurse cell dumping. Understanding the regulation of Fascin by PGs has relevance to cancer cell migration and metastasis, where independent studies have implicated critical roles for both PGs and Fascin. Current efforts focus on determining the mechanism by which PGs regulate Fascin in both *Drosophila* and human breast cancer cells. In *Drosophila* follicles, we find that Fascin localization, both nuclear and cytoplasmic, is altered by loss of PGs. We are also assessing the roles of PKC, Rho, and Rac as potential downstream effectors of PGs in the regulation of Fascin. These studies will advance our understanding of mechanisms controlling Fascin, which is becoming an attractive target for cancer therapeutics.

1812

### **Calling the Shots: Prostaglandins Temporally and Spatially Regulate Actin Remodeling During *Drosophila* Nurse Cell Dumping.**

A. J. Spracklen<sup>1</sup>, X. Chen<sup>1</sup>, T. L. Tootle<sup>1</sup>; <sup>1</sup>Anatomy and Cell Biology, University of Iowa, Carver College of Medicine, Iowa City, IA

Prostaglandins (PGs), small bioactive lipids that act as autocrine/paracrine signaling molecules, mediate numerous physiological and cellular processes including actin cytoskeletal remodeling. However, the exact mechanisms by which PG signaling regulates actin remodeling remain largely unknown. Previously, we have shown that PGs regulate actin cytoskeletal dynamics during *Drosophila* nurse cell dumping, providing a novel, developmental model in which to study PG-dependent actin remodeling. Lasting just thirty minutes, *Drosophila* nurse cell dumping is a highly dynamic process requiring spatial and temporal coordination of active actin cytoskeletal remodeling in order for the nurse cells to supply their cytoplasmic contents to the oocyte. Recently, we have found that loss of Pxt, the *Drosophila* COX-like enzyme, results in aberrant actin filament and extensive actin aggregate formation prior to the onset of canonical actin remodeling during nurse cell dumping. We are taking advantage of this temporal misregulation of actin remodeling to identify actin binding proteins and regulatory molecules acting downstream of PG signaling to tightly control the onset of actin remodeling. Specifically, we are using immunofluorescence to identify factors that co-localize to these aberrant, early actin structures and genetic interaction studies to identify factors that suppress or enhance aberrant, early actin structure formation in *pxt* mutants. By combining correlative microscopy with robust genetic analysis, we can begin to elucidate the mechanisms by which PG signaling temporally regulates actin cytoskeletal remodeling. Actin remodeling is tightly temporally regulated both during development and adult homeostasis. Temporal misregulation of actin remodeling directly contributes to the development and progression of multiple cardiovascular diseases, including developmental defects, heart attack, stroke, and cardiomyopathies. Understanding the molecular mechanisms by which PGs tightly regulate actin remodeling during nurse cell dumping may provide insight into the conserved mechanisms by which PG signaling temporally regulates actin remodeling.

1813

**Endothelial cell responses to fluid shear stress and inflammatory mediators.**S. N. Farwell<sup>1</sup>, L. J. Lowe-Krentz<sup>1</sup>; <sup>1</sup>Biological Sciences, Lehigh University, Bethlehem, PA

Vascular endothelial cells (ECs) are constantly exposed to fluid shear stress (FSS), chemical stresses (such as inflammatory cytokines, etc.), and immune cell trafficking. ECs must therefore respond to physical and chemical cues. Three key signaling systems involved in this regulation are the actin cytoskeleton, adherens junctions, and immune cell recruitment. Together, these modulate important downstream signaling induced by FSS and/or inflammation. However, studying these interactions *in vivo* is difficult and current *in vitro* models seldom mimic *in vivo* conditions or include FSS and chemical stressors. ECs initially respond to both FSS and inflammatory stressors with actin realignment, barrier changes, and immune cell recruiting; over time, FSS is athero-protective while inflammatory stress results in EC layer damage. In this study, we employ a FSS system to compare both primary large vessel and microvessel EC responses to FSS, with or without inflammatory stress, to static conditions. Our laboratory has established that high FSS (>15 dyn/cm<sup>2</sup>) induces an actin remodeling process beginning shortly after FSS exposure. We now show that FSS also induces an interaction between actin and  $\beta$ catenin in large vessel EC barriers after 90 minutes. TNF $\alpha$  induces actin remodeling within 30 minutes and barrier localization of  $\beta$ catenin after 60 minutes in static culture, similar to FSS effects. In microvessel ECs, actin remodeling and barrier stabilization in response to high FSS are similar, but appear somewhat delayed compared to large vessel cells. When challenged with TNF $\alpha$  under FSS, actin stabilization is hindered and barrier integrity is lost, as evidenced by a reduction in  $\beta$ catenin. In static culture, both EC types express the immunological signaling marker ICAM-1 in vesicles around the nuclear membrane. Under FSS, ICAM-1 translocates to the surface and cell-cell junctions around 30 minutes in large vessel ECs. Some ICAM-1 remains in cytoplasmic vesicles for several hours. In these same cells, 2 hours of static TNF $\alpha$  treatment results in ICAM-1 translocation to the cell surface. Unlike large vessel ECs, when microvessel ECs are challenged with TNF- $\alpha$  under FSS, surface ICAM-1 is upregulated quickly but does not localize to junctions. Short-term FSS and TNF $\alpha$  stimulation induce quite similar actin remodeling,  $\beta$ catenin localization, and ICAM-1 expression in both EC types. How long-term FSS contrasts with TNF $\alpha$  to result in vastly different effects remains an important question. Support from NIH award HL54269 to LLK and the BDSI funded by an HHMI undergraduate education grant to Lehigh University is gratefully acknowledged.

1814

**Turnover of focal adhesions required for efficient cell migration is regulated by parallel actin bundles.**N. Elkhatib<sup>1</sup>, M. Neu<sup>1</sup>, C. Zensen<sup>2</sup>, K. M. Schmoller<sup>2</sup>, D. Louvard<sup>1</sup>, A. R. Bausch<sup>2</sup>, D. M. Vignjevic<sup>1</sup>; <sup>1</sup>Institut Curie, Paris, France, <sup>2</sup>Technische Universität Muenchen, Garching, Germany

Cell initiates migration by extending membrane protrusions which are stabilized by focal adhesions (FAs) that link the actin cytoskeleton to the underlying extracellular matrix. A stress fiber is a bundle of actin filaments with mixed polarity cross-linked with  $\alpha$ -actinin and myosin II. It is not clear how tensile forces, generated by actomyosin contraction of stress fibers, can strengthen FAs at the cell front and disassemble FAs at the cell rear allowing cell migration. Using PA-GFP-actin we found that the distal part of the stress fiber anchored to the FA has a different actin organization, dynamics and function than the proximal part. It is a non-contractile bundle composed of parallel actin filaments cross-linked by fascin and deprived of myosin II. Fascin-depleted cells were more contractile and their adhesions were thinner and longer

suggesting that myosin II is more active. Indeed, myosin II ATP-ase and in vitro motility assays showed that fascin inhibits myosin II motor activity possibly through the competition for binding to actin filaments. The turnover of FAs in fascin-depleted cells was slower and using FAs disassembly assay, we found that fascin is required for FAs disassembly after microtubule re-growth. Based on those data we propose a following model: at the cell leading edge, the distal non-contractile bundle of a stress fiber indirectly strengthens FAs providing a necessary power to resist actomyosin contractile forces. However, at the cell rear, de-bundling of the stress fiber's distal part is necessary for efficient FAs disassembly. Thus, actin bundling by fascin could determine the fate of adhesions under force.

1815

#### Switching contractility in active actin networks by pH.

S. Köhler<sup>1</sup>, K. M. Schmoller<sup>1</sup>, A. H. Crevenna<sup>2</sup>, A. R. Bausch<sup>1</sup>; <sup>1</sup>E27 Cellular Biophysics, Technische Universität München, Garching, Germany, <sup>2</sup>Department of Chemistry and Biochemistry, Ludwig-Maximilians-Universität München, München, Germany

The interplay of local force generation by myosin-II motor filaments and crosslinking of actin filaments is essential for various cellular processes ranging from cell division to tissue formation. While recently the local organization principles in such active gels have been discovered, the regulation process of the active behavior still remains to be investigated. In vivo, cytoskeletal processes are controlled by various biochemical pathways. Whereas such biochemical signal cascades are intrinsically highly specific but rather slow, variation of pH might provide a fast alternative, which could trigger a rapid cytoskeletal response. Here we show that the contractility of active actin networks is tightly controlled by the local pH. The pH dependent intrinsic crossbridge strength of myosin-II can be employed to sharply switch the actomyosin network from contractile to non-contractile by a change in pH of only 0.1. The specific type and concentration of cross-linking protein used allows to sensitively adjust the range of pH where contraction occurs, which can recover the behavior found in *Xenopus laevis* oocyte extracts. Controlling the contractility of cytoskeletal structures by only a small variation in pH provides a new mechanism which can be expected to have broad implications in our understanding of cytoskeletal regulation.

1816

#### Molecular mechanism of Rickettsia Sca2-mediated actin assembly.

Y. Madasu<sup>1</sup>, D. J. Kast<sup>1</sup>, C. Suarez<sup>2</sup>, M. Cardwell<sup>3</sup>, J. J. Martinez<sup>3</sup>, D. R. Kova<sup>2</sup>, R. Dominguez<sup>1</sup>; <sup>1</sup>Physiology, University of Pennsylvania, Philadelphia, PA, <sup>2</sup>Molecular Genetics and Cell Biology, and of Biochemistry and Molecular Biology, University of Chicago, Chicago, IL, <sup>3</sup>Microbiology, University of Chicago, Chicago, IL

Many bacterial pathogens utilize the host cell actin cytoskeleton during invasion or to propel their movement within and between infected cells. Often, pathogens resort to mimicry for such activities, by expressing proteins that adopt the core functions of some key actin cytoskeletal components. In so doing, pathogens tend to bypass the intricate regulatory networks and interactions characterizing eukaryotic proteins, offering a rare opportunity to dissect their functions within a simplified system, with implications for our understanding of pathogenicity and the eukaryotic actin cytoskeleton alike. Rickettsia Sca2 is an outer membrane protein that promotes actin filament nucleation and barbed end elongation and has been implicated in the formation of the actin comet tails that promote Rickettsia motility. Although these activities have suggested that Sca2 functions by mimicking eukaryotic formins, the actual mechanism of actin assembly by Sca2 remains a mystery. Particularly, the lack of sequence similarity between

Sca2 and eukaryotic formins suggests a fundamentally different mechanism of nucleation, unlike those described so far for eukaryotic or bacterial nucleators. The passenger domain of *Rickettsia conorii* Sca2 (the species studied here) consists of 1482-aa and comprises a repeat of three WH2 domains toward the middle of the polypeptide, flanked by two Pro-rich sequences, which are often implicated in binding of profilin. Here, we have used a battery of biophysical approaches, including fluorescence, TIRF microscopy, ITC, x-ray crystallography and SAXS to determine the structural and functional bases for nucleation and elongation by Sca2. We show that Sca2 can be conceptually described as consisting two major functional domains, with one domain being primarily responsible for strong actin filament nucleation and the other domain involved in barbed end processivity. We have determined the atomic structure of the domain responsible for processivity, revealing a new fold and a unique mode of actin filament barbed-end tracking, as also confirmed by structure-based mutagenesis. In summary, the results suggest that *Rickettsia* Sca2 has adopted a novel mechanism of actin nucleation and elongation, which involves both mimicry of eukaryotic proteins and new adaptations without any parallel in the eukaryotic kingdom.

1817

**Eph/ephrin signaling is essential for precise cell-to-cell alignment during lens formation.**

C. Cheng<sup>1</sup>, X. Gong<sup>1</sup>; <sup>1</sup>*School of Optometry, University of California, Berkeley, Berkeley, CA*

Mammalian lenses are avascular and transparent organs made up of bulk elongated fiber cells covered by a monolayer of epithelial cells on the anterior surface. Equatorial epithelial cells elongate to form peripheral differentiating fibers that are precisely overlaid onto previous generations of fiber cells. Organization and tight packing of fiber cells is required to establish high refractive index and to maintain lens transparency. Disruption of Eph/ephrin signaling leads to cataracts in human and mouse lenses. We have investigated the roles of Eph/ephrin during lens development by using ephrin-A5 and EphA2 knockout (-/-) mice. Lens phenotypes of ephrin-A5(-/-) and EphA2(-/-) mice were examined, and confocal images of GFP-positive lens epithelial and fiber cells were collected. Cell-cell junctions, cell adhesions and cytoskeletal structures were studied by immunohistochemistry. Ephrin-A5(-/-) lenses often develop anterior cataracts associated with clusters of anterior epithelial cells undergoing epithelial-to-mesenchymal transition (EMT), and changes in E-cadherin and  $\beta$ -catenin staining further indicate that cell-cell junctions are compromised in these cells. Unexpectedly, anterior epithelial cells of EphA2(-/-) lenses show no obvious morphological changes, but equatorial epithelial cells fail to align into organized meridional rows. Immunostaining reveals that EphA2,  $\beta$ -actin, total and phosphorylated cortactin and phosphorylated Src are localized at cell membranes and are enriched at the vertices of wild-type hexagonal equatorial epithelial cells organized into meridional rows. In disorganized EphA2(-/-) equatorial epithelial cells,  $\beta$ -actin and total cortactin display abnormal clusters at the cell membrane, and there is a loss of phosphorylated cortactin and Src in these cells. EphA2 is crucial for lens equatorial epithelial cell alignment by regulating the phosphorylation of Src kinase and cortactin to recruit actin to cell vertices to form and align hexagonal cells into meridional rows. Actin dynamics control EphA2-mediated cell-cell packing of lens equatorial epithelial cells, and actin cytoskeleton changes probably lead to abnormal cell packing of EphA2(-/-) epithelial cells that result in misaligned fiber cells, causing subsequent changes in the refractive index of EphA2(-/-) lenses. The phenotypic difference between ephrin-A5(-/-) and EphA2(-/-) lenses suggests that these two molecules are not a receptor-ligand pair in the lens.

1818

**Perinuclear actin rim assembly upon mechanical stimulation.**

X. Shao<sup>1</sup>, Q. Li<sup>1</sup>, A. Bershadsky<sup>1</sup>, G. V. Shivashankar<sup>1</sup>; <sup>1</sup>Mechanobiology Institute, Singapore, Singapore

The ability of cells to sense the physical microenvironment and respond to mechanical cues is critical for their functions and survival. Actin cytoskeleton, connecting focal adhesions to the nucleus, plays a central role in cellular mechanotransduction. However, questions remain about how extracellular force is transmitted to actin, and how actin behaves upon a transient force application. Recently we have found that an intense mechanical stimulation by pushing the cell at periphery with micropipettes causes immediate actin cytoskeleton reorganization, namely, an actin rim incorporated with  $\alpha$ -actinin is quickly assembled at the cytoplasmic face of the nuclear envelope, which is detectable by phalloidin staining and live cell imaging using lifeact and F-tractin. The intensity of the nuclear rim reaches to its maximum in around 10-20 seconds and then recovers to the state before perturbation in another 40-60 seconds. The cells are able to respond to repeated stimulations. Blocking actin polymerization with Cytochalasin D eliminates the force-induced actin assembly, suggesting an important part of actin polymerization in this process. However, neither Arp2/3 inhibitor nor formin inhibitor SMIFH2 so far has precluded this phenomenon. Removing extracellular calcium by EGTA totally blocks the actin rim assembly, indicating the key role of calcium signaling. Furthermore, when adding thapsigargin or calcium ionophore A23187 that increases cytoplasmic calcium to the cell, a transient perinuclear actin rim shows up, same as induced by mechanical stimulation. Visualizing via an indicator Rhod-3, the intensity peak of calcium is a few seconds prior to that of actin. In summary, the force-induced perinuclear actin rim assembly is based on actin polymerization and regulated by calcium influx.

1819

**Cell plasticity is tightly linked to elastic stresses in the cytoskeleton.**

R. Gerum<sup>1</sup>, N. Bonakdar<sup>1</sup>, M. Kuhn<sup>1</sup>, A. Schilling<sup>1</sup>, A. Lippert<sup>1</sup>, M. Spoerler<sup>1</sup>, J. Wachsmann<sup>1</sup>, A. Mainka<sup>1</sup>, W. Goldmann<sup>1</sup>, B. Fabry<sup>1</sup>; <sup>1</sup>Biophysics, University of Erlangen-Nuremberg, Erlangen, Germany

Cells show pronounced non-linear visco-elastic and visco-plastic properties under large deformations and forces. These properties are important for protecting the cell against mechanical damage. We used a high-force magnetic tweezer setup to deliver unidirectional forces of up to 30nN with high precision to fibronectin-coated magnetic 5 $\mu$ m beads bound to cell surface adhesion receptors. To probe cells with bidirectional forces, the cell culture plate was placed on a rotational/translational stage such that the magnetic bead remained at a constant distance to the magnetic tweezer tip after a 180° rotation. Bead displacements were measured during application of force steps (creep response) and after the force was removed (recovery response). With increasing force magnitude, the cells stiffened, and the recovery became increasingly incomplete, indicating the emergence of plastic behavior. This plasticity was a constant fraction (~20%) of the total bead displacement. The plastic behavior is attributable to a buildup of excess slack in the cytoskeletal fibers; when the force direction was suddenly reversed, the beads jumped by twice the slack length in the opposite direction. The creep and the recovery response were fully characterized by a simple power-law vs. time with only two force-dependent parameters (viscoelasticity and slack). Our results show that plastic energy dissipation during large cell deformations is tightly linked to elastic stress dissipation and provides additional protection against mechanical damage.

1820

**Regulation of actin dynamics by cross-linking molecules.**

K. M. Schmoller<sup>1</sup>, T. Niedermayer<sup>2</sup>, C. Wurm<sup>1</sup>, C. Zensen<sup>1</sup>, A. R. Bausch<sup>1</sup>; <sup>1</sup>Physik Department E27, TU München, Garching, Germany, <sup>2</sup>Max Planck Institute of Colloids and Interfaces, Potsdam, Germany

The ability of cells to control the internal dynamics of actin filaments plays a crucial role in many cellular processes, including cell motility and cell division. We demonstrate that spontaneous fragmentation is the crucial process in the comparably slow steady state dynamics of in vitro actin filaments. Yet, in vivo, actin turn-over is enhanced by many different regulator proteins. Simultaneously, cells need mechanisms to locally stabilize actin filaments against induced depolymerisation in order to maintain certain actin structures for longer times. Using biochemical and fluorescence microscopy techniques we demonstrate that employment of cross-linking and bundling proteins not only gives cells a powerful tool to govern the architecture of cytoskeletal systems, but also allows for a drastic stabilization against internal kinetics by suppressing disassembly of cytoskeletal filaments. Even the actin depolymerizing factors are not sufficient to disintegrate highly cross-linked actin networks unless molecular motors are used simultaneously.

1821

**The specific actin bundling properties of alpha-actinin are tailored for cytokinesis in fission yeast.**

Y. Li<sup>1</sup>, A. Fok<sup>2</sup>, D. R. Kovar<sup>2</sup>; <sup>1</sup>Genetics, Genomics & Systems Biology, University of Chicago, Chicago, IL, <sup>2</sup>Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

During cytokinesis, the assembly and constriction of the contractile ring are mediated by the coordinated action of diverse actin-binding proteins, which nucleate, bundle, sever, and move along actin filaments. Alpha-actinin SpAin1 is the primary actin bundling protein for cytokinesis in fission yeast *Schizosaccharomyces pombe*. SpAin1 has a similar domain organization as animal isoforms, with an actin-binding domain followed by spectrin repeats that facilitate dimerization. Our goal is to biochemically elucidate the actin binding and bundling properties of SpAin1, and determine whether the specific properties are physiologically important for contractile ring function. Using bulk sedimentation assays and TIRF microscopy observation, we determined that SpAin1 binds and bundles actin filaments of mixed polarity. However, compared to animal alpha-actinins, SpAin1 bundles actin filaments with significantly lower efficiency. Because SpAin1 contains only two spectrin repeats for dimerization whereas animal alpha-actinins have four, we hypothesized that weak dimerization efficiency may contribute to SpAin1's weak bundling activity. We constructed various hybrid versions of SpAin1 by replacing its central dimerization domain with spectrin repeats from human alpha-actinin or commonly used synthetic dimerization peptides. As expected, replacement of the central dimerization domain enhanced SpAin1's F-actin bundling efficiency. We then examined whether changing SpAin1's actin filament bundling efficiency affects cytokinesis by expressing the hybrid versions of SpAin1 in cells. Fission yeast cells carrying the most efficient hybrid version of SpAin1 displayed severe cytokinesis defects including a high percentage of cells stalled in cytokinesis with abnormal rings, and/or excessive ring materials. We conclude that precise control of actin filament bundling activity is critical for proper ring dynamics. The spectrin repeats of SpAin1 make it a unique bundling factor with inefficient crosslinking efficiency, suitable for contractile ring dynamics in fission yeast. Excessive actin filament bundling might crosslink filaments so tightly that myosin fails to slide filaments during both assembly and constriction of the contractile ring.

1822

**RhoD regulates cytoskeletal dynamics via the actin nucleation-promoting factor WHAMM.**

V. Nehru<sup>1</sup>, A. Gad<sup>1</sup>, P. Aspenström<sup>1</sup>; <sup>1</sup>Microbiology, Tumor and Cell Biology, Karolinska Institutet, Stockholm, Sweden

RhoD is a member of the classical Rho GTPases sub family within the Ras superfamily. It has a role in the regulation of actin seen as the formation of filopodia and the bundles of actin filaments. Additionally, RhoD also plays an important role in endosome trafficking. The Rho GTPases are vital for fundamental cell processes such as cell motility, cell contraction, cell division and cell migration.

Here, we show that RhoD has a role in the organization of actin dynamics that is different from the better-studied members like Cdc42, RhoA and Rac1. We have identified the Filamin-A binding protein, FILIP1 and the nucleation-promoting factor, WASP homolog protein associated with actin, membranes and microtubules (WHAMM) as RhoD-interacting proteins. We show that FILIP1 and WHAMM belong to a group of proteins that possess similarities in their domain organization. Although both FILIP1 and WHAMM were found to possess a RhoD-binding capacity, they showed unique role in the control of the actin filament system. In agreement with the distinct function of these RhoD effectors, FILIP1 links to actin filaments via FLNa, whereas WHAMM acts through its C-terminal Arp2/3-binding motifs. In accordance with a key role of the RhoD in cytoskeletal dynamics, RhoD and its effectors were found to control vital cytoskeletal-driven cellular processes most notably cell attachment and cell migration.

1823

**The interplay between SCAR (WAVE) and WASP in actin-based motility.**

A. J. Davidson<sup>1</sup>, D. M. Veltman<sup>1</sup>, L. M. Machesky<sup>1</sup>, R. H. Insall<sup>1</sup>; <sup>1</sup>The Beatson Institute for Cancer Research, Glasgow, United Kingdom

The WASP family of proteins recruit and activate the Arp2/3 complex to promote actin polymerization. In particular, WASP family member SCAR (or WAVE) underlies protrusion (or 'pseudopod') extension during cell migration. Although the simple amoeba *Dictyostelium discoideum* is in many ways an ideal model for the study of cell migration, the limited but undeniable ability of the *Dictyostelium scar* null to extend pseudopodia and migrate has been a continued source of frustration and contention. Recently our lab has demonstrated that WASP is unexpectedly able to compensate for the loss of SCAR, adopting very different temporal and spatial dynamics compared to its normal behavior in wild-type cells (Veltman, D. M., *et al.* 2012. J. Cell Biol.)

A *Dictyostelium wasp* knockout has been unobtainable thus far and many people have assumed WASP must be essential for viability. We have now disrupted *wasp* by homologous recombination both alone and in combination with *scar*. We first confirmed that WASP is not required for normal cell migration in wild-type cells and instead predominantly localizes to sites of clathrin-mediated endocytosis. When visualized by TIRF microscopy, clathrin internalization is severely impaired in the *wasp* null and arrested clathrin pits accumulate on the plasma membrane. During cytokinesis, these trapped pits are swept into the forming cleavage furrow, which bulges and often fails to resolve. Our evidence suggests that the defective internalization of coated pits in the *wasp* null results in an impaired ability of the cell to remodel its plasma membrane, a process necessary for successful cleavage furrow formation and cytokinesis.

The loss of either SCAR or WASP alone has negligible effects on growth, however the loss of both has dire consequences. The double *scar/wasp* null has a severe defect in cell migration and is reminiscent of the recently published Arp2/3 depleted cells in morphology (Wu, C., *et al.* 2012. *Cell* & Suraneni, P., *et al.* 2012. *J. Cell Biol.*)

Having demonstrated that SCAR and WASP are each capable of driving actin-based protrusion and cell migration, we shall present the detailed analysis of cells that lack one or both of these proteins.

1824

**Regulation of actin polymerization during clathrin-mediated endocytosis by SLAC, a complex between Sla1 and Las17.**

D. Feliciano<sup>1</sup>, M. Hughes<sup>1</sup>, S. M. Di Pietro<sup>1</sup>; <sup>1</sup>Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

An important step during clathrin-mediated endocytosis is the polymerization of branched actin filaments nucleated by the Arp2/3 complex. Actin polymerization generates the necessary force to drive vesicle internalization. The homolog of the human Wiskott Aldrich syndrome protein (WASp), Las17, is the strongest Arp2/3 complex activator in yeast cells, it is not regulated by auto inhibition, and is present at sites of endocytosis 20 seconds before actin polymerization is detected. It is unclear how Las17 is inhibited during its initial 20 seconds of recruitment to sites of endocytosis limiting actin polymerization to late stages. In this study we demonstrate that Las17 and the clathrin adaptor Sla1 are co-recruited to endocytic sites in a pre-formed complex where Las17 is kept inhibited. Here we show that the Sla1- Las17 interaction is multivalent, direct, and strong, and is mediated by Las17 proline-rich sequences that simultaneously resemble class I and class II poly-proline motifs (class I/II). The mechanism by which Sla1 inhibits Las17 activity depends on the class I/II poly-proline motifs and is based on competition between Sla1 and monomeric actin for binding to Las17. Mutations in the Las17 class I/II poly-proline motifs that impede the interaction with Sla1 disrupt its ability to inhibit Las17 activity in *in vitro* pyrene-actin polymerization assays. In live cells, the same mutations uncoupled the recruitment of Sla1 and Las17 to endocytic sites, and altered the dynamics of actin polymerization. In addition, live cell imaging demonstrated that the interaction between Sla1 and Las17 is important for both bulk and clathrin-mediated endocytosis. Together, this study advances our understanding of how Sla1 and Las17 regulate actin polymerization during clathrin-mediated endocytosis (SLAC) as components of a stable complex.

1825

**The rhomboid protease Rbd2 regulates the actin cytoskeleton during clathrin-mediated endocytosis.**

C. L. Cortesio<sup>1</sup>, D. G. Drubin<sup>1</sup>; <sup>1</sup>Molecular & Cell Biology, University of California Berkeley, Berkeley, CA

Clathrin-mediated endocytosis (CME) is the main port of entry into yeast cells. This pathway is highly conserved and is critical for cell homeostasis. Defects in CME have been linked to several diseases including cancer, diabetes and cardiovascular disease.

The budding yeast, *Saccharomyces cerevisiae*, has served as an invaluable organism in which to analyze the ordered recruitment, activity and disassembly of endocytic proteins during CME. In yeast, actin polymerization is required to reshape the plasma membrane for endocytic vesicle formation, and a burst of actin assembly accompanies endocytic vesicle internalization. Despite

its key role in CME, only a limited understanding of the molecular signals that regulate the actin cytoskeleton currently exists.

Recent, large-scale screens identified several physical interactions between the relatively unstudied putative rhomboid protease, Rbd2, and known actin regulators including Las17 (yeast WASP), Sla1, Bzz1 and Lsb3/4. Rhomboid proteases are multi-pass, transmembrane proteins that regulate a variety of cellular events through the limited proteolysis of target substrates. Consequently, we tested the function of Rbd2 as a new molecular player in CME. Rbd2 affects endocytic protein lifetimes and morphology in yeast, with the most dramatic effects observed on proteins of the actin cytoskeleton. Rbd2 appears to be associated with one or more membrane compartments, and Rbd2-GFP comes in close contact with endocytic sites late in the pathway, coinciding with the initiation of actin polymerization. Yeast genetics combined with live-cell imaging demonstrate that actin polymerization is initiated earlier in an *rbd2* null strain, and suggest that Rbd2 negatively regulates actin polymerization upstream of the Las17 regulator, Bzz1. A catalytic mutant of Rbd2 phenocopies the *rbd2* null strain, indicating that Rbd2's protease activity is critical for its function during CME. Because rhomboid proteases are highly conserved, our research is expected to aid our understanding of actin regulation during CME in more complex eukaryotes.

**The analysis of the roles of the Arp2/3 complex activators in the endocytic actin patch assembly in fission yeast.**

*H. Bellinger*<sup>1</sup>, *E. Barone*<sup>2</sup>, *M. L. James*<sup>2</sup>, *V. Sirotkin*<sup>2</sup>; <sup>1</sup>*Department of Biology, Syracuse University, Syracuse, NY*, <sup>2</sup>*Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY*

In yeast and other organisms, endocytosis is dependent upon Arp2/3 complex-mediated actin assembly into endocytic actin patches, a highly organized process involving signaling molecules and regulatory proteins. The goal of this study is to determine the roles of three Arp2/3 complex activators Pan1, Myo1, and Wsp1, which bind Arp2/3 complex via their Central-Acidic (CA) domains, in stimulating actin patch assembly in fission yeast. To assess the contribution of these proteins to actin assembly, we performed quantitative image analysis of actin patch dynamics by tracking the GFP-tagged actin binding protein fimbrin Fim1 in *pan1*, *myo1* and *wsp1* mutants with deleted CA domains. In *myo1*ΔCA, like in the wild type cells, most patches internalized and patch dynamics was the same as in the wild type strain. In *pan1*ΔCA, most patches internalized but accumulated 2.3 times more actin and at the faster rate than in the wild type cells. In *wsp1*ΔCA, the majority of the patches failed to internalize, indicating failed endocytosis, and the rate of patch assembly and the total actin accumulation in the patch were decreased compared to the wild type cells. Next, we used genetic crosses and tetrad analysis to determine which of the CA domains of the Arp2/3 complex activators are essential for cell viability. We observed that combinations of *myo1*ΔCA with *pan1*ΔCA and *myo1*ΔCA with *wsp1*ΔCA resulted in viable cells, while the combination of *wsp1*ΔCA and *pan1*ΔCA mutants was synthetically lethal. This suggests that activation of the Arp2/3 complex by Wsp1 alone or Pan1 alone but not Myo1 alone is minimally sufficient for cell viability. Imaging Fim1-mGFP in cells with viable combinations of ΔCA mutations revealed that both the *myo1*ΔCA *pan1*ΔCA cells and the *myo1*ΔCA *wsp1*ΔCA cells contained actin patches, indicating that activation of Arp2/3 complex by either Wsp1 or Pan1 alone suffices to promote actin patch assembly. However, given the patch internalization defect in *wsp1*ΔCA but not in *pan1*ΔCA or *myo1*ΔCA mutants, we concluded that Wsp1 is the primary Arp2/3 complex activator at the endocytic sites, minimally sufficient to support actin assembly, cell viability, and endocytic internalization.

**Mechanism of Activation of the Arp2/3 Complex by Nucleation Promoting Factors.**

*M. Boczkowska<sup>1</sup>, G. Rebowski<sup>1</sup>, R. Dominguez<sup>1</sup>; <sup>1</sup>Physiology, University of Pennsylvania, Philadelphia, PA*

Arp2/3 complex is a ubiquitous actin filament nucleator comprised of seven proteins, two of which (Arp2 and Arp3) are related to actin. By itself Arp2/3 complex is inactive. It is activated by nucleation-promoting factors (NPFs), proteins that contain a C-terminal WCA sequence featuring binding sites for both actin (W) and Arp2/3 complex (CA). By bringing together actin and Arp2/3 complex and inducing a conformational change within Arp2/3 complex itself, NPFs catalyze a reaction that leads to the formation of a new actin filament branch bound at 70° angle to the side of a pre-existing (mother) filament. It is generally believed that the activation mechanism involves a conformational change within Arp2/3 complex that brings the two Arps close to one another, analogous to two parallel actin subunits of the actin filament. The two Arps, together with the actin monomer(s) delivered by NPFs, form a polymerization 'seed'. However, the exact mechanism of activation remains unknown, and there is disagreement as to which subunits of Arp2/3 complex interacts with NPFs and how. Currently, there are two competing models of activation. The first model is based on small angle X-ray scattering (SAXS) of Arp2/3 complex in complex with the WCA region of the NPF N-WASP and actin. According to this model only one NPF binds Arp2/3 complex and delivers the first actin monomer of the branch at the barbed end of the Arp2 subunit of Arp2/3 complex. The second model assumes that two NPF molecules are required for optimal activation, with the first actin monomer being delivered at the barbed end of Arp3, followed by binding of a second actin monomer (contributed by the second NPF) at the barbed end of Arp2. Of note, the studies in support of the latter mechanism do not directly analyzed binding of NPF carrying actin to Arp2/3 complex. Here, we present a study of the polymerization mechanism of the Arp2/3 complex that takes into consideration this critically missing factor, by using isothermal titration calorimetry (ITC) and fluorescence to investigate the interaction of NPFs carrying actin with Arp2/3 complex. Based on the results we propose a new model of Arp2/3 complex activation that reconciles the two previous competing models.

**Ena/VASP synergizes with the Arp2/3 complex via a molecular hand-off mechanism during actin-based motility.**

*P. Noguera<sup>1</sup>, S. Havrylenko<sup>1</sup>, J. Plastino<sup>1</sup>; <sup>1</sup>Institut Curie, Paris, France*

To investigate how actin is assembled for cell migration, we study an in vivo model for a lamellipodial type of cell motility: migration of the epidermal cells on the surface of the embryo during the ventral enclosure event of *Caenorhabditis elegans* embryogenesis. Enclosure is governed by the Arp2/3 complex and its activator, WAVE, a related protein, WASP, and Ena/VASP protein. Here we show that VASP's capacity to bind F-actin and profilin is key for its function in ventral enclosure. We use an in vitro motility assay to dissect the mechanism of action of VASP, and discover that VASP is recruited directly by Arp2/3 complex activators to potentiate actin assembly. Our data is consistent with a molecular "hand-off" mechanism whereby the Arp2/3 complex activator positions Ena/VASP so that the nascent barbed end issuing from the Arp2/3 complex branch is passed directly to Ena/VASP for protection against capping protein and retention at the surface, thus increasing the growth of the actin network and enhancing cell motility.

### Cell cycle regulation of actin cable organization and polymerization in *Saccharomyces cerevisiae*.

Y. Miao<sup>1</sup>, C. Wong<sup>2</sup>, A. Cormier<sup>1</sup>, J. Yates<sup>2</sup>, D. Drubin<sup>1</sup>; <sup>1</sup>University of California, Berkeley, Berkeley, CA, <sup>2</sup>The Scripps Research Institute, La Jolla, CA

Changes in actin cytoskeleton organization during the cell cycle underlie such processes as cell polarity development and cytokinesis. However, little is known about the mechanisms by which actin nucleation, filament organization and dynamics are regulated during the cell cycle to coordinate and arrange polarized cell processes. Using the yeast *Saccharomyces cerevisiae*, we have begun to address these mechanisms.

Having previously reconstituted Arp2/3-mediated branched actin network assembly on surfaces of micro-beads in yeast extracts, we have now successfully reconstituted formin-mediated actin cable polymerization in yeast cell extracts. Intriguingly, we found that actin cable formation is highly cell cycle regulated and dependent on Cdk1, which is different from Arp2/3-nucleated actin assembly. To identify the proteins that contribute to cell cycle regulated actin cable assembly, we performed comprehensive investigations by mass spectrometry of the actin cables polymerized in the cell extracts. We identified about 90% of the known actin cable regulatory proteins and a number of other subgroups of proteins including uncharacterized proteins. We found that one previously uncharacterized protein from our proteomic study associates with the polarisome, a structure found at sites of formin-mediated actin nucleation, and we showed that this protein functions as a potential actin filament-capping protein. Interestingly, in addition to this newly identified protein, several polarisome proteins are highly phosphorylated by Cdk1 with cyclin specificity. Consistently, both biochemistry and cell biology methods show Cdk1 kinase activity plays an important role in regulating actin cable assembly and organization. Finally, we also found evidence that such cell cycle regulation is conserved for yeast and vertebrate formin proteins.

### Dueling nucleation factors: Competition between formin and Arp2/3 complex for actin monomers.

C. Suarez<sup>1</sup>, M. L. James<sup>2</sup>, V. Sirotkin<sup>2</sup>, D. R. Kovar<sup>1,3</sup>; <sup>1</sup>Department of Molecular Genetics and Cell Biology, The University of Chicago, Chicago, IL, <sup>2</sup>Department of Cell and Developmental Biology, State University of New York Upstate Medical University, Syracuse, NY, <sup>3</sup>Department of Biochemistry and Molecular Biology, The University of Chicago, Chicago, IL

Cells simultaneously assemble and maintain differentially organized actin filament networks with specific architectures involved in diverse processes such as endocytosis, motility, polarization, cytokinesis. Actin filament organization is initially established by mechanistically distinct nucleation factors. Arp2/3 complex directs the formation of a branched dendritic network. Formin generates straight actin filaments. These nucleators are in competition for actin monomers, where formins have a disadvantage due to significantly lower cellular concentrations. Our hypothesis is that the small actin binding protein profilin allows formin to successfully compete with Arp2/3 complex. To test our hypothesis, we determined the contribution of profilin to actin-generated networks *in vivo* in the unicellular fission yeast

*Schizosaccharomyces pombe* utilizing genetics, chemical-genetic and live-cell imaging methods. Then, we reconstituted nucleator competition between the Arp2/3 complex and formin *in vitro* with 'bulk' pyrene actin assays, and by visualizing mixtures of formin- and Arp2/3 complex-nucleated actin filaments with Total Internal Reflection Fluorescence (TIRF) microscopy. We investigated a temperature sensitive profilin *cdc3-124* mutant. After 4 hours at the semi-permissive temperature of 33.5°C, the lack of functional profilin causes defects in 95% of formin Cdc12-dependent contractile rings. However, contractile ring defects are significantly reduced (60%) when Arp2/3 complex is inhibited via the small molecule inhibitor CK-666. We hypothesize that diminishing Arp2/3 complex decreases actin consumption in patches, liberating the remaining profilin-actin for assembly into formin-mediated structures. *In vitro* TIRF studies revealed that Arp2/3 complex-mediated branch density decreases in presence of profilin, favoring formin for the utilization of actin monomers. This study indicates that a primary role of profilin is to allow formin to efficiently compete with an excess of Arp2/3 complex for actin consumption.

1831

**Determination of the molecular basis for formin specification of profilin isoforms and its importance for fission yeast viability.**

A. Bestul<sup>1</sup>, A. Grzegorzewska<sup>1</sup>, E. Neidt<sup>1</sup>, D. Kovar<sup>1,2</sup>; <sup>1</sup>Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, <sup>2</sup>Department of Biochemistry and Molecular Biology, University of Chicago, Chicago, IL

Profilin stimulates rapid formin-mediated actin elongation by simultaneously binding both to the proline-rich formin FH1 domain and actin monomers. We found that formins variously utilize different profilin isoforms. The molecular basis for this isoform specificity does not stem solely from differences in profilin's affinity for the FH1 domain, suggesting that profilin's interaction with actin and/or the formin FH2 domain might also be critical. Interestingly, there is a direct correlation between profilin's ability to be efficiently utilized by the fission yeast cytokinesis formin Cdc12 *in vitro* and its ability to allow fission yeast cells to grow. We hypothesize that formin utilization of profilin-actin explains why profilin is required by fission yeast.

To test these hypotheses, we mutated a "suboptimal" profilin that is utilized poorly by a formin into an "optimal" profilin that can be utilized well by the formin. We are taking advantage of two important facts: (1) The fission yeast cytokinesis formin Cdc12 efficiently utilizes fission yeast profilin (SpPRF), but does not efficiently utilize budding yeast profilin (ScPFY), and (2) ScPFY does not complement a fission yeast profilin temperature sensitive mutant. Libraries of ScPFY mutants were prepared that systematically converted residues in ScPFY to match that of SpPRF. We identified a ScPFY mutant that has mutations in 9 amino acids that complements the fission yeast profilin-ts strain and is utilized significantly better by Cdc12 *in vitro*. Biochemical characterization revealed that the only biochemical parameters changed between the ScPFY mutant and wild-type profilin is its utilization by Cdc12 and slightly stronger PIP2 binding. The mutations lie in the actin-binding region of profilin, which also interacts with the formin FH2 region. We therefore propose a mechanism of specificity whereby the formin interacts with profilin at the barbed end of the actin filament, which helps release the profilin for subsequent cycles of filament elongation.

1832

### The Diaphanous-related formin dDia1 of *Dictyostelium discoideum* regulates cell migration.

M. Winterhoff<sup>1</sup>, M. Schleicher<sup>2</sup>, J. Faix<sup>1</sup>; <sup>1</sup>Institute for Biochemistry, Hannover Medical School, Hannover, Germany, <sup>2</sup>Institute for Cell Biology, Ludwig-Maximilians-University Munich, Munich, Germany

Formins are large multi-domain proteins that drive actin polymerization via de novo nucleation and elongation of unbranched filaments. The *Dictyostelium discoideum* genome project revealed that this organism expresses 10 different formins, from which nine belong to the Diaphanous-related formin (DRF) family. DRFs act as downstream effectors of Rho family GTPases, which in turn are major regulators of the actin cytoskeleton. Here, we focus on the DRF dDia1 (also known as formin F) from *Dictyostelium discoideum*. To explore its physiological role, we created null mutants by gene disruption or cell lines that overexpress dDia1. Analyses by time lapse phase-contrast microscopy revealed that random cell migration in dDia1 overexpressing cells was compromised. In contrast, loss of dDia1 led to a more than ~2-fold increase in cell speed. To ascertain the underlying cause of the motility phenotype, we analyzed the subcellular distribution of constitutive active dDia1 by indirect immunofluorescence microscopy. Notably, dDia1 was found to be accumulated evenly throughout the entire pseudopodium (the equivalent of the lamellipodium of mammalian cells) suggesting that it controls pseudopodial microfilament architecture to regulate cell migration. To biochemically analyze this formin in vitro, several C-terminal FH1FH2 constructs were expressed in *E. coli* and purified. Initial experiments employing actin pyrenyl assays and in vitro TIRF microscopy revealed that in absence of profilin dDia1 is a rather weak nucleator. Consistent with the interaction of all three profilin isoforms with the proline-rich FH1 region of dDia1 in Yeast two hybrid assays, recombinant profilin I-III accelerated formin-mediated actin filament barbed end elongation two to three fold in the TIRF microscopy assay. Interestingly, we frequently observed dissociation of the formin from fast growing barbed ends. These findings are consistent with dilution-induced depolymerization assays in the presence or absence of dDia1 FH1FH2 suggesting that dDia1 is weak capper when compared to heterodimeric capping protein.

1833

### Towards the better muscles in *Caenorhabditis elegans*: A tale of two formins.

L. Mi-Mi<sup>1</sup>, S. Votra<sup>1</sup>, K. Kemphues<sup>2</sup>, A. Bretscher<sup>2</sup>, D. Pruyne<sup>1</sup>; <sup>1</sup>Department of Cell and Developmental Biology, Upstate Medical University, State University of New York, Syracuse, NY, <sup>2</sup>Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY

Even though extensive studies have examined the structure of striated muscle actin cytoskeleton, not much is known about the mechanism of how actin filaments are incorporated into the sarcomere, the smallest unit in striated muscle organization. The barbed ends of actin filaments are anchored at the Z-lines that define the sarcomere ends, where net polymerization of actin filaments occurs favorably. It is known that formins, one of the highly conserved and most widespread families of actin nucleating factors (ANFs), have unique association with the barbed ends of action filaments.

In this study, we have shown that two nematode formins, CYK-1 and FHOD-1, work hand in hand to promote the growth of the contractile lattice and maintain the proper organization of the *C. elegans* striated muscle system. Through combination of genetic and microscopy methods, we have shown that depletion of either formin during larval development of *C. elegans* caused the stunted growth of contractile muscle lattice, and depletion of both formins severely reduced the lattice size and number of striations per muscle cell. Moreover, the near complete RNAi-

induced depletion of CYK-1 in *C. elegans* adults caused results ranging from the partial loss of Z-line-associated actin filaments to collapse of the entire muscle lattice.

In summary, our study provides the first *in vivo* genetic evidence of the existence of sarcomere-associated formins and their importance in growth and maintenance of the striated muscle contractile lattice.

1834

**Biochemical Characterization of the *Drosophila melanogaster* Ena/VASP Enabled and the formin Diaphanous.**

J. D. Winkelman<sup>1</sup>, J. A. Sees<sup>1</sup>, C. M. Bilancia<sup>2</sup>, M. Peifer<sup>2</sup>, D. R. Kovar<sup>1</sup>; <sup>1</sup>Cell and Molecular Biology, University of Chicago, Chicago, IL, <sup>2</sup>Department of Biology, University of North Carolina, Chapel Hill, NC

Formins and Ena/VASP family proteins stimulate the production of long-straight actin filaments. The general actin assembly properties of formins have been well established, revealing a common general mechanism whereby formins remain processively associated with the rapidly elongating barbed while directing the addition of 1000s of profilin-actin subunits before dissociating. Various formin isoforms have significantly different actin assembly rate constants, which tailors them for different cellular roles. Ena/VASP family proteins are less well understood. In solution they may remain processively associated with the elongating barbed end for the addition of only ~40 actin monomers and/or they may be highly processive when clustered on a surface. Both the formin Diaphanous (Dia) and the Ena/VASP family protein Enabled (Ena) assemble actin for the production of filopodia at the leading edge of *Drosophila melanogaster* cells. To better understand the general mechanism of how Formins and Ena/VASPs drive the rapid assembly of long-straight actin filaments, we have biochemically characterized the actin assembly properties of both Dia and Ena using bulk and single filament single/dual color TIRF microscopy. Dia behaves like a canonical formin, nucleating actin and processively adding profilin-actin at high rates to the actin filament barbed end. Surprisingly, in solution Ena also increases the elongation rate while remaining processively associated with the barbed end during the addition of ~1000 actin monomers. When at higher concentrations, Ena also nucleates and bundles actin filaments. The biochemical analysis of mixtures of Ena and Dia may help determine why cells possess two similar actin assembly factors for the production of filopodia.

1835

**Bud6 coordinates polarized actin cable assembly and maintenance of an ER-membrane diffusion barrier through its mechanistically distinct interactions with two formins.**

B. R. Graziano<sup>1</sup>, E. M. Jonasson<sup>1</sup>, J. G. Pullen<sup>1</sup>, C. J. Gould<sup>1</sup>, B. L. Goode<sup>1</sup>; <sup>1</sup>Brandeis University, Waltham, MA

Cell polarity in *S. cerevisiae* depends on formin-mediated nucleation of actin cables required for transport of secretory vesicles to the bud tip, and on septin structures at the bud neck, which are required to maintain membrane diffusion barriers between the mother and bud. We recently showed that the polarity protein Bud6 serves as an actin nucleation-promoting factor (NPF) for one of the two yeast formins, Bni1, located at the bud tip [1]. Other groups have shown that Bud6 is essential for maintenance of an endoplasmic reticulum (ER) membrane diffusion barrier at the bud neck [2], but whether there is any connection between these two functions of Bud6 has remained unknown. Here, we explored the potential role of Bud6 in regulating the bud neck formin, Bnr1, and whether there is any connection between its roles in actin regulation and maintenance of membrane diffusion barriers. Genetic analyses using *bud6* alleles defective in NPF activities in a *bni1Δ* background showed that Bud6 indeed serves as an NPF for Bnr1 in

vivo. Further, a purified C-terminal fragment of Bud6 (550-788) directly bound to Bnr1 and potently stimulated its actin nucleation activity in vitro. Strikingly, inclusion of adjacent sequences (489-549) masked Bud6 NPF effects on Bnr1, but not Bni1. Using endogenously-expressed Bud6-GFP, we isolated and identified by mass spectrometry a novel in vivo binding partner of Bud6, which we named Bud6-interacting ligand (Bil1). Bil1-GFP co-localized with Bud6-RFP at the bud neck, and depended on BUD6 for its localization. Purified Bil1 bound directly to the regulatory sequence in Bud6 (489-549) and unmasked Bud6's NPF effects on Bnr1. Genetic analysis showed that Bil1 is required for Bnr1-dependent actin cable assembly. To address whether Bud6 NPF effects are involved in maintaining the diffusion barrier at the neck, we used FLIP (fluorescence loss in photobleaching) to compare diffusion rates of Sec63-GFP, an integral ER membrane protein, in wild-type and bud6 mutant cells. This analysis revealed that mutants impaired in Bud6 NPF activity are as defective in maintaining the mother/bud ER diffusion barrier as *bud6Δ*. Taken together, our results demonstrate that through a Bil1-regulated mechanism Bud6 promotes Bnr1-mediated actin cable assembly at the neck, and that this function is closely integrated with its role in maintaining the mother/bud ER membrane diffusion barrier.

### Single Molecule Imaging of APC, mDia1, and EB1 Coordinated Effects on Actin Filament Assembly and Actin-Microtubule Crosstalk.

D. Breitsprecher<sup>1</sup>, R. Jaiswal<sup>1</sup>, J. P. Bombardier<sup>2</sup>, J. Gelles<sup>2</sup>, B. L. Goode<sup>1</sup>; <sup>1</sup>Biology, Brandeis University, Waltham, MA, <sup>2</sup>Biochemistry, Brandeis University, Waltham, MA

Mounting evidence suggests that the process of actin assembly in cells is catalyzed not by individual actin-nucleating proteins, but by sets of interacting proteins that form multi-component nucleation and elongation machines. We have begun to dissect the mechanism by which three interacting mammalian proteins, adenomatous polyposis coli (APC), the formin mDia1, and microtubule end-binding protein EB1, control the initiation and elongation of actin filaments, and coordinate actin and microtubule (MT) dynamics. By combining single-molecule TIRF microscopy with reconstituted actin polymerization, we defined an actin assembly "rocket launcher" mechanism mediated by mDia1 and APC. Fluorescently-tagged mDia1 and APC molecules formed dimer:dimer nucleation complexes that bound to actin monomers, leading to efficient formation of filaments even in the combined presence of the nucleation-suppressor profilin and filament capping protein CapZ. Formation of the nucleation complex required a direct interaction between APC and the C-terminal tail region of mDia1. At the onset of filament elongation, the mDia1-APC complex separated, resulting in mDia1 translocating at the growing barbed end and leaving APC behind at the pointed end. More recently, we have found that the APC-binding partner EB1 strongly inhibits APC nucleation activity, and we are currently testing its effects on mDia1-APC. Finally, to understand how this triad of interacting proteins coordinates actin and MT dynamics, we co-reconstituted actin polymerization and microtubule dynamic instability in two different colors in the same reaction. This system enables simultaneous analysis of the individual and combined effects of APC, mDia1, and EB1, each of which binds to MTs, on the spatial and temporal dynamics of the two polymer systems. Our preliminary data suggest that EB1 directs APC to MT tips, and that APC physically connects growing actin filaments with MTs. Combined with single-molecule imaging, this novel

experimental setup will provide unprecedented functional and mechanistic insights into the cellular mechanisms controlling actin-MT cross-talk.

## Microtubules and Associated Proteins

1837

### **CAMSAP2 and 3 cooperate to organize non-centrosomal microtubules and in turn regulate organelle assembly.**

*N. Tanaka<sup>1,2</sup>, W. Meng<sup>1,3</sup>, M. Takeichi<sup>1</sup>; <sup>1</sup>Center for Developmental Biology, RIKEN, Kobe, Japan, <sup>2</sup>Graduate School of Biostudies, Kyoto University, Kyoto, Japan, <sup>3</sup>Institute of Genetics and Developmental Biology, Chinese Academy of Sciences, Beijing, China*

Microtubules are one of the major components of the cytoskeleton, and play important roles in various aspects of eukaryotic cellular structure and functions, such as intracellular transport, organelle assembly, motility, and cell division. Animal cells contain two populations of microtubules, centrosomal and non-centrosomal. Centrosomal microtubules radially grow from the centrosome, with their minus ends anchored to the  $\gamma$ -tubulin ring complex. On the other hand, non-centrosomal microtubules are produced by various mechanisms, and their minus ends are located in the cytoplasm. In mammalian epithelial cells, their major microtubules are not anchored to the centrosome. Where they are nucleated and how their minus ends are stabilized are, however, little understood. Recent studies identified a novel protein, termed Nezha or CAMSAP3, that binds to the minus end of non-centrosomal microtubules. Moreover, two other proteins related to CAMSAP3, CAMSAP1 and CAMSAP2, were reported. However, their biological functions remain undetermined. Here we found that CAMSAP3 and CAMSAP2 cooperate to organize non-centrosomal microtubules in human Caco2 epithelial cells. We found that these two molecules cluster together at the minus ends of non-centrosomal microtubules, and cooperate to sustain their plus-end growth. Depletion of these molecules affected the pattern of microtubule assembly, causing a dramatic increase of centrosomal microtubules, and this effect was maximized by co-depletion of them. In CAMSAP-depleted cells, the Golgi apparatus was fragmented, and early endosomes displayed an altered distribution. Further analysis suggested that the ER-Golgi membrane trafficking was impaired in the absence of CAMSAPs. From these observations, we concluded that CAMSAPs play a key role in maintaining a population of non-centrosomal microtubules, and this population of microtubules is important for proper organelle assembly.

1838

### **Stathmin regulates mitotic entry in HeLa cells by controlling activation of both Aurora A and Plk1.**

*V. Caruso Silva<sup>1</sup>, L. Cassimeris<sup>1</sup>; <sup>1</sup>Biological Sciences, Lehigh University, Bethlehem, PA*

Microtubules have been an effective target for chemotherapeutics. However, microtubule disruptors also damage healthy tissues and not all cancer cells die during the mitotic arrests they induce; instead, they can exit without cytokinesis and continue to cycle as aneuploid cells. Improvements in current therapies would allow cancer cells to be selectively targeted without induction of further mutations. Loss of a microtubule regulator, stathmin, has been shown to slow the growth of certain cancer cells, accompanied by an accumulation of cells with 4N DNA content and an increase in cell death. We have shown previously by long term imaging that HeLa cells depleted of stathmin by siRNA had an increased interphase duration of about 5 hours in asynchronous cell populations, an increased interval from thymidine release to mitosis and

increased populations of interphase cells staining positive for cyclin B, cdk1Y15 or TPX2. From these data we hypothesized that stathmin depletion inhibited mitotic entry. We have now traced the delay to decreased activation of Aurora A kinase (AURKA) at the centrosome and Polo-like Kinase 1 (PLK1) on chromatin by measuring levels of phosphorylated (active) kinase by quantitative immunofluorescence. AURKA and PLK1 activation is reduced 50% and 70% respectively compared to control siRNA treated cells. By tracking live cell fates, we find that inhibition of Aurora A with selective inhibitor S1451 at 300nM resulted in a mitotic delay without a change in interphase timing. Inhibition of PLK1 with selective inhibitor BI2536 at 0.8nM caused a small interphase delay without a change in mitosis timing. Remarkably, treatment with both S1451 and BI2536 yields a long interphase delay of about 9 hours, which mimics loss of stathmin. To address how stathmin affects activation of AURKA and PLK1, we performed *in vitro* reactions with purified proteins. We discovered that AURKA phosphorylates stathmin at S16 and 63 and autoactivation of PLK1 is inhibited by stathmin, revealing a functional interaction between these proteins. It is possible that stathmin directly regulates activation of these two kinases. Alternatively, we have previously demonstrated that depolymerization of microtubules abrogates the stathmin depletion induced G2 delay, indicating that microtubules function as a relay signal. Therefore, stathmin influences mitotic entry either directly or via microtubules by controlling activation of key cell cycle enzymes.

1839

**Stu2p acts as a weak microtubule polymerase and a rescue factor *in vitro*.**

M. Podolski<sup>1</sup>, J. Howard<sup>1</sup>; <sup>1</sup>MPI-CBG, Dresden, Germany

Stu2p is a member of the Dis1/XMAP215 family of polymerases and is required for spindle orientation and metaphase chromosome alignment, and for anaphase B spindle elongation. Despite Stu2p having a phenotype suggesting that it promotes microtubule growth, studies till now with purified proteins indicate only that Stu2p antagonizes growth. To investigate the effect of Stu2p on microtubule dynamics *in vitro*, we purified recombinant Stu2p from insect cells and studied its effect in a total-internal-reflection fluorescence (TIRF) microscopy assay: GMPCPP-stabilized microtubules (seeds) were immobilized on the glass surface and varying amounts of fluorescently labeled porcine-brain tubulin, GTP and Stu2p proteins were added to the chamber. Images were acquired using time-lapse microscopy. In the presence of tubulin, Stu2p increased the microtubule growth rate, though to a lesser extent than XMAP215. Stu2p had no effect on the catastrophe frequency, but significantly increased the rescue frequency. In conclusion, Stu2p shares functional properties with its metazoan homolog XMAP215, though its polymerase activity is weaker. These properties go some way to explaining the phenotypes of the Stu2p-depleted cells.

1840

**The dynein regulator, Pac1p/LIS1, interacts with a STUbL.**

A. Alonso<sup>1</sup>, S. D'Silva<sup>2</sup>, M. Rahman<sup>1</sup>, J. Keeling<sup>1</sup>, N. Meednu<sup>2</sup>, R. K. Miller<sup>1</sup>; <sup>1</sup>Biochemistry, Oklahoma State University, Stillwater, TX, <sup>2</sup>Biology, University of Rochester, Rochester, NY

The function of Pac1p, the yeast homologue of Lis1, is closely associated with the minus-end directed motor protein, dynein. Mutations in Lis1 result in Miller-Dieker lissencephaly, a developmental brain syndrome caused by defects in neuronal migration. As part of the dynein pathway in yeast, Pac1p is important for recruiting dynein to the plus end of the microtubule. Dynein is subsequently "off-loaded" to the cortex where it pulls on cytoplasmic microtubules to move the mitotic spindle across the bud neck, a key step in spindle positioning. Although Pac1p plays a vital role in microtubule function, little is known about how it is regulated. Sumoylation is

a post-translational modification that covalently attaches the Small Ubiquitin-like Modifier (SUMO) protein to target substrates. Whereas sumoylation regulates many cellular processes, such as cellular transport, protein stability, and transcription, it has only recently been shown to regulate spindle positioning. Using a two-hybrid assay, Pac1p interacted with *SMT3*/SUMO and other key players of the sumoylation system. Ubiquitin-Like Protein-1 (Ulp1) is a protease that specifically cleaves Smt3p from its protein conjugates. Using a temperature-sensitive allele of *ULP1*, Pac1p displayed an accumulation of higher molecular weight bands, suggesting that SUMO can accumulate on Pac1p. In contrast to ubiquitination, sumoylation does not directly target its substrates for degradation. However, SUMO-Targeted Ubiquitin Ligases (STUbLs) can recognize a sumoylated substrate and promote its degradation by poly-ubiquitinating it. By two-hybrid analysis, Pac1p interacted with the STUbL enzyme Nis1p/Ris1p and the SUMO isopeptidase, Wss1p. Strains deleted for *RIS1* or *WSS1* displayed an accumulation of higher molecular weight Pac1p conjugates. Pull-down assays suggest that Pac1p is modified by both ubiquitin and SUMO. Modification of Pac1p was also increased by deletion of the dynein regulator, *SHE1*; and *KAR9*, protein required for correct positioning of the mitotic spindle. These findings also suggest that She1p is a novel inhibitor of Pac1p ubiquitination. This work has implications for the regulation of dynein's interaction with various cargoes, including its off-loading to the cortex. We suggest a novel model in which Pac1p is regulated via STUbLs.

#### **Molecular Determinants for Regulation of Microtubule-Severing by Katanin.**

*K. D. Grode<sup>1</sup>, S. L. Rogers<sup>1</sup>; <sup>1</sup>Biology, University of North Carolina, Chapel Hill, NC*

Microtubules (MTs) are dynamic cytoskeletal polymers that form complex and highly organized arrays essential for cell motility, morphogenesis, and division. MT-severing is a reaction that generates an internal break in the MT polymer and catalysis of MT-severing is required for the proper formation and function of MT-based arrays in a wide range of eukaryotic cells. The MT-severing enzyme Katanin is a conserved heterodimeric ATPase that severs and disassembles MTs, but the regulatory mechanisms that control MT-severing by Katanin are poorly defined. To better understand the regulation of Katanin, we conducted a structure-function study of Katanin in cultured *Drosophila* cells using a combination of high-throughput microscopy and live-cell imaging. We identified regions of the Katanin catalytic subunit that regulate its stability and MT-severing activity in cells and that are important for association with the Katanin regulatory subunit. We also identified regions of the Katanin regulatory subunit that regulate the MT-severing activity of the Katanin catalytic subunit and that are important for association with the Katanin catalytic subunit. By expressing differentially tagged Katanin catalytic and regulatory subunits alone or together in cells, we discovered that efficient MT-targeting by Katanin required both subunits. Furthermore, we found that the dynamic localization of Katanin on MTs was dependent on the ATPase activity of the Katanin catalytic subunit. These results indicate that both Katanin catalytic and regulatory subunits contribute to the activity and dynamics of Katanin in living cells.

#### **Myosin II Co-Chaperone UNC45A is required during natural killer (NK) cell functions.**

*Y. Iizuka<sup>1</sup>, M. Bazzaro<sup>1</sup>; <sup>1</sup>Masonic Cancer Center, University of Minnesota, Minneapolis, MN*

Natural killer (NK) cells are a component of the innate immune system whose functions is the lysis of virally infected and tumor target cells. Receptor-mediated recognition of target cells by NK cells triggers an orchestrated motion of microclusters toward the center of the contact area between effector and target cell (NKIS). This movement is associated with centripetal F-actin flow and polarization of the microtubule organizing center (MTOC) and perforin-containing

granules(1). Because polarization and exocytosis of lytic granules are necessary for NK cell cytotoxicity, understanding their mechanism of regulation is crucial for the understanding of physiological and pathological processes including autoimmune diseases and cancer. UNC45A is a member of the UCS family of proteins that interact with myosins to ensure their proper activity during cytokinesis, cell motility and contraction, as well as organelle trafficking within the cellular compartment(2). The myosin motor protein, myosin IIA (MYH9) has been recently shown to be recruited at the NKIS site and have a crucial role during re-direction and fusion of membrane fusion of lytic granules and NK cell cytotoxicity(3, 4). We and others have shown that myosin IIA functions are tightly regulated by the expression levels of its co-chaperone UNC45A(5, 6). Therefore, we sought of determining whether the myosin II co-chaperone UNC45A plays a role during NK cell functions. Herewith we report that : a) UNC-45 is expressed in primary NK cells and NK cell lines where it localizes and interacts with myosin II and Hsp90, b) UNC-45 genetic silencing results with impaired cytotoxic in NK cell lines and primary NK cells, c) UNC-45 plays a crucial role during release of lytic granules in NK cells. To our knowledge, this is the first report linking myosin II co-chaperone UNC45A function to natural killer cell activation.

**TIP150 molecular delineation, function, and regulation in cell migration.**

G. Adams Jr<sup>1</sup>, P. Xia<sup>2</sup>, Z. Wang<sup>2</sup>, X. Liu<sup>1</sup>, Y. Chu<sup>1</sup>, T. Ward<sup>1</sup>, X. Yao<sup>1</sup>; <sup>1</sup>Physiology, Morehouse School of Medicine, Atlanta, GA, <sup>2</sup>Anhui Key Laboratory of Cellular Dynamics and School of Life Sciences, University of Science and Technology of China, Hefei, China

The microtubule cytoskeleton orchestrates the cellular dynamics and plasticity that underlies cellular behavior such as cell cycle, morphogenesis and migration. Microtubule plus-end-binding proteins regulate the dynamic properties of microtubules during cell migration. Our recent study revealed that TIP150 is a novel plus end tracking protein interacting with EB1 and MCAK in vitro and in vivo (*EMBO Reports*. 2009. 10:857-65). We have also shown that TIP150 is essential for chromosome segregation, and governs proper kinetochore-microtubule attachment. It is, however, unclear whether TIP150 serves a functional role in cell migration when microtubule polymerization and depolymerization are spatiotemporally regulated, and how does the interaction with EB1 facilitate this dynamics process. We hypothesize that TIP150 functionally serves a role in cell migration and facilitates cellular dynamics during its migration. To delineate the molecular function of TIP150 and its regulation in cell migration, a combination of biophotonic analyses with RNA interference and chemical inhibitors was employed.

Immunofluorescence reveals that TIP150 localizes to EB1 in interphase cells. We speculate that phosphorylation disrupts the electrostatic interaction between EB1-TIP150 via hydrogen bonds between arginine of TIP150 and glutamate residues in the C-terminal tail of EB1.

**Dissecting the nanoscale distributions and functions of microtubule-end-binding proteins EB1 and ch-TOG in interphase HeLa cells.**

S. Nakamura<sup>1</sup>, I. Grigoriev<sup>2</sup>, T. Hamaji<sup>1</sup>, L. Cassimeris<sup>3</sup>, Y. Mimori-Kiyosue<sup>1</sup>; <sup>1</sup>Riken Center for Developmental Biology, Kobe, Japan, <sup>2</sup>Division of Cell Biology, Faculty of Science, Utrecht University, Utrecht, Netherlands, <sup>3</sup>Dept of Biological Sciences, Lehigh University, Bethlehem, PA

Recently, the EB1 and XMAP215/TOG families of microtubule binding proteins have been demonstrated to bind autonomously to the growing plus ends of microtubules and regulate their behaviour in in vitro systems @ (Bieling et al., Nature, 2007, 45, 1100-5; Brouhard et al., Cell, 2008, 132, 79-88). However, their functional synergy or redundancy in cells remains obscure.

Last year, we reported that ch-TOG is localized at more distal along the microtubules than EB1 in interphase HeLa cells using high-resolution SIM (structured-illumination microscopy) technique. Since then we carefully evaluated the SIM images and analysed large number of microtubules, and concluded that the ch-TOG accumulation sites protrude ~100 nm from the EB1 comets. Over-expression experiments showed that they bind to microtubule tips in a noncompetitive manner, confirming that they recognize distinct regions at the ends of microtubules. While both EB1 and ch-TOG have similar effects on microtubule plus end dynamics and additively increase microtubule dynamicity, only EB1 exhibits microtubule-cell cortex attachment activity. These observations indicate that EB1 and ch-TOG regulate microtubule organization differently through the distinct portion of microtubule plus ends.

1845

**Systematic analysis of the dynamic EB1 +TIP-interactome in budding yeast.**

B. Van Der Vaart<sup>1</sup>, P. Pichler<sup>2</sup>, A. Schleiffer<sup>3</sup>, S. Opravil<sup>2</sup>, J. Fuchs<sup>2</sup>, K. Mechtler<sup>2</sup>, S. Westermann<sup>1</sup>; <sup>1</sup>Molecular and Cellular Biology, Research Institute of Molecular Pathology (IMP), Vienna, Austria, <sup>2</sup>Mass Spectrometry Facility, Research Institute of Molecular Pathology (IMP), Vienna, Austria, <sup>3</sup>Bioinformatics Facility, Research Institute of Molecular Pathology (IMP), Vienna, Austria

The highly dynamic microtubule (MT) cytoskeleton plays many essential roles in chromosome segregation, intracellular transport and cell morphology. MT dynamics and attachment to cellular structures is regulated by a wide plethora of plus-end tracking proteins (+TIPs) that specifically interact with growing MT plus ends. The majority of +TIPs are recruited to MT ends by interacting with the End Binding (EB) family members. These are autonomous +TIPs considered to be at the “core” of the +TIP interaction network. Association of proteins to the highly conserved EBs is mediated by two distinct structural features; one involves the interaction between EB’s hydrophobic C terminal cavity with a short linear (S/T)x(I/L)P (SxIP) peptide motif in its partner and the second involves EB’s C terminal acidic and aromatic tail binding to CAP-Gly domains.

Recent advances in the field have greatly increased the number of known mammalian EB interactors and thereby the complexity of the EB1 +TIP-interactome. It has thus become difficult to dissect the specific roles of individual +TIPs in modulating MT function, in addition little is known about how the composition of the +TIP network is established and regulated both in time and space.

To circumvent the problem of increased mammalian complexity and to characterize +TIP networks in a genetically tractable organism, we use the budding yeast *S. cerevisiae* to systematically analyze the changing composition of the EB1 +TIP-interactome over the cell cycle.

By combining a bioinformatics approach to search the budding yeast genome for SxIP-motif containing proteins and a biochemical method in which EB1 interacting proteins are purified from defined cell cycle stages and analyzed by quantitative mass spectrometry, we have identified known EB1 interaction partners, such as Ipl1, Kar9 and Stu2, validating our approach. In addition, we have identified novel EB1 interactors that display differential EB1 affinities over the yeast cell cycle. We are currently using a combination of cell biology, biochemistry and fluorescent microscopy techniques to unravel the cell biological significance of these interactions as well as their structural basis.

1846

### **The critical role of EB1 and dynein in three-dimensional cell migration.**

A. Giri<sup>1,2</sup>, H. Jayatilaka<sup>1,2</sup>, N. Trenton<sup>1,2</sup>, G. D. Longmore<sup>2,3</sup>, D. Wirtz<sup>1,2</sup>; <sup>1</sup>Department of Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, <sup>2</sup>Johns Hopkins Physical Sciences - Oncology Center, Johns Hopkins University, Baltimore, MD, <sup>3</sup>Departments of Medicine and Cell Biology and Physiology and Bright Institute, Washington University School of Medicine, St. Louis, MO

Cell migration is important for various biological processes including embryogenesis, wound healing, inflammatory response, and cancer cell metastasis. Cell migration requires synchronization of many events such as polarization of signaling molecules, orientation of microtubule organizing center towards the direction of migration, and importantly the rapid reorganization of actin and microtubule cytoskeleton. Numerous studies have focused on elucidating the role of actin in cell migration; however, recent studies have shown that stabilization of microtubules plays a pivotal role in this process. Most of these studies have been performed in cells migrating on flat two-dimensional (2D) substrates, but cell migration *in vivo* predominantly occurs through 3D matrices and not much is known about the role of microtubule and microtubule-binding-proteins, EB1 and LIC2 in 3D motility. Here we report that both microtubule organization and dynamics are critical for 3D cell migration. Moreover, we show that destabilization of microtubules by depletion of EB1 and LIC2 attenuates cell migration by reducing protrusion activity.

1847

### **GTSE1 is a Microtubule Plus-end Tracking Protein that Regulates EB1-dependent Cell Migration.**

M. Scolz<sup>1</sup>, P. Widlund<sup>2</sup>, S. Piazza<sup>1</sup>, S. Reber<sup>2</sup>, T. Hyman<sup>2</sup>, C. Schneider<sup>1</sup>, A. W. Bird<sup>3</sup>; <sup>1</sup>Laboratorio Nazionale CIB (LNCIB), Trieste, Italy, <sup>2</sup>Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, <sup>3</sup>Max Planck Institute of Molecular Physiology, Dortmund, Germany

The regulation of cell migration is a highly complex process that is often compromised when cancer cells become metastatic. The microtubule cytoskeleton is necessary for cell migration, but how microtubules and microtubule-associated proteins regulate multiple pathways promoting cell migration remains unclear. Microtubule plus-end binding proteins (+TIPs) are emerging as important players in many of cellular functions, including cell migration. Here we identify a novel +TIP, GTSE1, that promotes cell migration. GTSE1 accumulates at growing microtubule plus ends through interaction with the EB1 +TIP. The EB1-dependent +TIP activity of GTSE1 is specifically required for cell migration, as well as for microtubule-dependent

disassembly of focal adhesions. GTSE1 protein levels determine the migratory capacity of both nontransformed and breast cancer cell lines. In breast cancers, increased GTSE1 expression correlates with invasive potential, tumor stage, and time to distant metastasis, suggesting that misregulation of GTSE1 expression could be associated with increased invasive potential.

1848

### **Clasp1 is essential for neonatal lung function and survival.**

A. L. Pereira<sup>1,2</sup>, L. Ferreira<sup>1</sup>, M. Jaegle<sup>3</sup>, N. Galjart<sup>3</sup>, H. Maiato<sup>1,2</sup>; <sup>1</sup>IBMC, Porto, Portugal, <sup>2</sup>Department of Experimental Biology, FMUP, Porto, Portugal, <sup>3</sup>Erasmus MC, Rotterdam, Netherlands

CLIP-Associating Proteins (CLASPs) are microtubule plus-end-tracking proteins with an important role in the regulation of microtubule dynamics and involved in chromosome segregation during mitosis. In *Drosophila* and yeast, CLASP loss-of-function resulted in the generation of mitotic abnormalities, with subsequent aneuploidy, indicating that this protein is essential for cell division and viability. In *C.elegans*, RNAi of the orthologue *cls-2* yielded embryonic lethality. In mammals, including humans, two paralogues, CLASP1 and CLASP2, exist, which prompted us to further investigate their individual roles. For that, we successfully generated *Clasp1* knockout (KO) mice through homologous recombination in embryonic stem cells. Our data demonstrate that targeted disruption of *clasp1* gene not only causes intrauterine growth restriction, as revealed by low body weight at birth, but also leads to early neonatal lethality as a consequence of an acute respiratory failure, with the KO animals displaying cyanotic features shortly after being born. Histological analyses of the KO animals proved lack of inflation in the lungs without any obstruction of the respiratory tract being observed. Our immunohistochemical results suggest a delayed fetal lung maturation characterized by decreased sacculation that, however, does not impair the presence of surfactant. Importantly, protein expression results show *Clasp1* presence in the lungs throughout embryonic development. Altogether, our findings reveal a novel and critical role for the plus-end tracking protein *Clasp1* in fetal growth, as well as proper lung development and respiratory function in a mammalian model system.

1849

### **Molecular mechanism of cooperative microtubule stabilization by microtubule plus-end tracking proteins CLASP2 and EB1.**

T. Maki<sup>1</sup>, I. Hayashi<sup>1</sup>; <sup>1</sup>Supramolecular Biology, Yokohama City University, Yokohama, Japan

Microtubules (MTs) are highly dynamic polymers that are essential for physiological events such as cell shape remodeling and intracellular transport. They possess a structural polarity, with fast growing plus-ends directed toward the cell periphery and minus-ends anchored at the centrosome. The plus-ends of MTs display alternating phases of growth and shrinkage, which is called dynamic instability. Growing plus-ends are composed of a layer of GTP-tubulin that stabilizes the MT structure, whereas the rapid depolymerization of the filament is attributed to the loss of the "GTP-cap."

A large number of MT-associated proteins (MAPs) contribute to the dynamics of MTs. The plus-end tracking proteins (+TIPs), which specifically localize to the MT plus-ends, directly regulate the MT behavior and are thought to link the MT-ends to the various cellular structures. One of the +TIPs, CLASP proteins, are members of the XMAP215/Dis1 family in the MAPs and work as stabilizing factor of MTs. While XMAP215 directly binds to the tubulin dimer and functions as a MT polymerase, CLASPs rather work as a rescue factor and suppress the catastrophic events of MTs. MT-binding regions are located in the N-terminal half, composed of two tubulin-binding

TOG-like domains and the Ser-rich (SR) region. EB1, known as a hub protein of the +TIPs at the plus-end, binds to the internal motif of the SR region, indicating that CLASPs associate with MTs in two distinct manners; MT lattice-binding through the MT-binding domains and the plus-end tracking via EB1. In addition, it has been known that the serine/threonine protein kinase GSK3 $\beta$  is involved in the regulation of CLASP-mediated MT dynamics. The putative phosphorylation sites are located in the vicinity of the EB1 binding sites, suggesting that the post-translational modification affects both to CLASP- and EB1- mediated MT stabilization.

In order to understand the molecular mechanism of both CLASP2-binding to MTs and MT regulation by EB1 via CLASP2, we have determined the crystal structures of two MT-binding domains in CLASP2. Both structures form six HEAT-repeats known as a TOG domain. The analysis of GTP hydrolysis by tubulin showed that the CLASP2 and EB1 complex influence MT stabilization *in vitro*. We will discuss the molecular mechanism of MT stabilization which may affect cell migration and chromosomal segregation.

1850

**EB1 and XMAP215 recognise structurally and functionally distinct binding sites at growing microtubule ends.**

S. P. Maurer<sup>1</sup>, G. Bohner<sup>1</sup>, E. Boutant<sup>1</sup>, N. Cade<sup>1</sup>, T. Surrey<sup>1</sup>; <sup>1</sup>London Research Institute, London, UK

Growing microtubule ends serve as transient binding platforms for essential plus end binding proteins (+TIPS) that regulate microtubule dynamics and their interactions with cellular substructures. The core of the +TIP network is formed by end binding proteins (EBs) that autonomously bind microtubule ends and recruit a diverse family of other +TIPs, which enable microtubule ends to participate in a variety of processes. Another prominent autonomous microtubule end tracking protein is the processive microtubule polymerase XMAP215, the *Xenopus* chTOG ortholog, which is able to increase microtubule growth speed up to 10-fold *in vitro* by increasing the association rate of tubulin. It is an open question of whether these two proteins bind to the same or different binding sites. It is clear that EBs recognise hundreds of binding sites located between protofilaments in an extended region at growing microtubule ends. Most likely, GTP hydrolysis is involved in the generation of the high affinity conformation of these sites. Strikingly, the majority of the extended EB binding region is lost before onset of microtubule depolymerisation (catastrophe), suggesting an interesting mechanistic link with the phenomenon of dynamic instability of microtubules. The nature of the XMAP215 binding site is less well understood. Here, we addressed the question of whether the two end trackers EB1 and XMAP215 potentially bind to sites at different positions at the microtubule end.

Using simultaneous two-colour TIRF microscopy, we imaged *in vitro* reconstitutions of purified microtubule end tracking proteins. Using automated image analysis, we investigated the spatial characteristics of the fluorescence signals of EB1-GFP and XMAP215-GFP at the end of microtubules grown in GTP. Averaged fluorescence signal profiles provided high-resolution insight into the distributions of the different +TIP binding sites. In contrast to the extended nature of the EB1 binding region covering several 100 nm at the microtubule end, the binding sites of XMAP215 fell into the region of a diffraction-limited spot, demonstrating that these two proteins recognise different features at growing microtubule ends. An interesting difference between these sites is that the XMAP215 binding sites remain present at an almost constant level throughout the dynamic cycle of the microtubule, in clear contrast to the EB sites. Therefore, the different features recognised by EB1 and XMAP215 likely reflect different sub-regions at the microtubule plus end with different functions in dynamic instability.

1851

**Microtubule stability mediated by new mammalian STOP domain family members.***I. A. Onyeneho<sup>1</sup>, T. Stearns<sup>1</sup>; <sup>1</sup>Stanford University, Stanford, CA*

Stable Tubule Only Polypeptide or STOP proteins are a class of microtubule-associated proteins that are unique in that they have been shown to protect microtubules from depolymerization under destabilizing conditions. To date, Map6 and the related protein Map6 domain containing 1 (Map6D1) are the only known mammalian STOP domain-containing proteins. However, through a recent screen identifying genes upregulated during ciliogenesis in multiciliated tracheal cells, we have identified two new uncharacterized mammalian STOP domain-containing proteins, which we have named Map6-like 1, and Map6-like 2 (Map6L1, Map6L2). Though Map6 has not been previously shown to localize to the primary cilium and centrosome, we sought to assess the ability of these new proteins to stabilize microtubules and their potential function at the cilium and centrosome. Proteins related to Map6L1 and Map6L2 are found in all vertebrates as well as *Drosophila* and *Chlamydomonas*. GFP tagged Map6L1 localizes to the centrosome and the primary cilium, and overexpressed protein stabilizes microtubules to cold treatment and anti-microtubule drugs in cells. Studies are currently in progress to establish specific microtubule binding domains and other protein-protein interactions. Though the similarity of Map6L1 and Map6L2 to Map6 is distant, both Map6L1 and Map6L2 contain extensive repeat sequences much like Map6, and we are currently investigating the role of this repeat structure in the function of the protein.

1852

**MAP65-1/Ase1 increase microtubule flexibility.***D. Portran<sup>1</sup>, M. Zoccoler<sup>1</sup>, J. Gaillard<sup>1</sup>, V. Stoppin-Mellet<sup>1</sup>, E. Neumann<sup>2</sup>, I. Arna<sup>3</sup>, J-L. Martiel<sup>1</sup>, M. Vantard<sup>1</sup>; <sup>1</sup>Institut de Recherches en Technologies et Sciences pour le Vivant, Grenoble, France, <sup>2</sup>Institut de Biologie Structurale, Grenoble, Grenoble, France, <sup>3</sup>Institut de Neurosciences, Grenoble, Grenoble, France*

Microtubule (MT) bundling plays a key role in the formation of functional MT arrays in numerous eukaryote cells. Although detailed mechanisms responsible for the formation of these self-organized bundles are not well understood, observations in living plant cells showed that physical collisions between MTs/small bundles at angles up to 40° result in their co-alignment and zippering. As MTs are rigid structures with a persistence length up to 1 mm and as they have to be locally deformed to co-align at such angles, we investigated whether MT cross-linkers that belong to the conserved MAP65 family (plant MAP65-1 and yeast Ase1) could manipulate MT flexural rigidity. We have reconstituted bundle arrays of growing MTs in the presence of MAP65-1/Ase1 in vitro. We observed that these two orthologous MAP65 induce the co-alignment and bundling of antiparallel MTs that encounter at angles up to 45°. During collision, MTs were deformed to amplitude that suggests a fine-tuning of their stiffness. To measure the rigidity of growing MTs in the presence of MAP65-1/Ase1, we developed an in vitro assay based on hydrodynamic flux and a biophysical model. We demonstrated that MAP65-1/Ase1 drastically increased the flexibility of both, single MTs and MT bundles (persistence lengths of single MTs in presence of MAP65-1 and Ase1 are 4 and 3.2 times smaller than that of single naked MTs). The MT binding domain of MAP65-1/Ase1 specifically mediates their softening effect. These data provide new insights on how these MT bundlers, by modifying MT mechanical properties control the issue of MT-MT encounters resulting into the spontaneous formation of self-organized ordered MT arrays.

1853

### **Formation of a parallel microtubule array by MAP4 is required for muscle cell differentiation.**

*B. Mogessie<sup>1</sup>, A. Straube<sup>1</sup>; <sup>1</sup>Centre for Mechanochemical Cell Biology, University of Warwick, Coventry, United Kingdom*

During muscle cell differentiation, myoblasts elongate and fuse into syncytial myotubes. Microtubule integrity and proper regulation of microtubule dynamics are essential to support these morphological changes. Myogenesis is accompanied by the remodelling of the microtubule cytoskeleton, involving disassembly of the centrosome and, crucially, the alignment of microtubules into a parallel array along the long axis of the cell. We show that microtubules in undifferentiated myoblasts are highly motile, and show bidirectional sliding movements that are largely driven by dynein. In contrast, microtubules are long-lived and relatively static in myotubes, suggesting that microtubules might be heavily crosslinked to provide physical support to these elongated cells.

Here, we identify a previously uncharacterised isoform of microtubule-associated protein MAP4, oMAP4, as a microtubule organising factor that is crucial for myogenesis. We show that oMAP4 is expressed upon muscle cell differentiation and is the only MAP4 isoform that is essential for normal progression of the myogenic differentiation programme. Depletion of oMAP4 impairs cell elongation and cell-cell fusion, causes a delay in centrosomal protein reorganisation and expression of sarcomer components. We find that oMAP4 is required for parallel microtubule organisation in muscle cells by preventing microtubule-microtubule sliding. Consistently, purified oMAP4 aligns dynamic microtubules in vitro. We propose a model in which zippering of microtubules by oMAP4 drives formation of a parallel microtubule network that supports myogenesis.

1854

### **Testing a Neuroprotectant for Improving Memory in Aged Rats.**

*O. Bullard<sup>1</sup>, U. S. Ikonne<sup>1</sup>, P. Quizon<sup>1</sup>, H. Romine<sup>1</sup>, B. A. Bahr<sup>1</sup>; <sup>1</sup>Biotechnology Research and Training Center, William C. Friday Laboratory, University of North Carolina at Pembroke, Pembroke, NC*

The aim of this research project was to test the effect of Z-phenylalanyl-alanyl-diazomethylketone (PADK), a proof-of-concept lysosomal modulator, in aged rats. This small molecule has gained key attention due to the many studies showing its ability to enhance lysosomal enzyme levels and produce protective clearance of PHF-tau (hyper-phosphorylated tau) and A $\beta$ 42 (Amyloid beta) in the brain. Both PHF-tau and A $\beta$ 42 have been thought to contribute to Alzheimer's disease (memory loss). Aged Fischer and Long Evans rats provide a natural model of aging and cognitive decline and may be more translatable to humans, as compared to transgenic mouse models used previously to assess lysosomal modulators – the mouse models focus only on one particular aspect of the disease. Two different tests were performed, the Spontaneous Alternation Behavior (SAB) Experiment and the Passive Avoidance Experiment, to demonstrate how age and the administration of PADK affects two different types of rats who are of different ages. The SAB experiment indicates that there was an age effect among the Young Long Evans and the Old Long Evans, substantiating indications that with age comes cognitive decline of the memory in both animals and humans. In the Passive Avoidance test, PADK was proven to work on the Fischer rats. The initial findings indicate that PADK-treated rats display upgraded passive avoidance behavior as compared to aged rats that received drug delivery vehicle only.

1855

**Small molecules synthesized by *Aspergillus nidulans* inhibit Tau aggregation.**

S. R. Paranjape<sup>1</sup>, Y-M. Chiang<sup>2,3</sup>, R. Entwistle<sup>1</sup>, C. C. Wang<sup>2</sup>, B. R. Oakley<sup>1</sup>, T. C. Gamblin<sup>1</sup>;  
<sup>1</sup>Molecular Biosciences, University of Kansas, Lawrence, KS, <sup>2</sup>Department of Pharmacology and Pharmaceutical Sciences, School of Pharmacy, University of Southern California, Los Angeles, CA, <sup>3</sup>Chi Nan University of Pharmacy and Science, Tainan City, Taiwan

Alzheimer's disease (AD) is the most common form of dementia, affecting millions of people every year. The treatments currently available in the field are limited either to improving the cognitive abilities for a short period of time or are controversial. They do not modify or reverse disease progression. In AD the microtubule-associated protein tau forms insoluble intracellular aggregates in the brain that correlate with dementia and neurodegeneration. Therefore anti-aggregation compounds inhibiting formation of these aggregates are seen as potential therapeutics for AD. In a previous study, 200000 compounds were screened for tau aggregation inhibitor activity and some compounds belonging to the class of anthraquinones were found to be effective [Mandelkow, E. *et.al.* (2005). *Journal of Biological Chemistry* **280** (5): 3628-3635]. *Aspergillus nidulans* has the ability to synthesize many natural products including anthraquinones as secondary metabolites through different biosynthetic pathways. We therefore tested 17 compounds synthesized by *Aspergillus nidulans* for their activity against tau aggregation *in vitro*. 10 compounds out of 17 showed a decrease in tau polymerization activity in a dose-dependent fashion in *in vitro* assays. The compounds affected the length and number of tau filaments formed as well as the total amount of polymerization. The most efficacious compounds were tested in *in vitro* reactions to determine whether they interfere with tau's normal function of stabilizing microtubules (MTs). While there was variability among compounds, the majority did not completely inhibit tau stabilization of MTs. These results will be further evaluated in various cellular systems and animal models. This study demonstrates that *Aspergillus nidulans* metabolites may provide a rich source of potential therapeutic lead compounds that inhibit tau aggregation without compromising its normal cellular functions of stabilizing microtubules. Supported by grant P01 GM 084077 and by the H. L Snyder foundation.

1856

**A Novel Tauopathy Model Utilizing *Dictyostelium discoideum*.**

K. E. Miller<sup>1</sup>, A. L. Erwin<sup>1</sup>, S. L. Hall<sup>1</sup>, M. L. Steinhilb<sup>1</sup>, C. K. Damer<sup>1</sup>; <sup>1</sup>Biology, Central Michigan University, Mount Pleasant, MI

Alzheimer's disease is a chronic, progressive brain disorder, affecting approximately 35 million people worldwide. Pathologically, Alzheimer's disease is characterized by the accumulation of two types of brain lesions: senile plaques and neurofibrillary tangles. Neurofibrillary tangles are found within neurons and are formed by the aggregation of paired helical filaments, in which the main component is tau, a microtubule associated protein. The mechanisms by which tau aggregates into filaments remains uncertain, but studies have shown that phosphorylation and proteolysis by calpain are major contributors to tau-mediated toxicity. Cleavage of tau by calpain is thought to result in a highly toxic form of tau called the 17kD fragment. In this study, we are using *Dictyostelium discoideum* as a novel tauopathy model to investigate how these post-translational modifications of tau lead to its cellular toxicity. *Dictyostelium* cells were transformed with plasmids to express wild-type (tau<sup>WT</sup>) and mutant forms of human tau (phosphorylation-incompetent, tau<sup>AP</sup>; calpain-resistant, tau<sup>CR</sup>; tau 17kD fragment, tau<sup>17</sup>). The constitutive expression of tau<sup>WT</sup>, tau<sup>CR</sup>, and tau<sup>17</sup> was sufficiently toxic to induce cell death. However, tau<sup>CR</sup> expression appeared to be slightly less toxic than expression of tau<sup>WT</sup> or tau<sup>17</sup>. Expression of tau<sup>AP</sup> was not toxic to *Dictyostelium* wild-type cells. These results suggest that phosphorylation

plays an important role in tau toxicity. Because the expression of tau under a constitutive promoter rapidly induces cell death, we are now using an inducible vector system in which transcription of the tau gene can be reversibly turned on with the addition of doxycycline. Thus far, tau<sup>WT</sup> has been successfully cloned into the inducible vector. Once all of the inducible vector plasmids are constructed, we will characterize the effect of tau and mutant tau expression on *Dictyostelium* survivability and cell division. Development of *Dictyostelium* as a tauopathy model may provide a unique system for high-throughput screening of new therapeutic molecules for the treatment of Alzheimer's disease.

### **$\alpha$ -tubulin K40 acetylation is dispensable for brain development but required for epithelium morphogenesis in the cornea.**

A. S. Aguilar<sup>1</sup>, T. Tedeschi<sup>2</sup>, T. Shida<sup>3</sup>, C. Iomin<sup>2</sup>, M. V. Nachury<sup>1</sup>; <sup>1</sup>MCP, Stanford University, Stanford, CA, <sup>2</sup>Mount Sinai School of Medicine, New York, NY, <sup>3</sup>The University of Chicago, Chicago, IL

Acetylation of lysine 40 of  $\alpha$ -tubulin is a highly conserved post-translational modification that predominates in long-lived microtubules such as those found in axons or cilia. Although  $\alpha$ -tubulin K40 acetylation is highly correlated to microtubule stability, the causal link between acetylation and stability is still elusive and the functional importance of tubulin acetylation remains unclear. Protozoa lacking  $\alpha$ -tubulin K40 acetylation display no overt phenotypes and their cilia appear normal while nematodes lacking  $\alpha$ -tubulin K40 acetylation have impaired mechanosensation.

In mammals,  $\alpha$ -tubulin K40 acetylation was previously shown to play a role in axonal polarization and in cortical neuronal migration. It is thus expected that  $\alpha$ -tubulin K40 acetylation plays a major role in brain development. To assess the contribution of acetylated tubulin to neural development in vivo, we genetically ablated the enzyme responsible for  $\alpha$ -tubulin K40 acetylation,  $\alpha$ TAT1, in mice. Surprisingly,  $\alpha$ TAT1-deficient mice are fertile and viable and do not present any obvious morphological or behavioral defect. Furthermore, although  $\alpha$ TAT1-deficient mice appear completely devoid of acetylated tubulin, their overall brain anatomy was indistinguishable from their wild-type littermates, and the number and length of their cilia were unaffected.

A remarkable pattern of acetylated tubulin is found in the adult corneal endothelium, the innermost cellular layer of the cornea. This epithelium is composed of a highly ordered array of hexagonal cells where the acetylated tubulin is restricted to a perinuclear ring of microtubules. Interestingly, in absence  $\alpha$ TAT1, cell shape, nuclei position and global tubulin organization are disrupted in the corneal endothelium, suggesting a role for  $\alpha$ TAT1 in corneal endothelium morphogenesis.

Finally, to address the long-standing question of whether  $\alpha$ TAT1 confers stability to microtubules, we studied microtubule stability in  $\alpha$ TAT1-deficient embryonic fibroblasts. Upon nocodazole treatment, fewer resistant microtubules were found in absence of  $\alpha$ TAT1.

Collectively, these results demonstrate that, as is the case in nematodes and protozoa,  $\alpha$ TAT1 is the major  $\alpha$ -tubulin K40 acetyltransferase. Surprisingly, and despite the fact that a large proportion of  $\alpha$ -tubulin is acetylated at K40 in the brain (27% by our measurements),  $\alpha$ TAT1 is dispensable for mammalian neural development. However, our work suggests that  $\alpha$ TAT1 participates in the establishment or the maintenance of epithelial morphology in vivo through its role in stabilizing microtubules.

**Klp59C and fidgetin: two microtubule disassembly proteins that help clear damaged regions of neurons.**J. Tao<sup>1</sup>, M. Rolls<sup>1</sup>; <sup>1</sup>Penn State, University Park, PA

A neuron extends one axon and several dendrites far from its cell body, leaving these extremely thin processes subject to various insults, including acute injury and neurodegenerative diseases. Both axons and dendrites are able to initiate a rapid intrinsic program to clear the severely damaged part in a short period of time. Microtubule (MT) fragmentation has been observed in both axon and dendrite degeneration. However, little is known about the intracellular mediators responsible for the physical degradation of the MTs in the degenerating axons or dendrites. In this study, we used a pulsed UV laser to induce a small-scale injury on the axon or dendrite of the ddaC neuron in the *Drosophila* larva. Through a genetic screen of MT depolymerizing or severing proteins, we found that decreasing Klp59C protein level by RNAi or a genetic deficiency delayed clearance of the distal part of injured axons or dendrites by 3 to 6 hours. To test whether reduction of Klp59C was likely to delay clearance through alterations in microtubules we tracked EB1-GFP comets after axon and dendrite injury. Comets were still observed at 1.5h or 4.5h post severing in transected Klp59C RNAi axons and dendrites, respectively, times at which MT dynamics are no longer seen in control neurons. This result suggests that Klp59C is activated shortly after axon or dendrite injury to disassemble MTs. In contrast to the general role of Klp59C in all types of neuron degeneration, we found that fidgetin is specifically involved in injury-induced dendrite degeneration. In fidgetin RNAi and mutant neurons, the onset of beading of injured dendrites was significantly delayed compared to controls. The timing of axonal clearance after injury was not, however, altered in these genetic backgrounds indicating that the role of fidgetin is more specific than that of Klp59C. We conclude that Klp59C acts as general microtubule destabilizer after injury of axons or dendrites whereas fidgetin acts specifically in dendrite degeneration. Moreover, the identification of these two factors supports the idea that microtubules are actively disassembled during neuronal degeneration, and that this disassembly is required for normal timing of axon or dendrite clearance.

1859

**What makes the Kinesin like protein (KLP) 11/11 chimeric motor nonprocessive?**S. Koesem<sup>1</sup>, Z. Oekten<sup>1</sup>; <sup>1</sup>TUM, 85748 Garching, Germany

Homodimeric kinesin motors power intracellular transport processes in most eukaryotic cells. Most kinesins involved in long-range transport are processive and can take multiple steps without dissociating from their microtubule track. For homodimeric kinesins, this is achieved by coordinating the ATPase activities of the catalytic head domains to ensure the attachment of at least one motor head to its track during the stepping cycle. The kinesin-2 class is unique among all double-headed kinesin motors because it combines two distinct polypeptide chains to function as a transport motor. Recently, by means of *in vitro* assays we could show that the kinesin-2 heterodimer KLP11/KLP20 of the *C. elegans* sensory cilium works in a processive manner. Intriguingly, processivity in the KLP11/KLP20 heterodimer is brought about by a combination of the nonprocessive subunit KLP11 with the processive KLP20 subunit, respectively. Consequently, chimeric constructs KLP20/20 and KLP20/11 (swapped head positions) were processive, whereas KLP11/11 resulted in a nonprocessive motor. To obtain a better understanding of why the KLP11/11 combination results in a nonprocessive motor, we have designed various truncated constructs, lacking the native tail domains to eliminate a putative inhibitory interference of the native tail domains in the motor's activity. Furthermore, we

introduced flexible residues, namely two, four and eight Glycine and Serine repeats between the head domains, with the aim to probe for possible steric hindrance which may prevent the KPL11/11 motor from taking consecutive steps. The motor heads were artificially zipped together by a stretch of the leucine zipper motif, GCN4, which has a strong propensity to form a coiled-coil. To follow and analyze those constructs by single molecule TIRF microscopy (under zero load conditions), all constructs were C-terminally tagged with a GFP. Interestingly, we observed no processive movement with the KLP11/11 motor domains when zipped together with the GCN4. However, processivity was reconstituted with the constructs containing the flexible head extensions. Taken together, the here presented findings suggest that relieving the steric hindrance indeed is sufficient to turn the KLP11/11 motor combination processive.

1860

**PKC and the Cytoskeletal Scaffold.**

*L. Harris<sup>1</sup>, S. Kavuma<sup>1</sup>, A. Gonzales<sup>1</sup>, R. Watts<sup>1</sup>, A. Candelaria<sup>1</sup>, R. Brubaker<sup>1</sup>, D. P. Baluch<sup>1</sup>;*  
*<sup>1</sup>Arizona State University, Tempe, AZ*

Protein Kinase C (PKC) is a common enzyme found in mammalian cells and is known to be associated with the regulation of many cellular activities such as secretion, proliferation and gene expression. Recent research has shown that PKC provides regulation for the stability of cytoskeletal elements such as microtubules to influence the establishment of polarity, growth cone formation, MTOC orientation and structural support for vesicle transport and other cellular activities. This introduces a new paradigm of thinking that there may be two levels of regulation which would include not only the direct signal transduction mechanism but also a system of scaffold regulation that is independent of the signaling cascade. Within this concept, inhibition of a scaffold mechanism would result in the mistaken interpretation that the signaling mechanism was being directly affected. In this study we are pursuing the theory that PKC isotypes are key signaling factors that are required to maintain the cellular scaffold system. FRET studies have identified close molecular proximity between PKC and the structural cytoskeletal elements such as alpha and gamma tubulin in both the cytoplasmic microtubule arrays and as well as associated with the mitotic spindle. Using SH-SY5Y neuroblastoma cells and various biochemical approaches we identified that disruption of microtubule polymerization results in an increase in various PKC isotype concentrations within the cell and upon restoration of the scaffold in the presence of a PKC zeta pseudosubstrate inhibitor, partial recovery occurred but there was also an increase in the concentration of other PKC isotypes. No recovery was seen when all isotypes of PKC were inhibited which suggests that there is a priority of PKC expression where some isotypes such as PKC zeta are predominate but is supplemented by other isotypes in changing cellular conditions. Furthermore, studies of vesicle and mitochondrial transport that requires a scaffold system showed the same disruption in the event of interrupted microtubule polymerization as compared to the same affect induced by PKC inhibition. These results support the theory that PKC has a role in maintaining a cytoskeletal scaffold system in the cell such that it helps maintain the spatial and temporal positioning of signaling elements but its function is separate from the signal transduction cascade.

1861

**Purification and biochemical analysis of recombinant type I  $\beta$ -tubulin.**

K. Kubara<sup>1</sup>, K. Takase<sup>1</sup>, K. L. Agarwala<sup>1</sup>, T. Kimura<sup>1</sup>, B. M. Seletsky<sup>2</sup>, K. Tsukahara<sup>1</sup>, K. Sagane<sup>1</sup>; <sup>1</sup>Eisai Product Creation Systems, Eisai Co., Ltd., Tsukuba, Japan, <sup>2</sup>Eisai Inc., Andover, MA

A large number of biochemical studies on tubulin have been performed using authentic tubulin proteins purified from mammalian brain or cultured cells. However, since these tubulins are mixtures of several tubulin isoforms, there are limitations in analyzing isoform specific properties and mutations. To address this bottleneck, we have developed a new method for purification of recombinant type I  $\beta$ -tubulin as a functional heterodimer with endogenous  $\alpha$ -tubulin from HeLa cells. BioEase<sup>TM</sup> (Invitrogen) tagged type I  $\beta$ -tubulin was stably expressed in HeLa cells using an episomal vector system. Then, we purified functional tubulin heterodimers by a cycle of polymerization/depolymerization followed by affinity chromatography. The resulting tubulin was >95 % pure and competent for microtubule assembly in vitro. In addition, drug-binding analysis by SPR (Surface Plasmon Resonance) showed that our recombinant  $\beta$ -tubulin bound to a tubulin-binder chemical probe (biotinylated eribulin) in a dose-dependent manner. In conclusion, recombinant  $\beta$ -tubulin molecules purified by our method are useful for cell-free biochemical studies.

**The role of tubulin acetylation in the maintenance of epithelial cell polarity.**

V. Singh<sup>1</sup>, L. Ligon<sup>1</sup>; <sup>1</sup>Biology and Center for Biotechnology, Rensselaer Polytechnic Institute, Troy, NY

The post-translational modification of tubulin subunits in microtubules is thought to provide directional cues to molecular motors so that cargoes may be efficiently delivered to specific sub-cellular domains. The precise delivery of cargoes is particularly important for the establishment and maintenance of epithelial cell polarity as different sets of proteins are needed in the apical and basal domains. Previously, we have shown that two tubulin post-translational modifications, acetylation and detyrosination, define functionally different populations of microtubules in epithelial cells. We also showed that there is a switch in the predominant form of tubulin modification from detyrosination to acetylation as cells become polarized, and that the two populations of modified microtubules are localized to distinct regions of MDCK cells at each stage of polarization. If these modified microtubules do provide the directional cues for polarized cargo traffic, then the establishment and maintenance of cell polarity may depend on this modified tubulin network. Here we have focused on the role of tubulin acetylation. Tubulin is acetylated by cellular tubulin acetyltransferases, including MEC-17, and deacetylated by tubulin deacetylases, including HDAC6. We have hyperacetylated the microtubule network by inhibition or knockdown of HDAC6 and hypoacetylated the microtubule network by overexpression of HDAC6 or knockdown of MEC-17. We then examined the trafficking of an apical cargo, the p75 neurotrophin receptor, as well as the localization of other apical markers such as ZO-1, E-cadherin, and par6 in order to determine whether the establishment and/or maintenance of epithelial cell polarity depends upon the proper balance of tubulin acetylation and deacetylation.

1863

**Changes in the post-translational modification of tubulin in response to ATP- depletion.**

S. Zaki<sup>1</sup>, G. Quinones<sup>1</sup>, L. Ligon<sup>1</sup>, B. A. Danowski<sup>2</sup>; <sup>1</sup>Biology, Rensselaer Polytechnic Institute, Troy, NY, <sup>2</sup>Biology, Union College, Schenectady, NY

Prior research has shown that ATP depletion in many cell types causes the formation of microtubules (MTs) which are more resistant to microtubule depolymerizing agents and more heavily detyrosinated. We investigated the relationships between ATP depletion, microtubule stability, and tubulin post-translational modifications in MDCK cells during the process of polarization. ATP depletion was achieved by treatment with 20 mM sodium azide and 10 mM 2-deoxyglucose; stable microtubules were identified by their resistance to 10 $\mu$ M nocodazole. We found that upon ATP depletion, there was an increase in stable MTs in both 2D-polarized (subconfluent monolayers) and 3D-polarized MDCK cells, and an increase in both tubulin detyrosination and acetylation. The majority of the stable MTs showed acetylation and/or detyrosination. This was surprising in part because we had previously shown that 3D-polarized cells have little detyrosinated tubulin. The pattern of acetylation was altered as well. Instead of small, discontinuous patches of acetylated tubulin, many MTs were acetylated along their entire lengths. Immunoblotting of cell lysates showed that in both 2D- and 3D-polarized cells, detyrosinated tubulin increased 4-5 fold. Acetylation increased substantially, as well. A sudden drop in ATP is one of several stressors known to activate adenosine-monophosphate kinase (AMPK), an energy-sensing kinase thought to be one of the master regulators of metabolism. Our preliminary experiments show that inhibition of AMPK partially blocks the increase in detyrosinated and acetylated microtubules induced by ATP depletion. In summary, ATP depletion leads to a global increase in both the acetylation and detyrosination of MTs, which overrides the normal pattern of these modifications that is established as MDCK cells acquired a polarized morphology. And preliminary results suggest that activation of the AMPK pathway can modulate tubulin acetylation and detyrosination. Supported by NSF Advance Grant 0820032 (BD) & American Cancer Society RSG-10-245-01-CSM. (LAL).

**Redundancy ensures microtubule plus-end targeting of MCAK in meiosis.**

A. S. Gayek<sup>1</sup>, P. Jevtic<sup>2</sup>, J. Gatlin<sup>2</sup>, R. Ohl<sup>1</sup>; <sup>1</sup>Department of Cell and Developmental Biology, Vanderbilt Univ Med Ctr, Nashville, TN, <sup>2</sup>Department of Molecular Biology, University of Wyoming, Laramie, WY

Female meiotic divisions segregate chromosomes using mechanisms similar to mitosis despite a much greater volume of cytosol. Because of this scaling challenge, special adaptations may aid the proper formation of meiotic spindles. We have tested the importance of the direct interaction between microtubule end-binding (EB) proteins and MCAK, a tip-tracking, microtubule-depolymerizing Kinesin-13, in the context of *Xenopus laevis* egg extracts. We mutated the EB-binding motif SxIP (SKIP in MCAK) to SKNN, and purified GFP-tagged wild-type and mutant proteins from SF9 insect cells. The SKNN mutation did not impair MCAK's catalytic activity. As expected, the mutation did disrupt binding of EB1 to MCAK as evaluated by in vitro pulldown. However, when added to egg extracts depleted of endogenous MCAK, MCAK-SKNN did not show full loss of tip-tracking. Although lattice binding of MCAK-SKNN was highly enhanced relative to its wild-type counterpart, a small amount continued to co-localize with EB1 and to tip-track. MCAK-SKNN was competent to rescue depletion of endogenous MCAK as evaluated by its ability to form bipolar spindles and the steady-state length of those spindles. Our results suggest that, in contrast to published results for mitotic tissue culture systems, MCAK can target plus-ends effectively in *Xenopus* egg extracts despite loss of direct

EB binding. We are working to determine the mechanism by which MCAK targets plus-ends without direct EB binding.

**Novel alleles of genes required for organelle distribution and motility in *Aspergillus nidulans*: a whole-genome sequencing approach.**

S. Reck-Peterson<sup>1</sup>, K. Tan<sup>1</sup>, M. Egan<sup>1</sup>, M. Chonofsky<sup>1</sup>, A. Roberts<sup>1</sup>; <sup>1</sup>Harvard Medical School, Boston, MA

Many organelles are transported long distances along microtubules in most eukaryotic organisms. To identify novel factors required for microtubule-based organelle distribution and motility, we performed a screen in the filamentous fungus, *Aspergillus nidulans*. As a model system, *A. nidulans* combines some of the advantages of yeast molecular genetics with the long-range microtubule-based transport of metazoans. Using whole-genome sequencing, we found a number of single nucleotide polymorphisms (SNPs) that resulted in misdistribution of peroxisomes, endosomes, or nuclei. Some of these SNPs were novel alleles of cytoplasmic dynein, dynactin, Lis1, and kinesin-1. Here, we characterize the transport defects in these novel mutants and report methods for using whole genome sequencing as a tool in mutagenesis studies in *A. nidulans*.

**CEP215 interaction with pericentrin is critical for centrosome maturation during mitosis.**

S. Kim<sup>1</sup>, S. Lee<sup>1</sup>, K. Rhee<sup>1</sup>; <sup>1</sup>Seoul National University, Seoul, Korea

The microtubule-organizing activity of the centrosome oscillates during the cell cycle, reaching its highest level at mitosis. At the onset of mitosis, the centrosome undergoes maturation, which is characterized by a drastic expansion of the pericentriolar matrix and a robust increase in microtubule-organizing activity. We previously revealed that PLK1 phosphorylation of pericentrin is a critical step for centrosome maturation. A number of the pericentriolar matrix proteins such as CEP192 and GCP-WD are recruited to the centrosome once pericentrin is phosphorylated by PLK1. On the other hand, CEP215 is also required for PCM accumulation for centrosome maturation. Depletion of CEP215 results in reduction of the PCM proteins at spindle poles. Among the PCM proteins, pericentrin was significantly reduced at spindle pole in CEP215-depleted cells. In fact, CEP215 physically interacts with pericentrin. Based on the results, we propose that CEP215 interaction with pericentrin is critical for centrosome maturation during mitosis.

1867

**The centrosome regulates the Rab11-dependent recycling endosome pathway at appendages of the mother centriole.**

H. Hehnl<sup>1</sup>, S. Doxsey<sup>1</sup>; <sup>1</sup>Molecular Medicine, University of Massachusetts Medical School, Worcester, MA

The recycling endosome localizes to a pericentrosomal area through microtubule-dependent transport. The observation that the mother centriole appendage protein, centriolin, interacts with Sec15, an effector of the recycling endosome component, Rab11-GTPase, suggests an interaction between centrosomes and endosomes. For the first time we show that the recycling

endosome associates with the centrosome, more precisely, with mother (older) centriole appendages. The mother centriole appendage proteins, centriolin and cenexin/ODF2, regulate the association of the endosome components Rab11, the Rab11 GTP-activating protein Evi5, and the exocyst at the mother centriole. We have developed an in vitro method for reconstituting endosome protein complexes onto isolated centrosomes. This in vitro method for reconstituting proteins has a number of applications from understanding the hierarchy of protein association at the centrosome to understanding microtubule nucleation. Our experiments illustrate that purified GTP-Rab11 but not GDP-Rab11 binds to mother centriole appendages in the absence of membranes. Furthermore, centriolin depletion displaces the centrosomal Rab11 GAP, Evi5, and increases mother-centriole-associated Rab11; depletion of Evi5 has the same effect on Rab11 localization. This suggests that centriolin localizes Evi5 to centriolar appendages to turn off centrosomal Rab11 activity. Depletion of centriolin or cenexin disrupts recycling endosome organization and function suggesting that mother centriole proteins can regulate Rab11 localization and activity at the mother centriole through Evi5 and the exocyst.

1868

**Structural analysis of Polo-Like Kinase-4's Cryptic Polo Box reveals a novel pair of tandem Polo Box Domains required for centriole assembly.**

*L. Slevin<sup>1</sup>, J. Nye<sup>2</sup>, D. Pinkerton<sup>1</sup>, D. Buster<sup>2</sup>, G. Rogers<sup>2</sup>, K. C. Slep<sup>1</sup>; <sup>1</sup>Biology, Univ. of North Carolina, Chapel Hill, NC, <sup>2</sup>Cellular & Molecular Medicine, University of Arizona, Tuscon, AZ*

Centrioles are barrel-shaped, microtubule-based structures responsible for nucleating polarized microtubule arrays. Importantly, the number of centrioles dictates the capabilities of these organelles: two centrioles form a centrosome, and two centrosomes are needed for formation of the bipolar mitotic spindle. Centriole biogenesis via duplication is cell cycle-controlled to prevent cells from developing multipolar microtubule spindles, a situation that promotes chromosomal instability. A key "licenser" of centriole duplication is Polo-Like Kinase-4 (Plk4), a polo kinase family member that localizes to the site of nascent centrioles in M/G1. Plk4's activity is tightly controlled through trans-autophosphorylation that primes SCF-mediated ubiquitination and degradation. Other polo kinase family members (Plks1-3) contain two polo box domains (PBDs), which are used to regulate kinase activity and localization. Conversely, Plk4 is thought to contain only one PBD in addition to a unique, conserved central region called the "Cryptic Polo Box," or CPB. Plk4's CPB was found to bind the centrosomal scaffolding protein Asterless, though the field of centriole biology currently lacks a mechanistic understanding of how Plk4 employs the CPB to achieve centriole duplication licensing. In this study, we employed x-ray crystallography to determine the structure of Plk4's CPB region to a resolution of 2.3 Å. Surprisingly, the structure reveals two tandem, homodimerized polo boxes, henceforth called PB1-PB2, that form a winged structure unique among the known PBD structures. Thus, Plk4 contains not one, but three PBDs: PB1-PB2 that compose the CPB plus the C-terminal PB, PB3. No other polo kinase family member contains a trimeric PBD array, suggesting that the conserved Plk4 PBDs play unique mechanistic roles in Plk4's function. Our cellular localization studies show that the PB1-PB2 homodimerized cassette is required for robust centriole targeting and Asterless binding. Together, our results represent a paradigm shift in the structural classification of polo kinase members: Plk4 contains a distinctive polo box architecture that facilitates oligomerization (requisite for trans-autophosphorylation) and centriole targeting, determinants that facilitate a single cell cycle centriole duplication licensing step.

1869

**Phosphorylation of centrosomal proteins in *Drosophila*.***J. Baumbach<sup>1</sup>, P. Conduit<sup>1</sup>, J. Raff<sup>1</sup>; <sup>1</sup>Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom*

The centrosome is the major microtubule-organizing center of almost all animal cells and it helps to set up the mitotic spindle. It consists of a pair of centrioles surrounded by the pericentriolar material (PCM), which is a protein meshwork harbouring proteins that have the ability to nucleate and organize microtubules. At the beginning of mitosis, the amount of PCM that is organized by the pair of centrioles increases dramatically, which results in an increase in microtubule-organizing activity and therefore promotes efficient mitotic spindle assembly. By comparing the centrosomal and cytoplasmic fractions of centrosomal proteins we show that many centrosomal proteins are phosphorylated when they are at the centrosome as opposed to when they are in the cytoplasm. It is assumed that phosphorylation activates these proteins and is needed for their localization to the centrosome. Using a phosphoproteomic approach, we have identified phosphorylation sites in Centrosomin, Asterless and DSpd-2, which are key proteins of the PCM recruitment pathway in *Drosophila*. Using a phosphospecific antibody we show that a phosphorylation site in Asterless is specifically phosphorylated only in mitosis. We are currently analyzing the biological functions of the phosphosites obtained by testing different phosphomutant constructs in the mutant backgrounds.

1870

**Nek2 stabilizes  $\beta$ -catenin through its interaction with known regulatory GSK3 $\beta$  sites in  $\beta$ -catenin.***B. Mbom<sup>1</sup>, K. Siemers<sup>1</sup>, W. Nelson<sup>1</sup>, A. Barth<sup>1</sup>; <sup>1</sup>Stanford University, Stanford, CA*

Beta-catenin is a multifunctional protein with critical roles in cell-cell adhesion, Wnt-signaling and bipolar spindle formation. Whereas the roles of  $\beta$ -catenin in adhesion and Wnt-signaling have been extensively studied, the mechanism(s) by which  $\beta$ -catenin promotes bipolar spindle formation is poorly understood. The centrosomal NIMA-related protein kinase 2 (Nek2) binds and phosphorylates  $\beta$ -catenin and stimulates centrosome separation. Nek2, like  $\beta$ -catenin, promotes bipolar spindle formation. Using in vivo and in vitro approaches, we analyzed the effects of Nek2 on  $\beta$ -catenin stability. Nek2 phosphorylates the same regulatory sites as GSK3 $\beta$  in the N-terminus of  $\beta$ -catenin as well as additional sites. Nek2 inhibits  $\beta$ -catenin ubiquitylation by preventing binding of the E3 ligase  $\beta$ -TrCP and promotes  $\beta$ -catenin stability independent of its kinase activity. These results indicate that although Nek2 protein is required for  $\beta$ -catenin stability, its kinase activity is not. Taken together, these results allow us to further elucidate the key role of Nek2 and  $\beta$ -catenin in regulating centrosome cohesion during the cell cycle.

1871

**The autoregulated instability of Polo-like kinase 4 limits centrosome duplication to once per cell cycle.***A. J. Holland<sup>1</sup>, D. Fachinetti<sup>1</sup>, Q. Zhu<sup>2</sup>, M. Bauer<sup>3</sup>, I. Verma<sup>2</sup>, E. Nigg<sup>3</sup>, D. Cleveland<sup>1</sup>; <sup>1</sup>Ludwig Institute For Cancer Research, University of California, San Diego, La Jolla, CA, <sup>2</sup>Laboratory of Genetics, The Salk Institute for Biological Studies, La Jolla, CA, <sup>3</sup>Biozentrum, University of Basel, Basel, Switzerland*

Centrioles are microtubule-based structures that contribute to the formation of the centrosome, the cells major microtubule-organizing center. Centriole duplication occurs once per cell cycle and accurate control of centriole number is critical for the maintenance of genomic integrity.

Centriole duplication is controlled by the conserved kinase Polo-like kinase 4 (Plk4) and overexpression of Plk4 promotes centriole overduplication and cell transformation. We have shown that Plk4 regulates its own stability by phosphorylating itself to promote its degradation by the proteasome. Using conditional gene targeting we now demonstrate that this autoregulated instability is required to control the abundance of endogenous Plk4 and limit centriole duplication to once per cell cycle. Preventing Plk4 autoregulation leads to centrosome amplification, activation of p53 and loss of cell proliferation; moreover, suppression of p53 allows the proliferation of cells carrying amplified centrosomes. We conclude that Plk4 autoregulation forms an essential pathway to guard against genome instability by limiting centrosome duplication to once per cell cycle.

1872

### **Polo activity controls centrosome maturation in *Drosophila*.**

*J. Dobbelaere<sup>1</sup>, C. Cowan<sup>1</sup>; <sup>1</sup>IMP, Vienna, Austria*

Centrosomes in mitosis mature through the addition of pericentriolar material (PCM) the site of MT-nucleation and anchoring. Mitotic centrosomes control the bipolar spindle formation by organising the MT-cytoskeleton and by the creation of spindle and astral MTs. Astral MTs contact the cell cortex and position the mitotic spindle according internal and external cues. How PCM recruitment is initiated and modulated in mitosis is not well understood. Our findings show that Polo kinase phosphorylation of the major *Drosophila* PCM protein centrosomin (Cnn) is key for PCM nucleation on top of centrioles when cells enter mitosis. Constant Polo phosphorylation is needed to maintain Cnn at the centrosome. Cnn phosphorylation only takes place on the centriole scaffold. Cnn is phosphorylated at serine 567. Mutation abolishing phosphorylation results in a strong reduction of the PCM. In contrast, mutation of serine 567 mimicking constitutive phosphorylation is very toxic and induces PCM formation during all cell cycle stages. Ectopic expression of active polo to interphase centriole induces PCM recruitment and aster formation. Thus, phosphorylation of Cnn by Polo in mitosis is both needed to initiate and maintain PCM in *Drosophila*.

1873

### **Mechanistic Insight and Regulatory Control of the Microtubule Organizing Center $\gamma$ -tubulin small complex ( $\gamma$ -TuSC).**

*J. L. Paluh<sup>1</sup>, T. D. Riehlman<sup>1</sup>, Z. T. Olmsted<sup>1</sup>, C. Branca<sup>1</sup>, A. G. Colliver<sup>1</sup>; <sup>1</sup>Nanobioscience, College of Nanoscale Science & Engineering, University at Albany-SUNY, Albany, NY*

Mitotic spindle formation into a bipolar structure is a critical control point for chromosome segregation. Distinct protein complexes at microtubule minus ends at the spindle pole form a microtubule organizing center (MTOC) complex. The  $\gamma$ -tubulin small complex ( $\gamma$ -TuSC) forms the direct link to growing microtubules and is embedded in a larger macromolecular structure, the  $\gamma$ -tubulin ring complex ( $\gamma$ -TuRC). We combine recent structural insights of  $\gamma$ -TuSC and GCP4 with our detailed genetic analysis, site-directed mutagenesis, cross-species functional studies and biochemical purification and nucleation assays to provide novel insights into MTOC nucleation and regulation. Included in our analysis are mechanistic details on  $\gamma$ -TuSC protein functional conservation and divergence as well as  $\gamma$ -TuSC regulation by a subset of Kinesin-14 kinesin-like protein (Klp) members. We have identified and refined key domain elements in the fission yeast Kinesin-14 Pkl1 Tail that drives targeting and regulatory interference at poles (TRIP). The TRIP domain is conserved within a subset of Kinesin-14 Klps from yeast to man and distinct from the previously identified microtubule targeting elements found in other Kinesin-14 members such as *Drosophila* Ncd. Our analysis supports application of the recent Kollman-

Agard structure as a general eukaryotic model, but also reveals species-specific protein constraints in the  $\gamma$ -TuSC between yeasts, or yeasts and man. We propose a model and supporting evidence for Kinesin-14 regulation of  $\gamma$ -TuSC during spindle assembly. Our findings have broad application towards a general understanding of cellular MTOC machinery and reiterate the flexibility of Kinesin-14 members to localize to multiple spindle compartments and participate in a diversity of cellular roles. Natural cellular machines more than ever are providing tools and inspiration for biomimicry and for resolution of societal grand challenges. This includes nanomanufacturing at the sub-50nm level. The studies here not only provide biological information that is expected to help expand targets for cancer therapeutics but also advance nanodesign principles. We are utilizing knowledge from cellular systems along with the purified MTOC complex, selected Klps and tubulin assembly dynamics to assemble complex microtubule-based structures that can inform us on trainable self-assembly platforms with regulatable nanonetworks.

**CEP120 interacts with CPAP and regulates centriole elongation.**

C-T. Wu<sup>1</sup>, Y-N. Lin<sup>1</sup>, Y-C. Lin<sup>1</sup>, W-B. Hsu<sup>1</sup>, C-J. C. Tang<sup>1</sup>, C-W. Chang<sup>1</sup>, T. K. Tang<sup>1</sup>; <sup>1</sup>*Inst. Biomed. Sci., Academia Sinica, Taipei, Taiwan*

The centrosome is the primary microtubule-organizing center, which is composed of two orthogonally arranged centrioles surrounded by the pericentriolar proteins. Centriole duplication begins with the formation of a single procentriole next to the pre-existing centriole and requires the assembly of centriolar microtubules. We (Tang et al., *Nat. Cell Biol.* 2009) and others (Kohlmaier et al., *Curr. Biol.* 2009; Schmidt et al., *Curr Biol.* 2009) previously reported that CPAP is involved in the process of procentriole elongation and controls centriole length. Here, we show that CEP120 is a CPAP-interacting protein, which plays a critical role in centriole elongation. Overexpression of CEP120 induces supernumerary centrioles and promotes the formation of abnormally long microtubule-based structures. Confocal immunofluorescence analysis showed that these elongated structures contain stable microtubules and several bona fide centriolar proteins, including STIL, SAS6, centrin, CP110 and CPAP. Further electron microscopy analysis showed that these extra-long structures are similar to that of CPAP-induced elongated centrioles. Intriguingly, we found that CEP120 directly interacts with CPAP, which was demonstrated by co-immunoprecipitation, GST pulldown, and yeast two-hybrid assays. Depletion of CEP120 inhibits CPAP-induced centriole elongation and results in a failure to localize CPAP, but not hSAS6 or STIL, to the centrioles. Similarly, CPAP depletion also blocks CEP120-induced centriole elongation and perturbs CEP120 targeting to the centrioles. Further analysis shows that CEP120 contains a microtubule-binding domain and a self-dimerization domain. Overexpression of either a CEP120-K76A mutant that fails to bind to microtubules or CEP120-E831P that disrupts the CEP120 dimerization activity significantly suppressed the formation of elongated centrioles. Together, our results indicate that CEP120 is a novel positive regulator that interacts with CPAP to promote centriole elongation and both the intrinsic microtubule binding and the dimerization activity of CEP120 are essential for centriole elongation.

**Two distinct functions for one kinase: casein kinase 1 $\delta$  regulates actin-mediated endocytosis and microtubule dynamics.**

Y. C. Peng<sup>1</sup>, A. Grassart<sup>1</sup>, R. Lu<sup>1</sup>, A. Michelot<sup>1</sup>, C. C. Wong<sup>2</sup>, J. Yates 3rd<sup>2</sup>, T. Giddings Jr<sup>3</sup>, M. Winey<sup>3</sup>, J. M. Kollman<sup>4</sup>, M. Moritz<sup>4</sup>, A. Lyon<sup>4</sup>, D. A. Agard<sup>4</sup>, G. Barnes<sup>1</sup>, D. G. Drubin<sup>1</sup>; <sup>1</sup>UC Berkeley, Berkeley, CA, <sup>2</sup>The Scripps Research Institute, La Jolla, CA, <sup>3</sup>University of Colorado, Boulder, CO, <sup>4</sup>UC San Francisco, San Francisco, CA

Across diverse eukaryotic organisms, actin assembly facilitates clathrin-mediated endocytosis while microtubule dynamics underlie mitosis. We found that the budding yeast casein kinase 1 $\delta$ , Hrr25, associates with and regulates both systems. Hrr25 is recruited to endocytic patches early in the pathway by the C-terminus of the yeast Eps15-like protein, Ede1, where it phosphorylates Ede1 and several other endocytic proteins. An analog-sensitive allele was created and used to show that Hrr25 kinase activity is required for the kinase's recruitment to endocytic sites and to control endocytic patch turnover. Furthermore, our results in mammalian cells demonstrate likely conservation of casein kinase 1 $\delta$  functions in higher organisms. In addition to co-purifying with Ede1, Hrr25 co-purifies with several spindle pole body proteins. In contrast to recruitment to endocytic patches, recruitment of Hrr25 to spindle pole bodies was not dependent on Ede1 or on Hrr25 kinase activity. Hrr25 phosphorylates several spindle pole body proteins and its activity plays a critical role in regulation of microtubule assembly nucleated at spindle pole bodies in vivo. Ongoing studies are aimed at elucidating the detailed mechanisms and specific in vivo phosphorylation targets underlying Hrr25's regulatory functions in endocytosis and mitosis.

**Understanding the function of centrosomes during asymmetric divisions in the interfollicular epidermis.**

A. Kulukian<sup>1</sup>, B. Vitre<sup>2</sup>, A. Holland<sup>2</sup>, D. W. Cleveland<sup>2</sup>, E. Fuchs<sup>1</sup>; <sup>1</sup>Laboratory of Mammalian Cell Biology and Development, Rockefeller University, New York, NY, <sup>2</sup>Ludwig Institute for Cancer Research, La Jolla, CA

Centrosomes, the major microtubule organizing centers of cells, are crucial for the formation of a bipolar spindle and for ciliogenesis in many organisms. Recent work emerging from invertebrate studies has potentially uncovered a novel role for centrosomes in cell fate determination. However, the mechanism by which centrosomes contribute to cell fate remains a mystery, although the regulation of asymmetric divisions is strongly implicated. Additionally, the presence of extra centrosomes has long been hypothesized to contribute to tumorigenesis. However, in light of research suggesting that tumorigenesis in the context of centrosomal dysfunction does not result from genetic instability, and that flies with extra centrosomes have defects in asymmetric divisions of neuroblasts, it remains untested whether the presence of extra centrosomes alters asymmetric divisions in the mammalian context. Thus, we are exploring the role of centrosomes in the development of the murine epidermis, a tissue in which asymmetric divisions are demonstrated to promote stratification and differentiation. By utilizing a mouse model which conditionally over-expresses Plk4, a kinase required for initiation of centrosome duplication, we are inducing the formation of extra centrosomes specifically in the epidermis. Our initial findings include increased cell death and disruption of keratin expression within the tissue, which suggest defects in proliferation and homeostasis. To further address the source of these errors, we are determining whether the presence of extra centrosomes affects asymmetric divisions, proliferation, and differentiation in ongoing experiments.

1877

**Asymmetry in centrosome activity is generated by blocking centrosome maturation.**

D. A. Lerit<sup>1</sup>, N. M. Rusan<sup>1</sup>; <sup>1</sup>Cell Biology and Physiology Center, National Institutes of Health, Bethesda, MD

As the microtubule-organizing centers (MTOCs) of most eukaryotic cells, centrosomes polarize cells and model tissues. Comprising an inner core of two centrioles surrounded by a cloud of pericentriolar material (PCM), centrosomes break the symmetry of cells by generating specialized cellular structures and localized enrichments of microtubules. Studies of centrosome activity within stem cells suggest asymmetries inherent to the centrosomes themselves may direct cellular symmetry-breaking events. For example, localization of a single centrosome defines the apical-basal polarity axis of neuroblasts (NBs), stem cells of the *Drosophila* larval brain. In NBs, the duplicated interphase centrosomes display a striking enrichment of centrosome protein content and MTOC activity at one dominant centrosome that remains tethered to the apical cortex. In contrast, the second centrosome fails to mature until just before mitotic onset, when the second MTOC appears at a distant basal site. How asymmetries in centrosome protein localization and activity are regulated is unknown. Using mutant analysis, we have identified a novel mechanism required to establish centrosome asymmetry. Our data indicate that *Drosophila* Pericentrin-like protein (D-PLP) functions to establish asymmetry in centrosome activity during interphase and is required for centrosome segregation before mitotic onset. Quantitative analysis indicates D-PLP affects the localization of several key PCM proteins known to regulate centrosome maturation. We show D-PLP blocks recruitment of the master regulator of centrosome maturation, Polo kinase, to the second (basal-fated) centrosome of interphase NBs. Likewise, loss of D-PLP results in ectopic enrichment of  $\gamma$ -Tubulin to the second centrosome, producing two equally active interphase MTOCs. Such centrosomes fail to segregate, resulting in two proximal MTOCs during nuclear envelope breakdown. These data suggest NBs selectively block the maturation of the basal-fated centrosome until mitosis to permit proper centrosome segregation. Our model demonstrates, for the first time, that the mechanism of centrosome maturation includes the removal of negative regulators of PCM recruitment.

1878

**Measuring centriole length: size matters!**

S. Montenegro Gouveia<sup>1,2</sup>, M. Bettencourt Dias<sup>1,2</sup>; <sup>1</sup>Gulbenkian Institute of Science, Oeiras, Portugal, <sup>2</sup>Marine Biology Laboratory, Woods Hole, MA

The centrosome is the primary microtubule-organizing centre (MTOC) in animal cells regulating cell motility, adhesion and polarity in interphase and organizing spindle poles during mitosis. Despite their essential functions, centriole biogenesis is still poorly understood. Centriole biogenesis is first seen during S phase of the cell cycle by the appearance of procentrioles that elongate as the cell cycle progresses to reach nearly full length in mitosis. Most mature centrioles in a healthy organism have similar length, yet very little is known on how centriole length control is exerted.

Our goal is to investigate centriole biogenesis, in particular centriole elongation, its kinetics and regulation. We ask a fundamental question: How is mature centriole length achieved? To tackle this question we are reconstituting centriole elongation in vitro in the context of xenopus egg extracts. We are using procentrioles isolated from mammalian GFP-tagged centrin cell line and monitor their elongation by TIRF live imaging. One of the great advantages of the xenopus in vitro system is the fact that we can manipulate easily its protein content by antibody depletion or in vitro mRNA transcription. This system allows us to express in the extract our fluorescent proteins of interest, in a wild type or depletion background, in order to better visualize and

understand centriole elongation. In addition, we are taking advantage of PLK4 centriole amplification in *Xenopus* extracts to induce MTOC assembly. Together, these approaches will allow us to study how different centriolar players interact with each other and microtubules to promote and control centriole length.

1879

**MEI-1/katanin is required for epithelial polarization.**

*J. L. Feldman<sup>1</sup>, J. R. Priess<sup>1</sup>; <sup>1</sup>Fred Hutchinson Cancer Research Center, Seattle, WA*

The centrosome is the major microtubule organizing center (MTOC) in dividing cells and in some post-mitotic, differentiated cells. In other cell types, however, MTOC function is reassigned from the centrosome to non-centrosomal sites. We are using *C. elegans* intestinal cells to analyze how MTOC function is reassigned to the apical surface of epithelial cells. After the terminal cell divisions, the centrosomes and nuclei of intestinal cells move near the future apical membranes, and the post-mitotic centrosomes lose all, or most, of their associated microtubules. We show that microtubule-nucleating proteins such as  $\gamma$ -tubulin and CeGrip-1 that are centrosome components in dividing cells become localized to the apical membrane, which becomes highly enriched in microtubules. Our results suggest that centrosomes are critical to specify the apical membrane as the new MTOC. First,  $\gamma$ -tubulin appears to redistribute directly from the migrating centrosome onto the lateral, then apical membrane. Second,  $\gamma$ -tubulin fails to accumulate apically in wild-type cells following laser ablation of the centrosome. These data suggest that the reassignment of MTOC function from centrosomes to the apical membrane is associated with a physical hand-off of nucleators of microtubule assembly. We show that the microtubule severing protein MEI-1/katanin is required for polarization of the epithelial cells; *mei-1* mutants have defects in apical distribution of  $\gamma$ -tubulin and the polarity protein PAR-3. These results suggest that the severing or disassembly of microtubules from the centrosome may be required for the redistribution of microtubule nucleators to the apical surface.

**Regulation of microtubule nucleation by GIT-PIX signaling cassette interacting with  $\gamma$ -tubulin.**

*M. Cernohorska<sup>1</sup>, S. Vinopal<sup>1</sup>, T. Sulimenko<sup>1</sup>, P. Draber<sup>1</sup>; <sup>1</sup>Institute of Molecular Genetics, Prague, Czech Republic*

$\gamma$ -Tubulin is an evolutionarily highly conserved protein responsible for microtubule nucleation from organizing centers. While essential  $\gamma$ -tubulin-interacting proteins forming the  $\gamma$ -tubulin ring complex responsible for MT nucleation have been identified, the regulatory mechanisms of microtubule nucleation remain largely unknown. Using co-immunoprecipitation experiments followed by mass spectrometry we have found in human osteosarcoma cells U2Os association of  $\gamma$ -tubulin with proteins forming the so-called GIT-PIX signaling cassette. The interactions were confirmed by co-immunoprecipitation experiments with antibodies to GIT and PIX and by the pull-down experiments with GST-tagged proteins. To elucidate the role of the GIT-PIX signaling cassette in microtubule nucleation, we depleted proteins by siRNA and quantified microtubule re-growth in nocodazole washout experiments. For this purpose we have developed automated image analysis software to measure microtubule densities close to the centrosome at various time intervals. Depletion of both proteins led to inhibition of microtubule nucleation from centrosomes. Collectively, our results suggest that the GIT-PIX signaling cassette could regulate microtubule nucleation.

**Centrosome homeostasis is controlled by ubiquitylation and deubiquitylation cycles**J. Li<sup>1</sup>, V. D'Angiolella<sup>1</sup>, E. Seeley<sup>2</sup>, T. Kobayashi<sup>1</sup>, S. Kim<sup>1</sup>, M. Pagano<sup>1,3</sup>, B. Dynlacht<sup>1</sup>;<sup>1</sup>Cancer Institute, NYU School of Medicine, New York, NY, <sup>2</sup>Department of Pathology, University of California, San Francisco, San Francisco, CA, <sup>3</sup>Howard Hughes Medical Institute, New York, NY

Centrosome duplication is a pivotal process required for cell division. In order to avoid genome instability, the duplication of centrosomes must be restricted to once per cell cycle. Different mechanisms that control centrosome duplication impinge on the regulation of CP110, an essential component of the centriole duplication process. Excessive CP110 drives centrosome over-duplication while loss of CP110 inhibits centrosome amplification. CP110 levels are controlled through ubiquitin mediated proteolysis by the SCF(cyclin F) during G2 and M phase of the cell cycle. From published mass spectrometry data, we have identified a de-ubiquitylating enzyme (DUB) as a CP110-interacting protein. We report a new mechanism to regulate centrosome duplication that entails DUB-dependent regulation of CP110 levels. Ubiquitylation and deubiquitylation cycles control CP110 stability and centrosome duplication. We further observe that the levels of this DUB and CP110 are markedly elevated in pancreatic ductal adenocarcinoma (PDAC), suggesting a rationale for inhibiting tumors associated with centrosome amplification. These studies have identified one of the first centriolar de-ubiquitinating enzymes whose expression regulates centrosome homeostasis by countering cyclin F-mediated destruction of a key centrosomal substrate.

1882

**Small brain and dwarfism: physiological consequences of centrosome abnormalities.**J-H. Sir<sup>1</sup>, M. Putz<sup>1</sup>, G. Woods<sup>2</sup>, F. Gergely<sup>1</sup>; <sup>1</sup>Department of Oncology, University of Cambridge, CRUK Cambridge Research Institute, Cambridge, United Kingdom, <sup>2</sup>Cambridge Institute for Medical Research, Cambridge, United Kingdom

Mutations in numerous genes coding for centrosomal proteins cause primary recessive microcephaly (MCPH), a condition that results in reduced brain size and low IQ. The molecular mechanism underlying MCPH remains elusive, but the current consensus is that the disease originates from a failure in stem cell expansion during foetal brain development. Like DNA, the centrosome duplicates once during a normal cell cycle. We have previously described a homozygous MCPH-causing mutation in the human CEP63 gene and demonstrated a requirement for CEP63 in centrosome duplication (1). CEP63 interacts with CEP152, a conserved centrosome duplication factor that is also mutated in MCPH (2,3,4). Both CEP63 knockout vertebrate cells and CEP63 patient-derived cells fail to accumulate CEP152 at centrosomes, thereby impairing centrosome duplication. Thus, the CEP152-CEP63 MCPH protein complex is essential for controlling centrosome numbers, a role that seems especially important for human cerebral cortex growth. Intriguingly, however CEP152 mutations also give rise to Seckel syndrome (5), a disease characterised by short stature and bone malformations in addition to microcephaly. Comparing MCPH- and Seckel-associated missense mutations in CEP152, we find that MCPH mutations weakly whereas Seckel mutations drastically impair the capacity of CEP152 to drive centrosome duplication. The degree of impairment thus seems to reflect the severity of the genetic condition with MCPH being less and Seckel more severe. It is therefore feasible that MCPH and Seckel syndrome are caused by the same cellular deficiency, and instead of being distinct diseases, represent different endpoints on a disease continuum. With the aim of identifying a common underlying mechanism, we will present our most recent data on the roles of MCPH and Seckel proteins, and intact centrosomes, in DNA damage signalling and genome stability.

### Neurological impairment in *centrosomin* mutant flies.

O. A. Cabrera<sup>1</sup>, M. Arbeitman<sup>1</sup>, T. L. Megraw<sup>1</sup>; <sup>1</sup>Biomedical Sciences, Florida State University, Tallahassee, FL

Autosomal recessive primary microcephaly (MCPH) is a neurodevelopmental disease that results in a small brain size due to loss of neural progenitors. The genetic cause of MCPH is heterogeneous and due to mutations in centrosomal genes, one of which is *CDK5RAP2*. In *Drosophila*, the *CDK5RAP2* ortholog *centrosomin* (*cnn*) does not exhibit a small brain phenotype. However, we show that *cnn* mutants, and mutants for other MCPH genes, have neurological defects including severe locomotor performance deficiencies. Actogram data show that *cnn* mutants are less active than isogenic wild type flies, due in large part to more frequent periods of complete inactivity. Our data indicate that the locomotor deficiency in *cnn* mutants is due to post-mitotic activities of the gene. In order to understand the mitotic and post-mitotic roles of *cnn*, we implemented a combination of genetic and proteomic approaches. Using 2D-Difference Gel Electrophoresis (2D-DIGE), we revealed about 60 protein spots that are differentially expressed or post-translationally modified between wild type and *cnn* mutant tissues. Our genetic screen identified 23 mutations that are viable but synthetic lethal with *cnn*. One of these mutants (#125) exhibits male infertility and a visible locomotor defect independent of *cnn*. We are currently mapping the #125 gene. With these approaches, we will investigate the mitotic and post-mitotic roles of *cnn* and understand the physiological basis of MCPH.

1884

### An alternative splice product of CNN localizes to mitochondria and converts mitochondria into MTOCs.

J. Chen<sup>1</sup>, T. Megraw<sup>1</sup>; <sup>1</sup>Florida State University, Tallahassee, FL

Mitochondria are energy centers in cells. In *Drosophila*, they also play a role in sperm tail elongation by providing a structural platform for microtubule (MT) organization to support the elongating tail. Little is known, however, about the molecular mechanism behind this special function of mitochondria. Centrosomin (CNN) is a core centrosomal protein whose gene expresses several variants. Its centrosomal forms (CNNC) are essential for functional centrosomes, which are the major Microtubule Organizing Centers (MTOCs) in animal cells. We recently found that the other alternative splicing forms of CNN (CNNT) were exclusively expressed in testes. And unlike CNNC, which localizes at centrosomes, CNNT localizes to spermatid mitochondria (nebenkerns). Ectopic expression of CNNT recruited the essential MT nucleating factor  $\gamma$ -tubulin to mitochondria, indicating an MTOC function for CNNT at mitochondria. In addition, expression of CNNT fragments in cell culture shows that the N terminus (shared by CNNC and CNNT) of CNNT functions in  $\gamma$ -tubulin recruitment, whereas the C terminal region (unique for CNNT) of CNNT is responsible for mitochondrial targeting. Ubiquitous expression of CNNT during development results in flies that lose bristles and have wing development defects that are indicative of cell fate determination defects. Ultrastructural examination by EM and live imaging of MTs will define the structure and dynamics of these

MTOCs organized by CNNT. We propose that CNNT promotes assembly of unique MTOCs on the surface of mitochondria where, in elongating sperm cells, it facilitates sperm tail growth.

### Primary cilia regulate the function of extraciliary TRPV4 in epithelial cells.

*K. Narita<sup>1</sup>, S. Sasamoto<sup>1</sup>, S. Koizumi<sup>2</sup>, S. Takeda<sup>1</sup>; <sup>1</sup>Department of Anatomy and Cell Biology, University of Yamanashi, Chuo, Japan, <sup>2</sup>Department of Neuropharmacology, University of Yamanashi, Chuo, Japan*

Primary cilia are eukaryotic cell organelle that function as biosensors to sense diverse chemical and mechanical stimuli from the extracellular environment. However, detailed molecular mechanisms underlying cilia-mediated sensing as well as its diversity among different cell types have not been fully understood. The transient receptor potential channel vanilloid superfamily type 4 (TRPV4) forms a divalent cation channel and localizes to cilia of some mammalian cell types, specifying the ciliary functions. TRPV4 is highly expressed in choroid plexus epithelial cells (CPECs), which we demonstrated have multiple primary cilia, but its ciliary localization and functional significance in this cell type have not been reported. In the present study, we investigated the functional relationship between TRPV4 and primary cilia in CPECs. Immunocytochemistry of CPECs demonstrated that TRPV4 was not localized exclusively to the primary cilia but broadly on the apical membrane in CPECs. Treatment of CPEC monolayer with TRPV4-specific agonist, GSK1016790A, augmented the basolateral-to-apical fluid transcytosis, suggesting its regulatory role in the cerebrospinal fluid production. Interestingly, upon deciliation using chloral hydrate, the TRPV4 protein levels as well as cellular responsiveness to GSK1016790A were significantly decreased. These functional relationships between TRPV4 and cilia were reproducible in IMCD3 cells, which also express extraciliary TRPV4: In IMCD3 cells with stable *Ift88* shRNA expression, impaired ciliogenesis was associated with decreases in both TRPV4 protein levels and cellular responsiveness to GSK1016790A. Immunocytochemistry of this cell line also suggested that the plasma membrane targeting of TRPV4 might be perturbed upon inhibition of ciliogenesis, while the global apical membrane protein composition remained unchanged. Overall, the present study demonstrated that loss of primary cilia could disturb the function of extraciliary TRPV4. These findings may provide insights toward better understanding of ciliopathy. In addition, our data also suggest that ciliary transport is dependent not only on the ciliary targeting signals of cargo proteins but also on the cell types, probably due to variations in the structural components of recipient cilia, that would determine which proteins to be retained in cilia.

1886

### Asymmetric inheritance of primary ciliary membrane in dividing neural progenitors.

*J. T. Paridaen<sup>1</sup>, M. Wilsch-Bräuninger<sup>1</sup>, W. B. Huttner<sup>1</sup>; <sup>1</sup>Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany*

The primary cilium is a microtubule-based protrusion of the cell surface that is involved in mediating extracellular signals, such as Sonic Hedgehog (Shh). The primary cilium is nucleated by the centrosome containing the eldest centriole (mother centriole). Prior to mitosis, the primary cilium is assumed to be disassembled in order for the centrosomes to be free to serve as the poles of the mitotic spindle.

Recent findings show that asymmetric inheritance of the centrosome containing the mother centriole is related to cell fate decisions during mammalian neurogenesis. However, it is unknown whether centrosome-associated structures such as the primary cilium are involved in this asymmetrical regulation of cell fate. Therefore, we set out to investigate the fate of the primary cilium upon cell division of developing neural progenitors and the possible involvement of the primary cilium in subsequent cell fate decisions in the developing mouse neocortex.

We find that in mitotic neural progenitors and cultured cell lines, a membrane structure containing the ciliary small GTPase Arl13b is associated with the centrosome that contains the mother centriole. By surface biotinylation of the apical membrane in explanted mouse telencephalic hemispheres, we show that this structure contains ciliary membrane and is derived from the primary cilium that was present at the cell surface prior to mitosis. Using live imaging, we find that upon completion of mitosis, this centrosome-associated ciliary membrane is asymmetrically inherited by one of the daughter cells. Furthermore, we show that inheritance of the ciliary membrane causes earlier reestablishment of the primary cilium on the cell surface after division. Interestingly, the association of the ciliary membrane with one centrosome in mitotic neural progenitors decreases as neurogenesis proceeds.

We hypothesize that the observed asymmetry in primary cilium reassembly after mitosis might differentially expose daughter cells to extracellular signals, such as Shh. Therefore, we speculate that inheritance of the ciliary membrane affects cell fate decisions during mammalian neurogenesis.

1887

### **Primary cilia assembly and signaling are required for normal development and repair of corneal tissue.**

C. Iomini<sup>1,2</sup>, T. Tedeschi<sup>1</sup>; <sup>1</sup>Ophthalmology, Mount Sinai School of Medicine, New York, NY, <sup>2</sup>Dev and Reg Biol, Mount Sinai School of Medicine, New York, NY

Damage and abnormal repair of the corneal layers due to trauma, diseases or aging can compromise corneal transparency and lead to blindness. Thus, understanding the complex signaling network orchestrating morphogenesis during development and repair

later in life of the cornea is crucial to identify specific molecular targets that can help to counteract loss of vision. Interestingly, patients affected by ciliopathies such as Bardet Biedl and Meckel syndromes present several conditions of the anterior eye including microcornea, sclerocornea, abnormal iridocorneal angle, opacity of the cornea, keratoconus, glaucoma, and cataract. We have recently shown that primary cilia are required for normal patterning of the corneal endothelium (CE) and re-assemble on corneal endothelial cells (CEC) involved in repair (Blitzer et al., 2011 PNAS).

We have now extended these observations to the other corneal cell types. Our data show that cilia assemble during development of the corneal epithelium and stroma and most of the cilia of these tissues disassemble in adults. We have detected ultrastructural differences of the primary cilia in the three corneal cell types that suggest distinct functions. Moreover, upon corneal epithelial injury we have observed a higher number of ciliated cells in newly migrated corneal epithelium on the injured area than we did in intact corneas. To determine the role of cilia during repair of different corneal tissues we have performed a mechanical injury of the corneal epithelium and endothelium in adult transgenic mice (*CAGG-creERTM; ift88<sup>flox/-</sup>*) in which the IFT88 gene, required for ciliary assembly, had been conditionally inactivated. As expected in control animals CEC neighboring the wound and involved in repair re-assembled a primary cilium, lost cytoplasmic acetylated microtubules, polarized their basal bodies and elongated toward the wound (Blitzer et al. PNAS). In contrast, CEC of *CAGG-creERTM; ift88<sup>flox/-</sup>* mice lacking IFT88 failed in re-assembling cilia and in disassembling cytoplasmic acetylated microtubules. These cells also failed to polarize and elongate toward the wound. In these mice

healing of epithelial circular wound is also delayed compared to healing of wild-type epithelium. These results suggest that the presence of cilia is required for proper repair of corneal tissues and identify the cilium as a possible pharmacological target in corneal repair.

**BBS4 Traffics Adrenoreceptors In *Chlamydomonas reinhardtii* Flagella.**

G. Garcia<sup>1</sup>, P. Avasth<sup>2</sup>, W. Marshall<sup>2</sup>; <sup>1</sup>University of California Berkeley, Berkeley, CA, <sup>2</sup>University of California San Francisco, San Francisco, CA

Cilia are found on most mammalian cells and play an important role in cell signaling. Mutations in cilia genes cause genetic disorders such as Bardet-Biedl syndrome which presents itself as polydactyly, kidney cysts, retinal degeneration, obesity, or mental deficiencies. Mutations in 16 genes have been identified as causing Bardet-Biedl syndrome. 7 of those genes compose the biochemically purified BBSome, a protein complex actively trafficked in cilia, but whose function remains mostly unknown. The BBSome component BBS4 is required for trafficking G-protein coupled receptors (GPCRs) into mammalian cilia. The BBSome genes are highly conserved between humans and the algae *Chlamydomonas reinhardtii*. When *Chlamydomonas* cells are treated with GPCR targeting compounds (including dopamine, serotonin, and adrenoreceptor-targeting compounds) known to affect flagellar length, *bbs4* mutants show a response that varies from that of wild type cells. Wild type cells also show flagellar binding of a fluorescently labeled adrenoreceptor-targeting compound, while cells lacking BBS4 do not show any flagellar binding. These findings demonstrate the role of BBS4 in adrenoreceptor trafficking, and likely other GPCRs, in flagella of *Chlamydomonas* and illustrate the conservation of BBS4 function.

1889

**Transforming growth factor beta (TGF $\beta$ ) signaling is regulated at the pocket region of primary cilia.**

C. A. Clement<sup>1</sup>, K. D. Ajbro<sup>2</sup>, M. P. de Jesus<sup>1</sup>, K. Koefoed<sup>1</sup>, M. L. Vestergaard<sup>1,2</sup>, L. B. Pedersen<sup>1</sup>, A. Benmerah<sup>3,4,5</sup>, C. Y. Andersen<sup>6</sup>, L. A. Larsen<sup>2</sup>, S. T. Christensen<sup>1</sup>; <sup>1</sup>Department of Biology, University of Copenhagen, Copenhagen, Denmark, <sup>2</sup>Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark, <sup>3</sup>Institut Cochin, Inserm U1016, Paris, France, <sup>4</sup>CNRS, Paris, France, <sup>5</sup>Universite Paris Descartes, Sorbonne Paris Cite, France, <sup>6</sup>Laboratory of Reproductive Biology, Rigshospitalet, Copenhagen, Denmark

TGF $\beta$  signaling extensively cross-talks with Hedgehog, Wnt and receptor tyrosine kinase (RTK) signaling to control cell proliferation, migration and differentiation, and when aberrantly regulated leads to developmental defects and cancer. TGF $\beta$  signaling is activated through the internalization of TGF $\beta$  receptors via clathrin-dependent endocytosis at which the receptor activates Smad2/3 transcription factors.

Here we investigated the relationship between TGF $\beta$  signaling and primary cilia using transcriptomics, imaging and molecular biology tools for expression, localization and activation of TGF $\beta$  signaling components in fibroblasts and in EC and human embryonic stem cells during their differentiation into cardiomyocytes and neurons. During cardiomyocyte differentiation expression of TGF $\beta$  receptors and Smad transcription factors were up-regulated and targeted to the pocket region of primary cilia, at which the receptor colocalized with clathrin-coated pits and vesicles as well as early endosomes to activate Smad2/3. This activation was blocked by receptor antagonists. In contrast, neuronal differentiation was associated with a loss of TGF $\beta$

signaling at the primary cilium. In mouse embryonic fibroblasts (MEFs) and human foreskin fibroblasts (hFFs), TGF $\beta$  stimulation increased the targeting of TGF $\beta$  receptors to the ciliary pocket region followed by activation of Smad2/3 signaling to promote cell cycle entry. In Tg737orpk MEFs there was a major reduction in TGF $\beta$ -induced Smad2/3 phosphorylation, and this was associated reduced activity of clathrin-dependent endocytosis at stumpy primary cilia. Similarly, inhibition of clathrin-dependent endocytosis blocked activation of Smad2/3 at the ciliary pocket region in fibroblasts. Our results suggest that the ciliary pocket functions as a unique site for regulation of TGF $\beta$  signaling through clathrin-dependent endocytosis and potentially in cross-talking with other signaling pathways during development and in tissue homeostasis.

**Epithelial to Myofibroblast transition is associated with the loss of the primary cilium: Topical susceptibility to TGF $\beta$  in the injured epithelium**

*M. D. Rozycki<sup>1</sup>, J. Lam<sup>1</sup>, P. Speight<sup>1</sup>, M. Lodyga<sup>1</sup>, K. Fatyol<sup>1</sup>, A. Kapus<sup>1</sup>; <sup>1</sup>Surgery, St. Michaels Hospital, Toronto, ON, Canada*

Epithelial-myofibroblast transition (EMyT), a key process in fibrogenesis, involves the activation of a myogenic program ( $\alpha$ -smooth muscle actin (SMA) expression) in the injured epithelium. EMyT is an important pathologic feature of polycystic kidney disease, the prototypic ciliopathy. However, the impact of EMyT on the cilium and the underlying mechanisms are largely unknown. Previously we have shown that an intact epithelium is resistant to the EMyT-provoking effect of TGF $\beta$ . Instead EMyT requires a two-hit scenario, wherein an injury (or uncoupling) of adherens junctions (AJs) and the presence of the fibrogenic cytokine TGF $\beta$  are both necessary to induce SMA expression in kidney tubular (LLC-PK1) cells. These inputs activate myocardin-related transcription factor and Smad3 respectively, the interplay of which elicits SMA expression. Here we followed ciliary changes in this two-hit EMyT model. EMyT was associated with a biphasic change in the primary cilium, characterized by initial growth followed by dramatic ciliary loss. AJ uncoupling induced by low calcium medium (LCM) triggered a 2-fold growth in ciliary length, TGF $\beta$  alone had no effect, while LCM+TGF $\beta$  (EMyT) led to deciliation at 48 h. Differential topical susceptibility to TGF $\beta$  was also observed in a wound model: TGF $\beta$  induced EMyT and the loss of the cilium exclusively in cells lining a wound edge (in the first few rows), while cells in the intact part of the same monolayer failed to transform and kept their cilia. Neither TGF $\beta$  alone in an intact monolayer, nor wounding in the absence of TGF $\beta$  induced deciliation. In addition to LLC-PK1 cells, human skin fibroblasts treated with TGF $\beta$  also lost their primary cilium as they differentiated into myofibroblasts. Next we investigated the signaling events that led to deciliation. We found that the loss of the cilium in EMyT is dependent on Smad3 signaling and cell contractility. Thus, downregulation of Smad3, or treatment of the cells with the Rho kinase inhibitor Y-27632 or the myosin blocker Blebbistatin suppressed the LCM+TGF $\beta$ -provoked deciliation. Additionally cells transfected with the active TGF $\beta$ RI receptor mutant (Alk5T204D) underwent deciliation only with LCM treatment, whereas those transfected with kinase dead Alk5 did not. AJ uncoupling facilitated the nuclear translocation of the Hippo transcriptional co-activator TAZ, a known nuclear retention factor for Smad3. Remarkably, overexpression of WT or constitutively nuclear TazS89A (while insufficient alone) provoked deciliation upon LCM treatment. We conclude that the myofibroblast is a deciliated cell. The contact-deprived epithelium becomes selectively sensitive to TGF $\beta$ -triggered deciliation. We propose that this topical susceptibility is due to contact disruption-enhanced, TAZ-promoted Smad3 signaling and a locally increased Rho-dependent contractility.

1891

### Differential Localization of Receptors to Primary Cilia and Activation of Ciliary TGF $\beta$ Signaling During Early Neurogenesis in NT2 Cells.

L. Lindbaek<sup>1</sup>, S. K. Brorsen<sup>1</sup>, S. T. Christensen<sup>1</sup>; <sup>1</sup>Department of Biology, University of Copenhagen, Copenhagen, Denmark

We recently showed that the primary cilium is a unique site for TGF $\beta$  signaling regulated through clathrin-dependent endocytosis at the ciliary pocket region. Canonical TGF $\beta$  signaling acts through the activation of transcription factors Smad2/3 to control diverse cellular processes during development and in tissue homeostasis. Further, we have shown that SMURF1, an inhibitor of the TGF $\beta$  pathway, is required for formation of mature neurons in P19.CL6 embryonal stem cells.

In this study we characterized the human teratocarcinoma tera 2 (NT2), pluripotent stem cell line as a model for ciliary TGF $\beta$  signaling during neurogenesis. Previous studies indicated that canonical TGF $\beta$  signaling is participating in the maintenance of pluripotency in embryonic stem cells, and that the inhibition of Smad2/3 results in a decrease in the expression of stem cell marker Oct3/4 (James et al., 2005). Initially, we here show that NT2 cells form primary cilia at all stages of differentiation, and transcriptomic analysis on differentially expressed genes in co-regulated gene networks, revealed that multiple pathways are affected during 21 days of NT2 differentiation, including axon guidance as well as TGF $\beta$ , mTor, Wnt, MAPK, ErbB, and Hedgehog signaling. Immunofluorescence microscopy (IFM), Western blotting (WB), and PCR analysis confirmed formation of mature neurons along with an up-regulation of neuronal markers, including the Paired box protein PAX6, an early transcription factor essential for neurogenesis. Further, IFM analysis showed that components in the various signaling pathways localized in a temporal and spatial manner to the cilium and/or the ciliary pocket region during neurogenesis. As an example, TGF $\beta$  receptors were localized to the ciliary tip and accumulated at a high level at the ciliary pocket region in non-differentiated cells positive for stem cell markers, SOX2, NANOG and OCT3/4, and this localization was gradually reduced as the cells became positive for PAX6, i.e., entered the early phases of neurogenesis. Conversely, we observed an accumulation of the TGF $\beta$  signaling inhibitor, Smad7, at the ciliary pocket region upon cell differentiation concomitantly with a reduction in Smad2/3 activation induced by TGF $\beta$ . In contrast, receptors in Wnt signaling, Frizzled-3, localized to the primary cilium in both undifferentiated and differentiating cells. The differential localization of TGF $\beta$  signaling components throughout NT2 differentiation, and the observation that the ciliary pocket area is enriched in clathrin-coated vesicles, indicating increased endocytosis in this region, suggest a role for the primary cilium in coordinating TGF $\beta$  signaling in NT2 cells, and that the absence of TGF $\beta$  at the primary cilium may participate in the induction of differentiation in NT2 cells.

### Hedgehog signaling is dependent on motile cilia in the sea urchin embryo.

J. Warner<sup>1</sup>, D. McCay<sup>1</sup>; <sup>1</sup>Duke University, Durham, NC

A recent frontier in Hedgehog (Hh) signaling research is the requirement of the primary cilium and intra-flagellar transport (IFT) proteins for signal transduction. Studies in vertebrates have shown that proper trafficking of Hh pathway components within the primary cilium is essential for Hh signaling. This machinery is not necessary, however, for Hh signal transduction in protostomes such as *Drosophila*. As a basal deuterostome, the sea urchin occupies a unique phylogenetic position and can provide crucial insight into the evolution of hedgehog signaling. Here we provide evidence that, as in vertebrates, Hh signaling in the sea urchin relies on the presence of cilia. It has been previously shown by Robert Morris and John Scholey that Kinesin II is essential for cilia assembly. Indeed, knockdown of Kinesin II using an antibody

phenocopies Hh morphants and leads to downregulation of the conserved Hh target Patched. These findings lead to a model of sea urchin Hh signaling that closely resembles the pathway as it functions in vertebrates. Furthermore, analysis of the cilia on Hh receiving cells reveal that they exhibit a 9+2 microtubule morphology consistent with motile cilia and implies that motile cilia are also capable of carrying out Hh signal transduction. This work indicates that the requirement of cilia for Hh signal transduction is not specific to vertebrates or primary cilia, but extends to other phyla and ciliary morphologies.

### **Smurf1 is a Ciliary Protein Involved in Cardiac Development and Congenital Heart Defects.**

*K. Koefoed<sup>1</sup>, K. D. Ajbrou<sup>2</sup>, C. A. Clement<sup>1</sup>, M. L. Vestergaard<sup>2</sup>, T. A. Andersen<sup>2</sup>, K. Moellgaard<sup>3</sup>, E. Bendtsen<sup>4</sup>, N. Tommerup<sup>3</sup>, S. T. Christensen<sup>1</sup>, L. A. Larsen<sup>2</sup>; <sup>1</sup>Department of Biology, University of Copenhagen, Copenhagen, Denmark, <sup>2</sup>Wilhelm Johannsen Centre for Functional Genome Research, University of Copenhagen, Copenhagen, Denmark, <sup>3</sup>Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark, <sup>4</sup>Fertility Clinic, Department of Obstetrics and Gynaecology, University Hospital of Odense, Odense, Denmark*

The transforming growth factor  $\beta$  (TGF- $\beta$ ) superfamily controls multiple events in heart development, including cardiomyogenesis, smooth muscle development, vessel stabilization and formation of chambers and endocardial cushion in a spatial and temporal manner. Recent studies in our lab showed that TGF- $\beta$  signaling is regulated through clathrin-dependent endocytosis at the pocket region of the primary cilium to control cardiomyogenesis.

In this study, we investigated the role of SMURF1 in human heart development and in cardiomyogenesis and formation of beating clusters of cardiomyocytes with pacemaker cells from cultures of P19.CL6 mouse EC stem cells. SMURF proteins are E3 ubiquitin ligases important for embryonic development and regulation of TGF- $\beta$  signaling in cell differentiation, migration and proliferation. SMURF1 was selected as a candidate disease gene among three genes located in a 486kbp de novo duplication of 7q22.1 in a patient with a congenital heart disease. Immunohistochemical analysis of human embryonic and fetal hearts revealed that SMURF1 has a spatially and temporally restricted expression pattern during cardiogenesis, which suggests that SMURF1 plays a specific role in chamber formation and in controlling the heart beating. Knockdown of SMURF1 by siRNA in P19.CL6 cells increased the rate of differentiation towards cardiomyogenesis, but clusters of cardiomyocytes showed altered morphology compared to mock-transfected cell cultures and were unable to beat. Immunofluorescence microscopy analysis revealed that no or very few pacemaker cells were formed in the clusters of siRNA treated cells, indicating that SMURF1 is required for neuronal development in P19.CL6 cells. Preliminary data shows that the amount of beating clusters and fully mature pacemaker cells increase when SMURF1 is over-expressed. Our analysis further showed that SMURF1 localizes to the ciliary pocket region and interacts with TGF- $\beta$  receptors and downstream signaling components, including Smad2/3. We suggest that ciliary TGF- $\beta$  signaling take part in the stimulation of cardiomyogenesis, and that deregulated signaling as a consequence of reduced SMURF1 expression at the cilium prevents the formation of beating clusters of cardiomyocytes due to defective formation and integration of pacemaker cells in the clusters.

**Primary Cilia in Appetite and Satiety.**

*N. F. Barbari<sup>1</sup>, R. C. Pasek<sup>1</sup>, E. B. Malarkey<sup>1</sup>, S. Z. Yazdi<sup>1</sup>, A. D. McNair<sup>1</sup>, W. R. Lewis<sup>1</sup>, R. A. Kesterson<sup>1</sup>, T. R. Nagy<sup>1</sup>, B. K. Yoder<sup>1</sup>; <sup>1</sup>Cell, Developmental and Integrative Biology, University of Alabama at Birmingham, Birmingham, AL*

Although primary cilia are well established as important sensory and signaling structures, their function in most tissues remains unknown. Hyperphagia associated obesity is a feature of some syndromes of cilia dysfunction, such as Bardet-Biedl syndrome (BBS) and Alström syndrome (ALMS). Recent data indicate that obesity in BBS mutant mouse models is due to defects in leptin receptor trafficking and subsequent leptin resistance. Furthermore, induction of cilia loss in leptin responsive POMC neurons results in obesity, implicating cilia on hypothalamic neurons in regulating feeding behavior. Here, we directly test the importance of the cilium as a mediator of the leptin response. In contrast to the current literature, a longitudinal study of conditional *Ift88* cilia mutant mice under different states of adiposity indicates that leptin resistance is present only when mutants are obese. Our studies show that caloric restriction leads to an altered anticipatory feeding behavior that temporarily abrogates the anorectic actions of leptin despite normalized circulating leptin levels. Interestingly, pre-obese *Bbs4* mutant mice responded to the anorectic effects of leptin and did not display other phenotypes associated with defective leptin signaling. Furthermore, thermoregulation and activity measurements in cilia mutant mice are inconsistent with phenotypes previously observed in leptin deficient *ob/ob* mice. Collectively, these data indicate that cilia are not directly involved in leptin responses and that a defect in the leptin signaling axis is not the initiating event leading to obesity associated with cilia dysfunction. Current studies suggest altered melanin concentrating hormone or hedgehog signaling may be responsible for the obesity phenotype associated with cilia dysfunction. This work will provide novel insights into the onset of obesity and more generally the importance of the cilium in regulating normal neuronal activity and energy balance.

**Bld10/Cep135 stabilizes basal bodies to resist cilia generated forces.**

*B. A. Bayless<sup>1</sup>, T. H. Giddings<sup>2</sup>, M. Winey<sup>2</sup>, C. G. Pearson<sup>3</sup>; <sup>1</sup>Cell Biology, Stem Cells and Development, University of Colorado Denver, Aurora, CO, <sup>2</sup>Molecular, Cellular, and Developmental Biology, University of Colorado at Boulder, Boulder, CO, <sup>3</sup>Cell and Developmental Biology, University of Colorado Denver, Aurora, CO*

Basal bodies nucleate, anchor and organize cilia. As the anchor for motile cilia, basal bodies must be resistant to the forces directed toward the cell as a consequence of ciliary beating. The molecules and generalized mechanisms that contribute to the maintenance of basal bodies remain to be discovered. Bld10/Cep135 is a basal body outer cartwheel domain protein that has established roles in the assembly of nascent basal bodies. We find that Bld10 protein first incorporates at basal bodies early during new assembly. A second Bld10 protein population incorporates at basal bodies after assembly and we predict that this is required to stabilize basal bodies. Additionally, we identify a novel mechanism for Bld10/Cep135 in basal body maintenance so that basal bodies can withstand the forces produced by motile cilia. Bld10 stabilizes basal bodies by promoting the stability of the A- and C-tubules of the basal body triplet microtubules and by properly positioning the triplet microtubule blades. The forces generated by ciliary beating promote basal body disassembly in *bld10Δ* cells. Thus, Bld10/Cep135 acts to maintain the structural integrity of basal bodies against the forces of ciliary beating in addition to its separable role in basal body assembly.

1896

### Configuration changes of *Chlamydomonas* dynein-f tail coupled with IC138 phosphorylation.

H. Sakakibara<sup>1</sup>, K. Oiwa<sup>1,2</sup>, H. Kojima<sup>1</sup>; <sup>1</sup>KARC, National Institute of Information and Communications Technology, Kobe, Japan, <sup>2</sup>Graduate School of Life Science, University of Hyogo, Hyogo, Japan

Inner-arm dynein-f of *Chlamydomonas* flagella is a hetero-dimeric dynein which has two heavy chains ( $\alpha$  and  $\beta$ ) forming the respective heads, three intermediate chains and light chains attached to the tail. It has been shown that an axonemal casein kinase I phosphorylates the 138K intermediate chain (IC138) and that this phosphorylation is involved in regulation of flagellar activity. To elucidate the regulation mechanisms of dynein-f functions through the IC138 phosphorylation, we examined molecular configuration changes of dynein-f coupled with IC138 phosphorylation by negative-staining electron microscopy and following single-particle image analyses. For the analyses, we picked up a dynein-f density map from the tomogram of axoneme, prepared projections of the map from various angles, and used tail parts of the projections as the templates for alignments. We found that (1) the distribution of the two heads' positions spread and distance between the  $\alpha$  and  $\beta$  heads became closer coupled with IC138 phosphorylation. (2) In ~10% classes, the tail showed forked structure which consisted of thick stem and the thin branch. It was suggested that this thin branch linked to the  $\beta$  head. The averaged image of the thin branch became smearing in phosphorylation conditions, suggesting that the branch positioning became unstable. From these observations, we suppose that the IC138 phosphorylation could first affect the thin branch positioning, then the  $\beta$ -head position should be shifted. In axonemes, position shift of the  $\beta$  head could affect the interactions of dynein-f and adjacent microtubule to change their operation mode.

1897

### Composition and function of the nexin-dynein regulatory complex.

R. Bower<sup>1</sup>, D. Tritschler<sup>1</sup>, K. VanderWaal<sup>1</sup>, L. Fox<sup>2</sup>, W. Sale<sup>2</sup>, M. E. Porter<sup>1</sup>; <sup>1</sup>Genetics, Cell Biology & Development, University of Minnesota, Minneapolis, MN, <sup>2</sup>Cell Biology, Emory University School of Medicine, Atlanta, GA

The nexin dynein regulatory complex (N-DRC) is a group of polypeptides thought to coordinate the activity of dynein arms and interconnect doublet microtubules (Piperno et al., 1994; Gardner et al., 1994; Heuser et al., 2009), but its precise role in flagellar motility is poorly understood. Here we take advantage of *drc4* mutations to identify novel components and evaluate the function of the N-DRC. We found that DRC4 is the *PF2* gene product in *Chlamydomonas* (Rupp & Porter, 2003) and that DRC4 is also modified in *sup-pf3* by transposon insertion and alternative splicing. Truncated DRC4 subunits assemble into *sup-pf3* axonemes, but several N-DRC subunits are missing. Transformation of *pf2* and *sup-pf3* with GFP-tagged DRC4 restores wild-type motility and repairs the mutant defects. Dikaryon rescue experiments reveal that DRC4-GFP does not readily exchange with wild-type DRC4, but assembles into *pf2* axonemes from tip to base within ~1 hour after mating. These observations show that DRC4 plays a key role in the assembly of the N-DRC linker domain. Biochemical strategies have identified at least nine N-DRC subunits that associate with DRC4 to form a discrete complex distinct from the radial spokes, calmodulin spoke associated complex, or ribbon fraction. Several subunits contain calcium signaling motifs or AAA domains. Phylogenetic comparisons indicate that N-DRC subunits are nearly ubiquitous in species with motile axonemes. However, *n-drc* mutants still maintain the normal 9+2 arrangement of outer doublet microtubules and also generate flagellar bending. To further evaluate the role of the N-DRC in flagellar motility, we analyzed microtubule sliding in isolated axonemes. Addition of 0.1 mM ATP to axonemes from wild-type or rescued strains results in intact axonemes or reactivated axonemal bending but no sliding

disintegration. However, addition of 0.1 mM ATP to *n-drc* mutant axonemes results in the splaying of outer doublets in the distal three-fourths of the axoneme, followed by occasional cycles of sliding-bending between splayed pairs of doublet microtubules, similar to that seen in protease treated axonemes (Aoyama and Kamiya, 2005). These results suggest that the N-DRC is required to maintain optimal alignment for productive microtubule sliding and that additional structures at the proximal end of the axoneme provide resistance for flagellar bending. (Supported by grants from the NIH to WSS and MEP).

**The microtubule associated protein CLAMP and Par-3/Par-6/aPKC are required for radial intercalation of multiciliated cells.**

*M. E. Werner<sup>1</sup>, P. Hwang<sup>1</sup>, B. Mitchell<sup>1</sup>; <sup>1</sup>Cell and Molecular Biology, Northwestern University Feinberg School of Medicine, Chicago, IL*

Multiciliated epithelia can be found in a variety of tissues such as the upper respiratory tract, the fallopian tube and the ependyma. The directed fluid flow created by multiciliated ciliated cells (MCCs) is essential for many biological processes during development as well as during normal adult tissue homeostasis. We use the skin of *Xenopus* embryos as a model system to study the development of multiciliated epithelia. In developing tadpoles, MCC precursors differentiate in an inner epidermal layer of the ectoderm before radially intercalating into the outer epidermal layer. Radial intercalation has been shown to be restricted to cellular vertices formed by multiple cells of the outer epidermal layer however the molecular mechanisms that regulate this process are largely unknown. MCCs contain roughly one hundred basal bodies that duplicate prior to intercalation. We observe that these basal bodies cluster close to the apical surface during intercalation accompanied by a significant accumulation of microtubules at the leading edge of the intercalating cell. Interestingly, disruption of the microtubule network with the microtubule de-polymerizing drug Nocodazole leads to defects in radial intercalation suggesting that microtubules are required for this process. The Par-3/Par-6/aPKC complex has been shown to regulate cell polarity, centrosome positioning and cell migration. Overexpression of dominant negative variants of Par-3 or kinase dead aPKC specifically in MCCs prevents apical positioning of basal bodies and blocks radial intercalation. Furthermore, we observe that the striated rootlet associated protein CLAMP, that exhibits weak homology to EB1, also associates with cytoplasmic microtubules in *Xenopus* embryos. Interestingly, the human homologue of CLAMP has been shown to stabilize microtubules when overexpressed. We show that CLAMP dynamically associates with the microtubule lattice and that depletion of CLAMP by morpholino oligonucleotides severely disrupts radial intercalation. Interestingly, depletion of CLAMP does not prevent apical positioning of the basal body cluster suggesting that CLAMP acts downstream of the Par-3/Par-6/aPKC complex. We propose that radial intercalation of MCCs requires the Par-3/Par-6/aPKC dependent apical localization of basal bodies followed by CLAMP dependent stabilization of apical microtubules.

1899

**Outer-Inner Dynein Linker Regulates the Flagellar Beating.**

*T. Oda<sup>1</sup>, T. Yagi<sup>1</sup>, H. Yanagisawa<sup>1</sup>, M. Kikkawa<sup>1</sup>; <sup>1</sup>Dept. Cell Biology, University of Tokyo, Tokyo, Japan*

Cilia and flagella are elaborate organelles for motility and are conserved in a wide range of eukaryotes. Defects in the motility of cilia and flagella result in hydrocephalus, situs inversus, bronchiectasis and infertility in mammals. Thus, it is of great importance to understand the mechanism of the ciliary/flagellar motility. The beating motion of cilia and flagella is driven by

two species of dynein motors: the outer dynein arm (ODA) and the inner dynein arm (IDA). ODA and IDA play distinct roles in the generation of the beating. ODA is required for generating normal beat frequency while IDA is necessary for propagation of the bending waves with appropriate amplitude. However, functional communications between the two species of the motors have not been investigated. In this study, we found that, in *Chlamydomonas reinhardtii*, a mutation introduced to the amino-terminus of the intermediate chain 2 (IC2) of ODA caused reduction in the bend amplitude as well as defects related to the malfunction of ODA. The phenotype of the mutant suggested that the mutation within ODA disrupt not only ODA's function but also the activity of IDA. Recent studies by cryo-electron tomography of axonemes revealed new structures linking between ODA and IDA. We performed three-dimensional reconstructions of the structures of streptavidin-labeled ODA bound to microtubules and showed that the position of the amino-terminus of IC2 coincided ODA-end of the previously reported ODA-IDA linker. Furthermore, we demonstrated that the IC2 was cross-linked with one of the components of the dynein regulatory complex (DRC) within the axoneme. These observations suggest that IC2 is involved in the regulation of the motor activities of both ODA and IDA via ODA-DRC connection. This is the first report that there are physical and functional interactions between ODA and IDA.

**The Mia complex is a conserved dynein regulator required for normal ciliary motility.**

R. Yamamoto<sup>1</sup>, K. Song<sup>2</sup>, H-A. Yanagisawa<sup>3</sup>, L. Fox<sup>1</sup>, T. Yagi<sup>3</sup>, M. Wirschell<sup>1</sup>, M. Hirono<sup>4</sup>, R. Kamiya<sup>4</sup>, D. Nicastro<sup>2</sup>, W. S. Sale<sup>1</sup>; <sup>1</sup>Cell Biology, School of Medicine, Emory University, Atlanta, GA, <sup>2</sup>Biology, Rosenstiel Science Center, Brandeis University, Waltham, MA, <sup>3</sup>Cell Biology and Anatomy, Graduate School of Medicine, University of Tokyo, Tokyo, Japan, <sup>4</sup>Biological Sciences, Graduate School of Science, University of Tokyo, Tokyo, Japan

Ciliary motility requires precise regulation and coordination of the activities of a complex array of axonemal dyneins. However, the mechanisms that regulate and coordinate ciliary dyneins are poorly understood. We analyzed two *Chlamydomonas* mutants, *mia1* and *mia2* (modifiers of inner arms): the mutants are defective in phosphorylation of IC138 (the 138 kD regulatory intermediate chain of inner dynein arm "I1", also known as dynein "f"), swim slowly and fail to perform phototaxis (King and Dutcher, 1997). These phenotypes mimic mutants defective in I1 dynein. Analysis of four *mia1* alleles and the *mia2* mutant confirmed the altered IC138 phosphorylation and slow swimming phenotype. We also discovered that the *mia* mutants display reduced ciliary beat frequency, a feature consistent with a defect in outer dynein arm function or regulation. By AFLP mapping and sequencing, we determined that the *MIA1* and *MIA2* genes encode conserved coiled-coil proteins, FAP100 and FAP73, respectively. We further determined that these proteins form a complex in the axoneme, the "Mia complex". Protein-protein interaction analysis revealed that the Mia complex interacts with IC138. Consistent with an interaction between I1 dynein and the Mia complex, cryo-electron tomography of *mia*-mutant axonemes revealed the Mia complex is located immediately distal to the IC138 IC/LC sub-complex (Bower et al., 2009) of I1 dynein. Moreover, density reduced in the *mia* mutants appears to extend from I1 dynein to the Nexin-DRC (Heuser et al., 2009). Notably, in axonemes from mutants that lack both the Mia complex and outer dynein arms, I1 dynein fails to assemble in the axoneme, suggesting a role for the Mia complex in stable assembly of I1 dynein. Together, the results demonstrate that the Mia complex regulates I1 dynein activity and, either directly or indirectly, regulates outer dynein arm activity to control axonemal waveform and beat frequency, the key parameters of normal ciliary motility and physiology.

1901

**Amplitude and curvature development at the switch-points of the beat cycle in bull sperm are augmented by ADP and reduced by ATP that is un-complexed with Mg<sup>2+</sup>.**

*K. A. Lesich<sup>1</sup>, T. G. dePinho<sup>1</sup>, C. B. Lindemann<sup>1</sup>; <sup>1</sup>Biological Sciences, Oakland University, Rochester, MI*

We investigated the roles of ADP, Mg<sup>2+</sup>, and ATP in the beat cycle of Triton X-100- extracted bull sperm models. We recorded the motility of reactivated sperm models that were firmly attached to a glass surface by their heads with their flagella beating freely. The curvature of the flagellum at ~7 μm from the head tail junction was measured on images that were closest to the point of beat direction reversal. These images corresponded to the principal and reverse bend switch-points. The amplitude of the beat frequency was measured by tracking the excursion of a point on the flagellum 20 μm from the head tail junction relative to the origin on the midline axis of the sperm head when the flagellum is straight. Beat frequencies were hand calculated. The curvature at the switch-point, the amplitude at 20 μm and the beat frequency provided a quantitative basis to evaluate changes of the beat cycle in response to changes in ADP, Mg<sup>2+</sup>, and ATP concentration. We found that bull sperm exhibit well-developed beat cycles at all concentrations of Mg-ATP between 0.1 mM and 10 mM, but only if the concentrations of Mg<sup>2+</sup> and ATP are equal. ATP in excess of the Mg<sup>2+</sup> concentration resulted in a reduction of beat amplitude and curvature at the switch-points, and increased beat frequency. A concentration of 4 mM or greater ATP combined with 1 mM Mg<sup>2+</sup> effectively terminated the beat cycle by reducing amplitude and curvature to extinction. Increasing ADP from 0 to 4 mM increased the amplitude and curvature developed at the switch-points and offset the reduction in amplitude and curvature produced by high ATP with Mg<sup>2+</sup> held at 1 mM. This suggests that ADP has a strong effect on elevating the curvature and amplitude of the beat that is independent of Mg<sup>2+</sup> concentration. The rescue of the beat by ADP occurs with a reduction in frequency. Therefore, the beat cycle is restored in spite of a slowing of the dynein cross-bridge cycle. These results can best be understood in the context of the geometric clutch (GC) hypothesis. In the GC hypothesis, switching occurs when the transverse force overcomes the adhesion of the dyneins onto their adjacent doublet. If ADP increases that adhesion by increasing dynein microtubule binding affinity and ATP un-complexed with Mg<sup>2+</sup> has the opposite effect, then the balance between these factors will regulate the switch-point for dynein release in the beat cycle. Support: NSF MCB-0918294.

1902

**Analysis of extraordinary flagellar beat patterns suggesting switching mechanisms of flagellar activity.**

*Y. Wada<sup>1</sup>, S. A. Baba<sup>2</sup>, S. Kamimura<sup>1</sup>; <sup>1</sup>Biological Sciences, Chuo University, Tokyo, Japan, <sup>2</sup>Biology, Ochanomizu University, Tokyo, Japan*

Sea urchin spermatozoa show active swimming by beating flagella toward eggs when spawned in sea water. The flagellar motility is based on the activity of dynein motors that hydrolyze ATP and produce power to generate microtubule sliding. In many cases, spermatozoa quickly lose their motility in 10-20 min after spawning probably due to the depletion of energy sources. However, ATP would not be depleted completely since spermatozoa can continue respiration by mitochondria and we sometimes observed active sperm swimming in a tightly sealed chamber for more than an hour. Sperm is a kind of disposable machine for DNA delivering without any repairing and maintaining system such as IFT. Thus, we assumed that accumulation of mechanical damage(s) inside flagellar axoneme may gradually cause the change of wave generation and propagation, which would partially lead to the cessation of active swimming.

Here, we used sea urchin sperm (*Clypeaster japonicus*, *Hemicentrotus puicherrimus*, and *Anthocidaris crassispina*) with extraordinary beating by aging or mechanical damages to examine the details of modified motility. As for the case of extraordinary motility, we chose spermatozoa that showed relatively symmetric beating at the proximal regions of flagella with waves diminishing when propagating towards the distal ends. Since sea urchin spermatozoa have been shown to have loose head-to-neck junction, we can assume the distal straight parts to be a 'non-sliding site' that can be used as for reference points of microtubule sliding instead of sperm heads. Although the flagellar motion was in irregular forms, we expected more precise analysis of sliding activity around the neck region of spermatozoa that could not be clarified by conventional methods. Our results showed that flagellar beat frequency and phase were kept almost constant when propagating along the axoneme. Amplitude or amount of sliding (shear angle amplitude) was constant in the proximal region, but diminished when propagating into the latter distal regions of axoneme. In most cases, the transient point from constant wave propagations to declined sliding activity was at around a 1/2 of wave length (1/3 of flagella length,  $\approx 15\mu\text{m}$ ) from base of flagella. This point would be corresponding to a region of the functional discontinuity of sperm flagella where turn on and off the activity of dynein arms.

1903

#### **Formation of planar waves on sea urchin sperm flagella.**

S. Ishijima<sup>1</sup>; <sup>1</sup>Bioengineering, Tokyo Institute of Technology, Tokyo, Japan

The function of  $\text{Ca}^{2+}$  and cAMP in extruding doublet microtubules from sea urchin sperm axoneme and generating flagellar waves was investigated in order to clarify the regulatory mechanism of microtubule sliding and the formation mechanism of beating patterns of cilia and flagella. Almost all potentially asymmetric spermatozoa, which were demembrated with Triton in the absence of  $\text{Ca}^{2+}$ , beat with planar waves, whereas potentially symmetric spermatozoa, which were demembrated with Triton and millimolar  $\text{Ca}^{2+}$ , beat with three-dimensional waves if they were reactivated with low  $\text{MgATP}^{2-}$ . At a low  $\text{Ca}^{2+}$ , cAMP enhanced the three-dimensionality of the flagellar waves. These changes in the flagellar waves were caused by different regulations of the microtubule sliding by  $\text{Ca}^{2+}$  and calmodulin and cAMP. Increase in beat frequency with high  $\text{MgATP}^{2-}$  converted the three-dimensional waves into the planar waves. These results suggest that the planar flagellar waves are generated at high  $\text{Ca}^{2+}$  and calmodulin or by rapid beating.

#### **Measurement of human airway ciliary waveforms in the presence of polyethylene glycol and dextran.**

P. R. Sears<sup>1</sup>, K. Thompson<sup>1,2</sup>, M. R. Knowles<sup>1</sup>, C. W. Davis<sup>1</sup>; <sup>1</sup>Cystic Fibrosis Center, University of North Carolina, Chapel Hill, Chapel Hill, NC, <sup>2</sup>Institute of General Physiology, University of Ulm, Ulm, Germany

Mammalian airways are covered with cilia which transport mucus out of the airways. They are surrounded by a periciliary layer and covered by a distinct mucus layer. Our goal was to gain insight into the mechanism of the ciliary beat from the responses of cilia to altered environments.

Human airway cultures were grown with an air-liquid interface. For imaging, culture membranes were folded to image cells in profile and then sandwiched between cover-glasses forming a channel. Through this channel, buffer with polyethylene glycol (PEG) or dextran was introduced and then washed out. The average molecular weights tested were 8000 for PEG and several molecular weights up to  $2 \times 10^6$  for dextran. Both were tested with concentrations up

to 50%. Beating cilia were analyzed by manually altering a model superimposed over videos of beating cilia.

The following waveforms were compared: plain buffer, PEG or dextran, and washout of PEG or dextran with plain buffer. Both PEG and dextran caused a decrease in the ciliary beat frequency and amplitude. The dextran effect increased in proportion to its concentration. At the highest concentrations of dextran, some motion was still observed. PEG had a sudden effect above 15% with an increased coordination of adjacent cilia. At higher concentrations, cilia clumped together and motion completely stopped. Both PEG and dextran washed out and resulted in a normal ciliary beat but the PEG solution required a longer washout time. With some cilia in the presence of dextran, it was also possible to observe curvatures that spanned shorter than normal distances along the cilium. This made it possible to measure propagation of curvature which is not seen in cilia beating in plain buffer.

Overall, PEG and dextran acted differently at similar viscosities and this may be due to specific effects of PEG on the ciliary surface. The PEG effects suggest that the surface properties of cilia are important in waveform generation. The application of dextran unmasked a propagating mechanism that was not observed in plain buffer.

## Kinetochores

1905

### Kinetochore structure dissection. A Super-Resolution Microscopy issue.

*G. Vargiu<sup>1</sup>, C. Flors<sup>2</sup>, T. Fukagawa<sup>3</sup>, B. Earnshaw<sup>1</sup>; <sup>1</sup>Wellcome Trust Centre for Cell Biology, University of Edinburgh, Edinburgh, UK, <sup>2</sup>Instituto Imdea Nanociencia, Madrid, Spain,*

*<sup>3</sup>Molecular Genetics, National Institute of Genetics and The Graduate University for Advanced Studies, Mishima, Japan*

The kinetochore is a highly complex proteinaceous structure that assembles at the primary constriction of sister chromatids. Kinetochores hold a primary role during mitosis because they direct the process of chromosome segregation. In particular, growing interest has been raised towards the Constitutive Centromere Associated Network (CCAN) components, which seem to take part in the formation of a scaffold involved in kinetochore assembly. Therefore much effort has been put in trying to understand both their distribution and their role in kinetochore functions. In the last decade, novel super-resolution microscopy techniques have been developed that can reach a subdiffraction spatial limit resolution of tens of nanometers. Amongst these, Photo-Activated Localization Microscopy has been recently applied to study the organization of extended fibers of kinetochore chromatin. On linearized chromatin fibers, PALM allows us to localize with a resolution of approximately 37 nm single molecules of the blinking fluorescent protein Dronpa fused to the N-terminal region of CENP-A relative to the position of other antigens labeled with Alexa-tagged antibodies. In our study we are taking advantage of the high homologous recombination efficiency in DT40 B-lymphoma chicken cell line which allowed us to obtain conditional knockouts of several CCAN components. We are using those conditional knockouts to study the localization of several CENPs and post-translational histone modifications relative to Dronpa:CENP-A on unfolded centromere chromatin fibres by PALM Microscopy. This system represents a unique and reliable model to visualize at high resolution how CENPs and epigenetic histone marks change either in composition and distribution along the chromatin fibre following the deletion of different CCAN components.

1906

**Understanding the architecture of vertebrate kinetochores using quantitative proteomics.**

*L. Wood<sup>1</sup>, S. Ohta<sup>2</sup>, K. Samejima<sup>1</sup>, T. Fukagawa<sup>3</sup>, J. Rappsilber<sup>1</sup>, W. Earnshaw<sup>1</sup>; <sup>1</sup>Wellcome Trust Centre for Cell Biology, University of Edinburgh, Edinburgh, UK, <sup>2</sup>Center for Innovative and Translational Medicine, Kochi University, Kochi, Japan, <sup>3</sup>Department of Molecular Genetics, National Institute of Genetics and The Graduate University for Advanced Studies, Mishima, Japan*

When cells divide, a series of events must proceed in a timely and co-ordinated manner to ensure that all DNA is replicated and partitioned equally amongst the two daughter cells. A central component of this process is the kinetochore, a large proteinaceous complex found within the centromere of all mitotic chromosomes. Despite the fact that many kinetochore components are conserved from yeast to human and that these sub-complexes are functionally well studied, the way these components come together to form a fully operational kinetochore is still poorly understood.

Recently, chromosome isolation techniques from chicken DT40 cells, combined with stable isotope labeling by amino acids in cell culture (SILAC), were used to define all chromosome associated proteins. Applying the same method we here compare the proteome of mitotic chromosomes isolated from different kinetochore knockout (KO) cell lines. This includes components of the inner kinetochore; CENP-C, CENP-T and CENP-W, and a sub-unit of the Ndc80 complex important for microtubule attachment. With these large data sets we have focused on the impact these depletions have on the architecture of the holo-kinetochore by measuring the SILAC ratios of individual proteins. We have found that proteins within the same complex typically behave in a similar manner across the different KO conditions. Multivariate data analysis reveals dependency pathways, as well as highlighting potential novel kinetochore proteins worthy of further study.

The KO cell lines listed above all exploit the doxycycline inducible shut-down of gene expression that has proven to be a highly valued system in the study of many cellular processes. However, although gene expression is abolished immediately, full loss of function requires that proteins translated before drug addition are degraded. Depending on protein stability, this can take hours, or even days, and lead to the accumulation of unwanted secondary effects. To address this problem, we are using an auxin-inducible degron (AID) system to rapidly reduce the expression of kinetochore sub-units at the protein level. We find that AID-tagged CENP-T in DT40 cells is rapidly depleted within 1 hour of auxin addition, immediately preventing further proliferation. Importantly, this gives us a unique opportunity to study the effects and phenotypes of CENP-T depletion in a highly regulated way at different phases of the cell cycle.

1907

**Systematic analysis of kinetochore assembly and disassembly in human cells.**

*K. E. Gascoigne<sup>1</sup>, I. M. Cheeseman<sup>1</sup>; <sup>1</sup>Whitehead Institute for Biomedical Research, Cambridge, MA*

Accurate chromosome segregation requires assembly of the multi-protein kinetochore complex. Prior work has identified over 100 kinetochore components in human cells. However, little is known about the regulatory processes that specify their assembly upon mitotic entry, or that control the disassembly of the complex at mitotic exit. Previously, we have identified two parallel pathways for kinetochore assembly involving the constitutive centromere proteins CENP-T and CENP-C. Here we demonstrate that multiple regulatory mechanisms converge on these

pathways to control outer kinetochore assembly. Using a live-cell imaging based assay to map kinetochore assembly dynamics, we systematically assess the role of potential regulatory mechanisms in timely kinetochore assembly. We find that kinetochore assembly and disassembly is primarily controlled by the coordinated mitotic phosphorylation of key kinetochore proteins by Cyclin B1/Cdk1. In addition, we find that the subcellular localization of key kinetochore proteins prior to mitosis is important for timely kinetochore formation. In total, we find that the coordinated temporal regulation of parallel kinetochore assembly pathways is essential for accurate cell division.

1908

**Phosphorylation of Zwilch by MPS-1 Is Required for Recruitment of the Fibrous Corona.**

A. Z. Raja<sup>1</sup>, J. M. Kasuboski<sup>1</sup>, P. S. Vaughan<sup>1</sup>, K. T. Vaughan<sup>1</sup>; <sup>1</sup>Biological Science, University of Notre Dame, Notre Dame, IN

Kinetochores are robust protein scaffolds at centromeres that link chromosomes to the mitotic spindle and mediate chromosome movement. Kinetochores are also responsible for generating diffusible signals that inhibit anaphase onset until the successful completion of chromosome alignment. The Vaughan laboratory has deciphered the basis of checkpoint silencing at metaphase focusing on regulation of dynein and dynein-associated proteins at the kinetochore. Ongoing studies reveal that the Rod-Zw10-Zwilch (RZZ) complex is central to both checkpoint signaling and the recruitment of microtubule (MT) binding proteins required for chromosome movement (Kasuboski et al., 2011). The RZZ complex functions as a platform for assembly of the outer layers of the kinetochore and the fibrous corona, including molecules responsible for microtubule binding, chromosome movement and checkpoint signaling. Monopolar spindle-1 (MPS-1) kinase has been linked to recruitment of the SAC components, Mad2, Bub1, Bub3, Mad1 and BubR1/Mad3 to kinetochores (Hardwick et al., 1996; Abrieu et al., 2001; Vigneron et al., 2004; Wong and Fang, 2005). Although MPS-1 has been identified as a critical mitotic kinase, the complete list of substrates is not known. Inhibition of MPS-1 with reversine perturbed recruitment of the fibrous corona, affecting dynein, dynactin, the RZZ complex, spindly, BubR1 and Mad2 but not Zwint-1 or Hec1. We used in vitro kinase assays to identify candidate substrates and identified Zwilch but not Zw10 as a novel substrate for MPS1. LC/MS/MS analysis of phosphorylated Zwilch revealed 3 novel phosphorylation sites. A triple-A (3A) mutant of Zwilch localized to kinetochores and induced defects similar to MPS1 inhibition. 3A-Zwilch expression led to a loss of dynein, dynactin, spindly and anaphase inhibitors from kinetochores. We also observed defects in mitotic progression including the “frozen” phenotype during prometaphase and premature anaphase onset. These studies suggest that MPS1 phosphorylation of Zwilch is required for assembly of the fibrous corona and proper coordination of checkpoint signaling with chromosome alignment.

1909

**The role of CLASP2 phosphorylation at the kinetochore-microtubule interface.**

H. Pemble<sup>1</sup>, K. Jaqamar<sup>2</sup>, P. Kumar<sup>1</sup>, A. Schönichen<sup>1</sup>, T. Wittmann<sup>1</sup>; <sup>1</sup>UCSF, San Francisco, CA, <sup>2</sup>Harvard University, Boston, MA

Accurate chromosome segregation is essential for the faithful distribution of the genetic material during cell division. Microtubules attach to chromosomes through the kinetochore, and facilitate metaphase chromosome alignment and anaphase chromosome segregation. During these processes, chromosomes undergo drastic movements yet remain attached to kinetochore microtubules. Therefore, the plus-ends of kinetochore microtubules must remain dynamic and the kinetochore-microtubule attachment has to be precisely regulated. Although an extensive list

of kinetochore components has been identified, the mechanism by which kinetochores regulate their attachments to dynamic microtubules is incompletely understood. CLASPs are proteins that associate with growing microtubule plus-ends and stabilize microtubules in the periphery of interphase cells. During mitosis, CLASPs localize to kinetochores and are thought to mediate microtubule polymerization at the kinetochore. We have found that CLASP2 is hyperphosphorylated during mitosis by Glycogen Synthase Kinase 3 beta (GSK3 $\beta$ ) on serine residues within its plus-end tracking domain. GSK3 $\beta$ -mediated phosphorylation is dependent on priming phosphorylation of CLASP2 by cyclin-dependent kinases, and completely disrupts CLASP2-microtubule interaction during mitosis. Expression of non-phosphorylatable CLASP2, in which either all phosphorylation sites or only CDK priming sites are replaced with alanine residues, restores CLASP2 microtubule plus-end tracking during mitosis. Because phosphorylated CLASP2 does not bind microtubules in mitotic cells, we hypothesize that CLASP2 phosphorylation is tightly controlled at the kinetochore to regulate kinetochore-microtubule interactions. To test this hypothesis, we are analyzing how non-phosphorylatable and phospho-mimetic CLASP2 constructs affect mitosis and kinetochore dynamics. HaCaT keratinocytes depleted of CLASP2 by lentivirus-mediated shRNA exhibit characteristic chromosome congression and spindle orientation defects. While expression of EGFP-tagged wildtype CLASP2 can partially rescue mitotic defects of CLASP2 knockdown cells, non-phosphorylatable and phospho-mimetic versions of CLASP2 cannot. This indicates that proper phosphoregulation of CLASP2 is required for normal mitosis. We are currently using 3D imaging of CENPA-mCherry labeled kinetochores in combination with advanced computational analysis of kinetochore dynamics to determine how CLASP2 phosphorylation controls kinetochore and spindle dynamics.

1910

**Linker-scanning mutagenesis of the Ndc80 kinetochore protein.**

J. Tien<sup>1</sup>, K. Fong<sup>1</sup>, N. Umbreit<sup>1</sup>, C. Payer<sup>2</sup>, A. Zelter<sup>1</sup>, M. Dunham<sup>2</sup>, T. Davis<sup>1</sup>; <sup>1</sup>Biochemistry, University of Washington, Seattle, WA, <sup>2</sup>Genome Sciences, University of Washington, Seattle, WA

During chromosome segregation, kinetochores physically link centromeric DNA to spindle microtubules. This linkage requires the Ndc80 complex, an essential and conserved kinetochore component. The complex features globular domains on both ends, and a long coiled coil in between. At the N-terminus, the Ndc80 protein contains a microtubule-binding calponin-homology domain. The remainder of Ndc80, most of which is predicted to form a coiled coil, remains uncharacterized. We performed a saturated linker-scanning mutagenesis screen to identify the essential regions of the budding yeast Ndc80 protein. Using an *in vitro* transposition system, a library of ~11,000 insertion events was generated in a plasmid carrying the *NDC80* gene and screened for function *in vivo*. We found that ~4% of insertions were lethal. Illumina sequencing was used to map these lethal insertions. Combining linker-scanning mutagenesis with high throughput sequencing provided a powerful way to identify new functionally important regions of Ndc80. The insertions clustered in five distinct locations within Ndc80. Two clusters are in the calponin-homology domain, and three clusters are in the coiled coil domain. The only proposed function of the latter is to mediate tetramerization of Ndc80 complex components. However, the lethal insertions in the coiled coil domain do not disrupt assembly of the purified recombinant complex. Therefore, linker scanning identified functionally essential regions of the coiled coil that are not involved in complex assembly.

1911

**The Ndc80 kinetochore complex directly modulates microtubule dynamics.**

N. T. Umbreit<sup>1</sup>, D. R. Gestaut<sup>1</sup>, J. F. Tien<sup>1</sup>, B. S. Vollmar<sup>1</sup>, T. Goner<sup>2</sup>, C. L. Asbury<sup>3</sup>, T. N. Davis<sup>1</sup>; <sup>1</sup>Biochemistry, University of Washington, Seattle, WA, <sup>2</sup>Janelia Farm Research Campus, Howard Hughes Medical Institute, Ashburn, VA, <sup>3</sup>Physiology and Biophysics, University of Washington, Seattle, WA

The conserved Ndc80 complex is an essential microtubule-binding component of the kinetochore. Recent findings suggest that the Ndc80 complex influences microtubule dynamics at kinetochores *in vivo*. However, it was unclear if the Ndc80 complex mediates these effects directly, or by affecting other factors localized at the kinetochore. Using a reconstituted system *in vitro*, we show that the human Ndc80 complex directly stabilizes the tips of disassembling microtubules and promotes rescue (the transition from microtubule shortening to growth). *In vivo*, an N-terminal domain in the Ndc80 complex is phosphorylated by the Aurora B kinase. Mutations that mimic phosphorylation of the Ndc80 complex prevent stable kinetochore-microtubule attachment, while mutations that block phosphorylation damp kinetochore oscillations. We find that Ndc80 complex with Aurora B phosphomimetic mutations is defective at promoting microtubule rescue, even while robustly coupled to disassembling microtubule tips. This impaired ability to affect dynamics is not simply due to weakened microtubule binding, as an N-terminally truncated complex with similar binding affinity is able to promote rescue. Together, these results suggest that in addition to regulating attachment stability, Aurora B controls microtubule dynamics through phosphorylation of the Ndc80 complex.

1912

**Microtubule-end bound complexes power chromosome movement during chromosome segregation.**

N. Tamura<sup>1</sup>, R. L. Shrestha<sup>1</sup>, V. M. Draviam<sup>1</sup>; <sup>1</sup>Genetics, University of Cambridge, Cambridge, UK

During mitosis, the microtubule plus-ends play an important role in rapidly capturing subcellular organelles and precisely powering their movements. However, microtubule-end bound protein complexes in mitotic cells are not well characterised, limiting our understanding of molecular mechanisms that control microtubule powered organelle movement. Using a combination of inhibitor treatment, immunoprecipitation and mass spectrometry, we have identified protein complexes that interact with the autonomous plus-end binding protein, EB1 in mitotic cells. This first effort has revealed nearly 15 different protein interactors of EB1 in distinct stages of mitosis, including previously known kinetochore - and cortex- bound proteins. To learn about how plus-end complexes power organelle movement, we used a high-throughput imaging assay to identify those plus-end bound proteins that are essential for attaching chromosomes to microtubule ends but not microtubule walls. Plus-end binding proteins important for end-on attachment interact with several members of the KMN network of outer kinetochore proteins and EB1 directly, as revealed by our yeast two-hybrid interaction studies. We are now investigating the mechanisms that control the interactions between protein domains of EB1 interactors and the KMN network to understand how plus-end complexes are loaded and unloaded at the kinetochore to ensure precise control over chromosome movements.

1913

**The KMN network makes major conformational changes with kinetochore microtubule formation not exhibited by other outer domain proteins like RZZ and CENP-F.**

A. Suzuki<sup>1</sup>, X. Wan<sup>1</sup>, E. D. Salmon<sup>1</sup>; <sup>1</sup>Biology, UNC at Chapel Hill, Chapel Hill, NC

Faithful chromosome segregation is important for maintenance of life in all organisms. Kinetochores, assembled at the periphery of centromeres attach chromosomes to the plus ends of spindle microtubules (MTs) to form kinetochore microtubules (kMTs). At metaphase, human kinetochores become attached on average to ~20 kMTs when their chromosomes are properly aligned at the spindle equator. The KMN network of outer kinetochore proteins (KNL1 (Blinkin) complex, Mis12 complex and Ndc80(hsHEC1)) complex are required for robust kMT attachment and control of the spindle assembly checkpoint that governs entry into anaphase. Previous studies have determined the average protein architecture of the KMN network at metaphase human kinetochores, but information is critically needed for unattached kinetochores to understand how the kMT attachment sites are formed.

We have developed a chromosome spin-down assay for nocodazole treated HeLa cells that frequently orients sister chromosome pairs side-by-side on the surface of coverslips. This orientation enhances enormously the accuracy and speed for analysis of the protein architecture of unattached human kinetochores by our K-SHREC fluorescence microscopy method. Measurements of the average separation of red and green fluorescent labels along the sister-sister kinetochore axis were made at nm scale accuracy as described by Wan et al., 2009, Cell.

We find a major change in the conformation of the KMN network of proteins between unattached kinetochores and kinetochores with a full complement of kinetochore microtubules at metaphase. The end-to end separation for the Ndc80 complex and KNL1 (Blinkin) complex are much shorter within unattached kinetochores compared to their separations along kMTs at normal metaphase. However, the average positions of outer kinetochore components, such as CENP-E, CENP-F, and RZZ complex, do not change between both conditions.

These conformational changes indicate that interactions of unattached prometaphase kinetochores with the plus ends of spindle microtubules is important for the self-assembly of metaphase kMT attachment sites. The conformational changes are also likely important for preventing errors in kMT attachment and for controlling the spindle assembly checkpoint. Our measurements also address issues about how the KMN network is linked to chromosomes by members of the Constitutive Centromere Associated Proteins (CCANs), like CENP-T.

1914

**Location of the Mad1/Mad2 Complex, Zwint1, the Rod/Zw10/Zwilch (RZZ) Complex, and the Dynein Motor Recruitment Factor Spindly Within the Substructure of the Kinetochore.**

D. Varma<sup>1</sup>, X. Wan<sup>1</sup>, R. Gassmann<sup>2</sup>, J. Lawrimore<sup>1</sup>, A. Desai<sup>3</sup>, E. D. Salmon<sup>1</sup>; <sup>1</sup>Biology, UNC-Chapel Hill, Chapel Hill, NC, <sup>2</sup>Institute for Molecular and Cell Biology, Porto, Portugal, <sup>3</sup>Cellular and Molecular Medicine, University of California, San Diego, La Jolla, CA

Zwint1, the Rod/Zwilch/Zw10 (RZZ) complex, the Mad1/Mad2 complex, Spindly, and the Dynactin/Dynein motor all localize to kinetochores where they play a major role in the spindle assembly checkpoint (SAC) and kinetochore microtubule (kMT) attachment. An important unresolved question is how these components integrate into the core kMT attachment site comprised of Knl1 (Blinkin), the Ndc80 (Hec1) complex, and the Mis12 complex. We have used high-resolution two-color fluorescence light microscopy at the nm scale (Delta analysis) to map the average positions of these components within metaphase kinetochores after uncoupling the dynein-dynactin complex from Spindly to prevent their removal during SAC inactivation. Relative to the Hec1 CH domain: the Mad2-binding region of Mad1 and the C-terminus of Zw10 are

located ~35 nm internal (i.e. closer to centromeric chromatin) and very close to the measured loci for Knl1 N-terminus; and the N-terminus of Rod, Zwilch, and the N-terminus of Zw10 are ~10 nm internal. The Zw10 interactor Zwint1 is located ~50 nm internal to the Hec1 CH domain and in close proximity to the C-terminus of Knl1. The C-terminus of Spindly is located near the Hec1 CH domain while its N-terminus is about 70 nm outside the outer end of the Ndc80 complex and within the coronal domain of the kinetochore. Our measurements suggest that the checkpoint protein module is closely juxtaposed with Mis12, the Ndc80 complex and Knl1 in these metaphase-arrested cells. Depletion of Zwint1 by RNAi reduced RZZ and Mad1 kinetochore localization by 60 & 40% respectively, while depletion of Knl1 abolished RZZ, Mad1 and Zwint1 kinetochore localization at kinetochores of nocodazole-treated cells. Zwint1 depletion reduced Knl1 kinetochore localization by 60%, suggesting a co-dependence between these tightly complexed proteins, which may explain the intermediate effect of Zwint1 depletion on RZZ and Mad1 localization. These results establish how checkpoint complexes are positioned relative to components of the core kMT attachment site. Consistent with the observation that Zwint1 forms a tight complex with Knl1, our results also suggest that the Knl1-Zwint1 complex, rather than Zwint1 by itself, recruits RZZ and the Mad1/Mad2 complex to kinetochores.

1915

#### **A structural basis for kinetochore recruitment of the Ndc80 complex via two distinct centromere receptors.**

*F. Malvezzi<sup>1</sup>, G. Litos<sup>1</sup>, A. Schleiffer<sup>1</sup>, A. Heuck<sup>1</sup>, T. Clausen<sup>1</sup>, S. Westermann<sup>1</sup>; <sup>1</sup>Research Institute of Molecular Pathology, Vienna, Austria*

The Ndc80 complex, composed of Ndc80, Nuf2, Spc24 and Spc25 subunits, is the key microtubule-binding element of the kinetochore. In contrast to the well-characterized interaction of Ndc80/Nuf2 heads with microtubules, little is known about how the Spc24-25 heterodimer connects to centromeric chromatin. Here we present the crystal structure of Spc24-Spc25 in complex with the histone-fold protein Cnn1/CENP-T illustrating how this interface ultimately links microtubules to chromosomes. The conserved Ndc80 receptor motif of Cnn1 is bound as an alpha-helix in a hydrophobic cleft at the interface between Spc24 and Spc25. Interestingly, point mutations that disrupt the Ndc80-Cnn1 interaction are lethal in yeast, though Cnn1 is a non-essential gene. We demonstrate that the same mutations in Spc24-25 abrogate the interaction with the essential Mtw1 complex, and we identify a Cnn1-related binding motif in its Dsn1 subunit. Phosphorylation of the Cnn1 N-terminal domain serves to coordinate the Ndc80 interaction with two competing binding partners. Together our data reveal a modular kinetochore architecture, in which Ndc80 complexes connect to distinct interaction partners through a common interface.

1916

#### **CENP-A at human centromeres and neocentromeres forms octameric nucleosomes with loose superhelical termini.**

*K. J. Salimian<sup>1</sup>, T. Panchenko<sup>1</sup>, D. Hassor<sup>2</sup>, M. U. Salman<sup>1</sup>, P. E. Warburton<sup>2</sup>, B. E. Black<sup>1</sup>;  
<sup>1</sup>Department of Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA,  
<sup>2</sup>Department of Genetics and Genomics Sciences, Mt. Sinai School of Medicine, New York, NY*

The centromere is the chromosomal locus that serves as the site of kinetochore formation and spindle microtubule attachment in mitosis. Centromere protein A (CENP-A) is a histone H3 variant that epigenetically specifies centromere location. Conflicting evidence has emerged regarding the histone composition and stoichiometry of CENP-A nucleosomes, as well as the

handedness of DNA that wraps them. While we have proposed that these disparate models might be reconciled by a cell cycle-coupled program of centromeric nucleosome maturation, the predominant form of the CENP-A nucleosome remains controversial. Indeed, two very recent microscopy-based studies (Bui et al., 2012, *Cell* 150:317-326; Shivaraju et al., 2012, *Cell* 150:306-316) propose that CENP-A exists in half-nucleosomes or 'hemisomes' (i.e. one copy each of CENP-A, H4, H2A, and H2B) for the majority of the cell cycle. We have developed novel genomic analysis tools that we marry to existing massively parallel paired-end, long-read DNA sequencing technology to probe CENP-A nucleosome structure at centromeres. Using this approach in patient-derived cells harboring a neocentromere—a newly arisen functional centromere—we simultaneously identify the length and complete sequence reads of nucleosome positions at base pair resolution on normal repetitive centromere DNA and the unique sequences underlying neocentromeres. Unlike bulk nucleosomes from the same preparations that predominantly protect a single peak size (~150 bp) from nuclease digestion, CENP-A nucleosomes occupy two major peak sizes (~130 and ~110 bp) and a minor peak (~150 bp). Each peak is substantially longer than what could be protected by a hemisome or any other tetramer of histones (i.e. protection of ~60-80 bp from nuclease digestion). Further, the prominent position on centromeric DNA of the 110 bp peak is internal to the most prominent position of the 130 bp peak, indicating a stable, protected nucleosome core with loose termini. Strikingly, pure, reconstituted octameric CENP-A nucleosomes yield similarly sized terminally digested DNA fragments under conditions where their canonical H3-containing counterparts protected ~150 bp of nucleosomal DNA. Our findings indicate that the fundamental unit of functional centromeric chromatin is an octameric nucleosome with loose termini.

1917

**The kinetochore protein CENP-Q directs chromosome movement by controlling microtubule dynamics.**

*J. M. Bancroft<sup>1</sup>, C. P. Samora<sup>1</sup>, A. D. McAinsh<sup>1</sup>; <sup>1</sup>Centre For Mechanochemical Cell Biology, University of Warwick, Coventry, United Kingdom*

During mitosis the faithful alignment of chromosomes to the metaphase plate and their segregation during anaphase are crucial to ensure accurate partitioning of genetic material into the two daughter cells. These processes are mediated by the kinetochores, protein complexes that assemble at the centromere of each chromatid providing an attachment site for bundles of spindle microtubules (k-fibers) as well as driving chromosome movement. Here we show that the kinetochore protein CENP-Q, a subunit of the CCAN, is required for normal kinetochore movement during mitosis. Depletion of CENP-Q by siRNA results in chromosome congression defects with a polar chromosome population and a pronounced mitotic delay. High temporal and spatial resolution imaging of kinetochores revealed that normal oscillatory dynamics are perturbed in CENP-Q depleted cells, as was the ability of these kinetochores to make possessive movements in one direction. Kinetochore movements are largely powered by microtubule dynamics and our previous work has shown that CENP-Q is able to bind microtubules (Amaro et al., *Nat. Cell. Biol.*, 12: 319-29, 2010). We find that depletion of CENP-Q increases the number of kinetochore-bound microtubules, reduces their rate of turnover but decreases their attachment stability. Using in vitro reconstitution we find that purified CENP-Q directly modulates microtubule dynamics. We propose that CENP-Q directly controls kinetochore-microtubule dynamics to promote chromosome congression during mitosis.

1918

### Deformations within Moving Kinetochores Reveal Different Sites of Active and Passive Force Generation.

S. Dumont<sup>1</sup>, T. Salmon<sup>2</sup>, T. Mitchison<sup>3</sup>; <sup>1</sup>UCSF, San Francisco, CA, <sup>2</sup>UNC Chapel Hill, Chapel Hill, NC, <sup>3</sup>Harvard Medical School, Boston, MA

Kinetochores mediate chromosome segregation at mitosis. They are thought to contain both active, force-producing and passive, frictional interfaces with microtubules whose relative locations have been unclear. We inferred mechanical deformation within single kinetochores during metaphase oscillations by measuring average separations between fluorescently labeled kinetochore subunits in living cells undergoing mitosis. Inter-subunit distances were shorter in kinetochores moving toward poles than those moving away. Inter-subunit separation decreased abruptly when kinetochores switched to poleward movement, and decreased further when pulling force increased, suggesting that active force generation during poleward movement compresses kinetochores. The data revealed an active force-generating interface within kinetochores, and a separate passive frictional interface located at least 20 nm away poleward. Together, these interfaces allow persistent attachment with intermittent active force generation.

1919

### A New Fidelity Mechanism Operating at the Kinetochore During Chromosome Segregation.

D. K. Cheerambathur<sup>1</sup>, K. Oegema<sup>1</sup>, A. Desai<sup>1</sup>; <sup>1</sup>Ludwig Institute of Cancer Research, Ludwig Institute of Cancer Research, La Jolla, CA

Fidelity of chromosome segregation requires the spindle checkpoint, which senses unattached kinetochores, and Aurora B kinase, which detects and corrects attachment errors. Here, we describe a new fidelity mechanism mediated by direct crosstalk between the dynein motor module and the Ndc80 complex at the kinetochore. We show that the core microtubule-binding activity of the kinetochore, resident in the Ndc80 complex is inhibited by removal of dynein from the kinetochore. Prior work had proposed that Rod/Zwilch/Zw10 (RZZ) complex, which recruits dynein, is responsible for this inhibition and transiently regulates the core microtubule attachment made by the Ndc80 complex in early mitosis. We have identified Ndc80 complex variants that are resistant to RZZ-mediated inhibition *in vivo*, employing a single copy transgene insertion system in the *C. elegans* embryo. Mutation of 4 Aurora B sites in the basic N-terminal tail of Ndc80 did not affect regulation by RZZ *in vivo*. In contrast, deletion of the Ndc80 tail eliminated RZZ-mediated regulation even though it did not affect load-bearing attachment formation or lead to visible missegregation in the one-cell embryo. The Ndc80 tail deletion, but not the Aurora B site mutant, was compromised for viability and displayed a phenotypic spectrum consistent with reduced fidelity of chromosome segregation. Biochemical and yeast two-hybrid analysis revealed a direct interaction between the Rod subunit of RZZ and Ndc80 that is dependent on the basic tail of Ndc80. Taken together, these findings suggest that RZZ directly interacts with Ndc80 at the kinetochore in an Ndc80 tail-dependent manner to hold the microtubule-binding activity of the Ndc80 complex in check until a dynein-dependent reaction turns off this inhibition. We propose that this regulation, which is distinct from the spindle checkpoint and Aurora B kinase-mediated error correction, acts as a mechanical fidelity mechanism, ensuring the proper hand-off from dynein-mediated initial capture to Ndc80-mediated stable end-on attachments during chromosome segregation.

**Spatial contribution of chromatin and kinetochores to microtubule nucleation and meiotic spindle assembly *in vitro*.**

K. Tamawska<sup>1</sup>, F. Nedelec<sup>1</sup>; <sup>1</sup>EMBL, Heidelberg, Germany

We can distinguish two important regions on chromosomes taking part in microtubule (MT) nucleation: the chromosome arms (chromatin) and kinetochores. These two areas send two different signals to trigger MT nucleation. It's been recently shown that kinetochores play a larger role in the chromosome-mediated nucleation pathway of mitotic spindle assembly compared with chromatin in centrosomes ablated cells. Importantly, *Xenopus laevis* eggs lack centrosomes and therefore, egg extract serves as a perfect system for investigating chromatin-mediated spindle formation. The RanGTP gradient created by RCC1 localization on chromosome arms is sufficient for MT nucleation and spindle assembly. However spindles can assemble in *Xenopus* egg extract also in the absence of RanGTP gradient, but in that case they form around sperm nuclei and not around chromatin-coated beads indicating that kinetochores are required. Recent work further showed that kinetochore signaling involves Aurora B kinase, a part of the Chromosomal Passenger Complex (CPC). For precise analysis of signaling pathways involved in chromosome-mediated MT nucleation we physically separate different signals that are normally overlapping in living cells. Using RCC1 coated beads and CPC coated beads in our *in vitro* spindle array we can discriminate the specific contribution of the two signaling pathway for MT nucleation, the temporal order and importance of each one of them.

**Investigating the structural and mechanical properties of the kinetochore by combining laser microsurgery and confocal microscopy.**

E. Roscioli<sup>1</sup>, G. Cojoc<sup>2</sup>, L. Zhang<sup>3</sup>, J. Gregan<sup>3</sup>, I. M. Tolić-Nørrelykke<sup>2</sup>, D. Cimini<sup>1</sup>; <sup>1</sup>Biological Sciences, Virginia Tech, Blacksburg, VA, <sup>2</sup>Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, <sup>3</sup>Max F. Perutz Laboratories, University of Vienna, Vienna, Austria

Accurate chromosome segregation during cell division ensures equal partitioning of the genome, and depends on proper attachment of microtubules (MTs) to kinetochores (KTs). The KT is a multidomain, multi-layer structure that assembles during mitosis to create the MT-binding sites on the centromere, thus playing a key role in ensuring accurate chromosome segregation. Although mounting evidence suggests that the mechanical properties of KT may contribute to faithful chromosome segregation, an in-depth characterization of such properties is still lacking. In the present study, we used merotelic KT as a tool to investigate the biophysical properties of the vertebrate KT, with particular focus on its plastic and elastic properties. Merotelic KT are bound to MTs emanating from opposite spindle poles, and during anaphase, they lag behind at the spindle equator and become stretched due to pulling forces exerted by MTs emanating from the two spindle poles. To study the elasto-plastic properties of the KT, we used PtK1 cells stably expressing GFP-tagged Hec1 (outer KT component), in which we promoted the formation of merotelic KT using a nocodazole-washout protocol. We then microinjected X-rhodamine-labeled tubulin to visualize the KT fibers in cells that displayed merotelically attached anaphase lagging chromosomes. Finally, we performed laser ablation on one of the two MT bundles attached to the merotelic KT, and analyzed the changes in KT size/stretching upon release of the pulling forces from one side. We found that stretched KT progressively shortened after MT severing with a very significant decrease in length immediately following the ablation, after which a majority of KT continued to progressively and slowly shorten over time, whereas for a smaller fraction of KT the shortening seemed to arrest after the change that immediately followed the ablation. Preliminary observations also indicate that

none of the KT's shortened enough to regain the size of un-stretched KT's, suggesting that the outer KT displays both elastic and plastic properties. Future experiments will be performed to investigate the behavior, and thus the biophysical properties, of different KT domains (e.g., inner vs. outer KT), with the aim of unveiling the biophysical properties of the KT and its subdomains.

### The role of KIF4A in microtubule organization and midbody formation

D. G. Booth<sup>1</sup>, K. Samejima<sup>1</sup>, W. Earnshaw<sup>1</sup>;

<sup>1</sup>Wellcome Trust Centre, Edinburgh University, Edinburgh, Scotland

The spindle is a microtubule-based machine used for the segregation of chromosomes into two daughter cells. During anaphase and through to cytokinesis, anti-parallel microtubules of the spindle midzone undergo radical repositioning, from relatively loosely associated, individual microtubules, into a highly organized and compact midbody. The midbody acts as a docking site for numerous proteins essential for the finale of cell division, abscission. Midbody formation is orchestrated by the recruitment of several key midbody components in a spatio-temporal dependant manner.

KIF4A is a plus-end directed kinesin motor protein with a dynamic localization pattern: It is nuclear (during interphase), and during mitosis it localizes to the chromosome axes, midzone microtubules and midbody. Previous studies have revealed functions for KIF4A in chromosome condensation, chromosome segregation and spindle organization. The purpose of this study was to further characterize the role of KIF4A during late mitosis and cytokinesis.

We have established a KIF4A conditional knockout in chicken DT40 cells, where expression of KIF4A is rapidly suppressed through the addition of doxycycline to culture media. Using both fluorescence and correlative light electron microscopy (CLEM) we have analyzed KIF4A depleted cells, in which frequent abscission failure was observed. It is likely that this phenotype was a result of several other defects identified, including: an abnormal spindle length, mis-localization of other midbody proteins and a loss of midbody microtubule organization. These results begin to further define the role for KIF4A in the regulation of midzone and midbody microtubule organization and dynamics.

1923

### Behavior of Sister vs. Non-Sister Pericentric Chromatin Reveals Motor and Chromatin Cross-linking in the Spindle.

A. D. Stephens<sup>1</sup>, C. E. Snider<sup>1</sup>, J. Haase<sup>1</sup>, R. A. Haggerty<sup>1</sup>, K. Bloom<sup>1</sup>; <sup>1</sup>Department of Biology, University of North Carolina - Chapel Hill, Chapel Hill, NC

In the mitotic spindle apparatus, spindle microtubules exert an extensional force pulling sister chromatids towards opposite poles while the pericentric chromatin, chromatin proximal to the microtubule attachment site, resists with contractile spring-like properties. Tension generated from these opposing forces silences the checkpoint giving way to segregation. However, it is unknown how the cell senses tension across multiple attachment sites bound to microtubules with stochastic dynamics. In budding yeast, there is one microtubule attachment site per chromosome. Using this model system we label the pericentric chromatin on two different chromosomes using LacO/LacI and TetO/TetR. Non-sister attachment sites on the same side of

the spindle display coordinated motion dynamics relative to the spindle pole whereas sisters are not coordinated. Pericentromere stretching occurs rarely in wild-type cells, visualized as LacO/LacI-GFP transitioning from a focus into a line signal. Pericentromere stretching is also coordinated between different chromosomes (non-sisters) while sisters show no coordinated stretching. The coordinated motion and stretching is dependent on the kinesin 5 motor, Cin8. In addition, coordinated stretching is also dependent on the chromatin-linking complex cohesin. Both the cross-linking of microtubules by motors and chromosomes by cohesin function to coordinate motion in the mitotic spindle.

**RanBP2 interacts with Karyopherin beta1 to orchestrate accurate chromosome segregation in mitosis.**

*C. Hashizume<sup>1</sup>, R. W. Wong<sup>1</sup>; <sup>1</sup>Laboratory of Molecular and Cellular Biology, Department of Biology, School of Natural System, Institute of Science and Engineering, Kanazawa University, Kanazawa, Japan*

Cancer cells often display perturbed chromosome segregation and disorganized mitotic spindles during cell division. Several nuclear pore proteins, including RanBP2/Nup358, are often abnormally expressed in cancers. Recent studies indicate a link between RanBP2/Nup358 and chromosome segregation during mitosis; however, the molecular details underlying this dynamic process remain unknown. Here we report a novel interaction between RanBP2/Nup358 and karyopherin beta/importin-beta that functions synergistically in the control of dynamic chromosome segregation. We found that RanBP2/Nup358 directly interacts with the N-terminal of karyopherin beta1 and that karyopherin beta1 binds to the Ran-binding domain (RBD) to zinc finger motif region of RanBP2/Nup358. Observed through live cell imaging, RNA interference-mediated knockdown of RanBP2/Nup358 caused a severe chromosome mis-segregation phenotype and disrupted karyopherin beta1 expression and localization. On the other hand, karyopherin beta1 RNAi also disrupted Nup358/RanBP2 localization and RanGAP1 sumoylation. Notably, we performed a series of rescue and dominant negative experiments to further confirm that the RanBP2-RAN GAP1-karyopherin beta1-RAN subcomplexes orchestrate proper chromosome segregation.

1925

**Removal of antagonistic spindle forces can rescue metaphase spindle length and reduce chromosome segregation defects.**

*V. Sirovatkina<sup>1</sup>, C. Fu<sup>1,2</sup>, P. Tran<sup>1,3</sup>; <sup>1</sup>Cell & Developmental Biology, University of Pennsylvania, Philadelphia, PA, <sup>2</sup>Department of Biochemistry, University of Hong Kong, Hong Kong, Hong Kong, <sup>3</sup>Institut Curie, Paris, France*

Metaphase describes a phase of mitosis where chromosomes are attached and oriented on the bipolar spindle for subsequent segregation at anaphase. In diverse cell types, the metaphase spindle is maintained at a relatively constant length. Metaphase spindle length is proposed to be regulated by a balance of pushing and pulling forces generated by distinct sets of spindle microtubules and their interactions with motors and microtubule-associated proteins (MAPs). Spindle length appears important for chromosome segregation fidelity, as cells with shorter or longer than normal metaphase spindles, generated through deletion or inhibition of individual mitotic motors or MAPs, showed chromosome segregation defects. To test the force balance model of spindle length control and its effect on chromosome segregation, we applied fast microfluidic temperature-control with live-cell imaging to monitor the effect of switching off different combinations of antagonistic forces in the fission yeast metaphase spindle. We show

that spindle midzone proteins kinesin-5 cut7p and microtubule bundler ase1p contribute to outward pushing forces, and spindle kinetochore proteins kinesin-8 klp5/6p and dam1p contribute to inward pulling forces. Removing these proteins individually led to aberrant metaphase spindle length and chromosome segregation defects. Removing these proteins in antagonistic combination rescued the defective spindle length and, in some combinations, also partially rescued chromosome segregation defects. Our results stress the importance of proper chromosome-to-microtubule attachment over spindle length regulation for proper chromosome segregation.

1926

#### **Characterization of mitotic defects in transformed cells.**

*J. A. Herman<sup>1</sup>, J. G. DeLuca<sup>1</sup>; <sup>1</sup>Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO*

Advances in techniques such as whole genome RNAi screening have led to the finding that cancer cells can become dependent on specific proteins that are non-essential to healthy cells. Interestingly, several such 'synthetically lethal' proteins have been identified that are specifically involved in mitotic cell division. This suggests that the cell cycle in cancer cells has been altered to result in fundamental changes in mitotic chromosome segregation when compared to normal cells. To understand these changes we have generated a set of cell lines that model different levels of the transformation process. Genetic changes were introduced stepwise to primary retinal pigment epithelial cells to create a spectrum of four cell lines that increase in tumor forming capacity. Specifically, cells were modified so that they accumulated specific traits associated with transformation including: (i) potential for infinite replication by expression of hTert, (ii) loss of contact inhibition and anchorage dependence by inhibiting tumor suppressor proteins, (iii) ability to stimulate proliferation pathways independent of environment by hyperactivating Ras. Using these cell lines, we demonstrate that as cells undergo the transformation process, errors in chromosome segregation are increased. In addition, cells decrease in their ability to generate normal kinetochore-microtubule attachments as they undergo transformation. Finally, using this system, we have determined that transformation alters the requirement or regulation of specific kinetochore proteins.

1927

#### **Mitotic Misregulation and Aging.**

*J. C. Macedo<sup>1,2</sup>, H. Maiato<sup>1,2</sup>, E. Logarinho<sup>1,2</sup>; <sup>1</sup>Chromosome Instability and Dynamics, IBMC-Instituto de Biologia Celular e Molecular, Porto-Portugal, Portugal, <sup>2</sup>Faculdade de Medicina da Universidade Porto, Porto, Portugal*

Cancer is primarily an age-related disease. How aging promotes late-life cancer remains largely unknown. Our working hypothesis is that cellular aging compromises mitotic fidelity leading to chromosomal instability. To address this issue we have ascertained the effect of both natural aging and replicative senescence (in vitro model of aging) in mitotic progression using long-term time-lapse phase contrast microscopy. We performed comparative analysis between dermal fibroblasts derived from neonatal, young-age and old-age humans and mice, as well as between low passage and high passage/senescent fibroblasts. We found a significant mitotic delay in both aged and replicative senescent adult fibroblasts. High resolution time-lapse microscopy of those fibroblasts indicated a prometaphase delay, which was shown to be dependent on the activation of the spindle assembly checkpoint (SAC). Consistently, fixed cell analysis revealed increased number of prometaphase cells with spindle defects and chromosome misalignment. Furthermore, we found a higher frequency of aneuploid and polyploid cell karyotypes. Our

working model is that by inducing chromosomal instability, aging might lead to potential loss of tumor suppressor pathways.

1928

**Chromosomes mis-segregated into micronuclei trigger chromosomal instability by further mis-segregating at subsequent mitoses.**

*B. He<sup>1</sup>, A. Hinman<sup>1</sup>, D. Cimini<sup>1</sup>; <sup>1</sup>Department of Biological Sciences, Virginia Tech, Blacksburg, VA*

A micronucleus (MN; plural MNi) is a small nucleus that emerges from a chromosome or chromosome fragment that fails to segregate into a daughter nucleus during cell division. The mitotic behavior of a chromosome or chromosome fragment enclosed in a MN is not clear. Here, we specifically focused on whole-chromosome MNi and investigated the behavior of such chromosomes (mnChrs) at the mitotic cell division following MN formation. To this end, we used PtK1 cells and experimentally induced anaphase lagging chromosomes, which are known to form MNi upon mitotic exit. The day following MN formation, many micronucleated cells underwent further mitotic division. High-resolution phase contrast time-lapse microscopy showed that 89% of dividing micronucleated cells exhibited chromosome segregation errors, including anaphase lagging chromosomes, unaligned chromosomes, and MN reformation. To investigate the contribution of mnChrs to such segregation errors, we used PtK1 cells expressing Photoactivatable GFP-histone H2B, and marked MNi in prophase cells, just before nuclear envelope breakdown. We found that the majority of micronucleated cells progressed into anaphase and segregated their chromosomes. However, the sister chromatids from mnChrs often failed to fully separate at anaphase and co-segregated to the same daughter cell. Moreover, most of the mnChrs formed new MNi in the daughter cells, suggesting that MNi can self-sustain. We also observed that many of the mnChrs were not fully condensed at the time of nuclear envelope breakdown. Accordingly, quantitative fluorescence microscopy showed histone H3 (Ser10) phosphorylation on most mnChrs was delayed compared to chromosomes in the main nucleus of the same prophase cells. Finally, we found that such under-condensed mnChrs could become trapped by the cleavage furrow causing furrow regression and cytokinesis failure. In conclusion, our work shows that although anaphase lagging chromosomes frequently segregate to the correct daughter cell, the MN that they form represents a severe threat to chromosomal stability at subsequent cell cycles.

1929

**Activation of p38 prevents proliferation in response to aneuploidy**

*S. L. Thompson<sup>1</sup>, S. S. Taylor<sup>1</sup>; <sup>1</sup>Faculty of Life Sciences, University of Manchester, Manchester, United Kingdom*

Most solid tumors are highly aneuploid and this abnormal number of chromosomes is generated by persistent loss and gain of chromosomes in a process called chromosomal instability. Research from the past few years has shown that normal, diploid cells arrest due to p53 stabilization following chromosome mis-segregation, preventing aneuploid cells from accumulating in healthy tissues. It remains unclear by what mechanism p53 is activated to prevent healthy diploid cells that have mis-segregated chromosomes from proliferating and how this is overcome in cancer cells. We sought to determine what occurs upstream of p53 to generate a cell cycle arrest following chromosome mis-segregation. Here we show that when we induce chromosome mis-segregation in otherwise diploid cells, we see activation of the p38 stress kinase pathway. Within 2 hours of inducing chromosome mis-segregation, we see increased levels of phospho-p38 as well as phosphorylated forms of p38 activators MKK3/6 and

downstream targets HSP27 and MAPKAPK2. Activation of p38 is followed by accumulation of p53 and p21, verifying what has previously been published. This response does not appear to be due to elevated levels of reactive oxygen species, contrary to what has been shown previously for cells with a deficient mitotic checkpoint, suggesting alternative mechanisms may exist to prevent proliferation under conditions of high and low levels of chromosome segregation. In conclusion, our data suggest that a p38 dependent pathway generates an early response followed by proliferative arrest in diploid cells that have mis-segregated chromosomes. We are currently investigating upstream regulators of p38 to determine what signal aneuploidy generates to evoke this p38 response.

1930

**A genetic screen to identify components involved in correct transmission of broken chromosomes.**

*M-C. Claverie<sup>1</sup>, C. Soler<sup>1</sup>, A. Royou<sup>1</sup>; <sup>1</sup>IBGC-IECB-CNRS, Pessac, France*

The mechanisms that safeguard cells against aneuploidy are of great interest as aneuploidy contributes to tumorigenesis. To gain insight into these mechanisms, we studied the behaviour of cells entering mitosis with damaged chromosomes. We used the endonuclease I-Crel to generate acentric chromosomes in *Drosophila* larvae. While I-Crel expression produces acentric chromosomes in the majority of cells, remarkably, it has no effect on adult survival. Live studies reveal that acentric chromatids segregate efficiently to opposite poles. The acentric chromatid poleward movement is mediated through DNA tethers that connect the acentric fragment to its centric partner. These tethers are decorated with Polo kinase, a key mitotic regulator, the spindle checkpoint component BubR1 and two chromosomal passenger complex (CPC) proteins, INCENP and Aurora-B. Reduced BubR1 or Polo function results in abnormal segregation of acentric chromatids, a decrease in acentric chromosome tethering and a great reduction in adult survival. This led to the proposal that BubR1 and Polo facilitate the accurate segregation of acentric chromatids by maintaining the integrity of the tethers that connect acentric and centric fragments.

To identify novel *Drosophila* genes involved in this mechanism, we are taking advantage of our observation that when the function of BubR1 or Polo, two components involved in tether function, is reduced, the survival of third instar larvae to adulthood is dramatically decreased upon I-Crel expression. We have performed an unbiased genetic screen to identify mutations that are synthetic lethal with I-Crel expression. The genes involved in tether function are likely to have additional roles in mitosis or other physiological functions. Consequently, the probability that homozygote null mutations of these genes induce lethality prior to adulthood is high, as is the case for key mitotic players already identified, eg BubR1 and Polo. Therefore, we have favoured the use of ethyl methyl sulfonate, which creates point mutations that are likely to be hypomorphic. We will describe the identification of mutations on the X chromosome that are synthetic lethal with I-Crel expression.

1931

***In vivo* measurement of chromosome stretching tension in budding yeast.**

*J. M. Chacon<sup>1</sup>, A. Lane<sup>1</sup>, B. Schuster<sup>1</sup>, M. Gerami-Nejad<sup>1</sup>, D. J. Clarke<sup>1</sup>, M. K. Gardner<sup>1</sup>;  
<sup>1</sup>Genetics, Cell Biology, and Development, University of Minnesota, Minneapolis, MN*

During cell division, a microtubule-based mitotic spindle is built by the cell which acts to align and stretch duplicated sister chromatids prior to their ultimate segregation into daughter cells. This chromosome stretching tension is thought to provide an important tension-based signal that promotes proper chromosome segregation, and thus contributes to the prevention of

aneuploidy. However, the magnitude of chromosome stretching tension forces during mitosis have not been characterized. By using a novel imaging-based technique to measure thermal fluctuations of chromosome-associated fluorescent markers, we calculated *in vivo* chromosome stiffness via the equipartition theorem. Our measurements of wild type chromosome stiffness in yeast yielded values of  $\sim 26$  pN/ $\mu$ m, and this stiffness remains relatively constant over the range of *in vivo* stretching distances. We then used our stiffness measurements to quantitatively evaluate *in vivo* metaphase chromosome stretching forces in budding yeast cells. We found that chromosome stretching forces are  $\sim 9$  pN, which are well above thermal forces, and are surprisingly high given the presence of single kinetochore-microtubule attachments in budding yeast. These high forces are consistent with a model in which kinetochore-microtubule attachments could be stabilized by mechanical chromosome stretching tension.

1932

### **Sgo1 recruits PP2A to chromosomes to ensure sister chromatid bi-orientation in mitosis.**

H. D. Eshleman<sup>1</sup>, D. O. Morgan<sup>1</sup>; <sup>1</sup>Departments of Physiology and Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA

To ensure proper chromosome segregation into mother and daughter cells, each sister-chromatid pair must be bi-oriented on the mitotic spindle. Errors in sister-chromatid attachment are detected by the spindle assembly checkpoint, which inhibits the initiation of anaphase until attachment is corrected. The protein Sgo1 is required in budding yeast mitosis for normal error correction, but its precise function has not yet been identified. Sgo1 recruits the PP2A subunit Rts1 to centromeres in meiosis, and deletion of either protein causes sensitivity to spindle poisons in mitosis. Thus, the mitotic function of Sgo1 might be to recruit PP2A-Rts1 to the centromere, where it somehow promotes correct sister-chromatid attachment. Consistent with this hypothesis, we found, using fluorescence microscopy in budding yeast, that Sgo1 is required for Rts1 localization to the centromere in mitosis. Mutations in the predicted PP2A-binding region of Sgo1 both abolish Rts1 localization and prevent proper sister chromatid bi-orientation after treatment with spindle poisons.

In early anaphase, both Sgo1 and Rts1 disappear from the centromere. Cellular Sgo1 levels also decline abruptly in anaphase, suggesting that its removal from the kinetochore, and thus the removal of Rts1, might depend on destruction of Sgo1 via the anaphase promoting complex (APC). We tested this possibility and found that budding yeast Sgo1 is a substrate for ubiquitination by the APC *in vitro*. We identified a motif required for its ubiquitination, and deletion of this motif rendered it resistant to degradation *in vivo*. Stabilized Sgo1 had no clear mitotic phenotype, and stabilized Sgo1 (as well as Rts1) still detached from the centromere at anaphase. We are currently pursuing the other regulatory mechanisms that govern the removal of these proteins from the chromosome.

1933

### **Cell lineage-specific cell cycle abnormalities in a kleisin- $\beta$ mutant mouse**

A. J. Wood<sup>1</sup>, J. Woodward<sup>1</sup>, V. Chalei<sup>1</sup>, W. Bickmore<sup>1</sup>; <sup>1</sup>The University of Edinburgh, Edinburgh, United Kingdom

Condensin complexes regulate higher order chromosome structure and are required for chromosome partitioning during mitosis. This essential function has largely precluded their study in the context of mammalian development. We describe highly cell lineage specific phenotypes in a mouse carrying homozygous missense mutations in *Cap-H2*, encoding the kleisin- $\beta$  subunit of condensin II. Surprisingly, homozygous *Cap-H2*<sup>nes/nes</sup> mice are viable and fertile, indicating that this lesion does not perturb condensin function in most cell lineages. However, *Cap-H2*<sup>nes/nes</sup> homozygotes show a severe but incomplete block during thymic T cell development. In

wildtype resting thymocytes, productive VDJ recombination at the *T Cell Receptor (TCR)  $\beta$*  locus triggers an intense burst of cellular proliferation before cell cycle exit in G1/G0 and rearrangement of the *TCR $\alpha$*  locus. *Cap-H2<sup>nes/nes</sup>* thymocytes express TCR $\beta$  chains at normal levels and re-enter the cell cycle, but transcriptome differences between stage-matched mutant and wildtype cells are better explained by cell cycle abnormalities than by direct effects on transcription. Consistent with these findings, nesy thymocytes frequently arrest with a 4n, rather than 2n DNA content and exhibit prolonged metaphase during *ex vivo* culture. The 4n arrested cells lack sister chromatid cohesion, suggesting that they originate from abortive cytokinesis. This results in a >100-fold reduction in the CD4+/CD8+ thymocyte subset, and a reduced peripheral T cell pool. These data demonstrate that subtle perturbation of a condensin II component has catastrophic consequences during T cell development, yet causes little or no problem in other cell lineages, including the parallel pathway of B cell development. Thus, T cell development may impose atypical demands on the chromosome segregation machinery.

1934

**Mitotic cells have a proximity sensor that utilizes histone H3.3 Ser31 phosphorylation to identify and mark individual misaligned chromosomes.**

*K. Karranjeet<sup>1</sup>, E. H. Hinchcliffe<sup>1</sup>; <sup>1</sup>Hormel Institute, Univ. Minnesota, Austin, MN*

During mitosis chromosomes (chrms) become congressed at metaphase, as their kinetochores bind to microtubules (MTs) emanating from spindle poles. The balance of force between k-fibers and chrm cohesion at centromeres silences the checkpoint that down-regulates cell cycle progression into anaphase. Congression and spindle assembly are often coordinate, but any lagging chrms automatically generate this “wait anaphase” signal to ensure that anaphase does not precede congression, thus preventing segregation mistakes that can generate aneuploidy. However, it is not clear whether misaligned chrms create other positional cues, outside of the kinetochore-mediated spindle assembly checkpoint (SAC). Here we show that misaligned chrms generate a “proximity sensor” that is distinct from the SAC and monitors chrm position within the dividing cell, relative to the position of the other chrms. This sensor involves the highly conserved histone variant H3.3, which assembles into nucleosomes via a replication-independent mechanism, and differs from the canonical H3 by 5 AA substitutions (Cell 2004 116:51-61). One of these is Serine 31, which is conserved from yeast to humans, and during mitosis becomes phosphorylated at the centromeres of all congressed chrms (PNAS 2005 102:6344-9). Here we find that misaligned chrms are decorated with anti-S31P along their arms, whereas congressed chrms in the same cell are decorated only at their centromeres. S31P labeling is highest on severely misaligned chrms that are outside the spindle, i.e. located within the astral MT array between a pole and the cortex. These single, mono-oriented chrms do not recruit chromokinesins -4, -10, or -12 to their arms, but do show a dramatic increase in the amount of kinesin-7 (CENP-E) at kinetochores, which drives chrm congression in the absence of k-fiber attachment (NCB 2009 11:832-8). If BSC1 cells are treated with nocodazole (Noc), MTs disassemble, and the SAC is activated, but there is no increase in S31P at centromeres or localization along arms. However, when Noc is added for 1 hr, then washed out, there is a substantial increase in misaligned chrms, and often single poles detach from the spindle – along with a varying numbers of chrms (1-6). We show that there is a 12x increase in the amount of S31P along individual, misaligned chromosomes associated with a detached pole, compared to labeling of congressed chrms. Interestingly, the levels of S31P sharply decrease as >1 chrms accumulate near a detached pole. This suggests that clustered chrms activate PP1, which normally dephosphorylates S31 H3.3 during anaphase (PNAS 2005 102:6344-9). We have also identified the H3.3 S31 kinase as Aurora A. We propose a model, in which H3.3 S31P increases along the arms of misaligned chrms. As they congress they are brought in proximity of other chrms, and S31P is removed by PP1. The marking of misaligned chrms may recruit

factors necessary to maintain cohesion, or facilitate spindle attachment and congression. We are currently investigating potential binding partners for S31P. However, this is the first time a mitotic function has been described for either H3.3 or its S31P modification. H3.3 is often mutated in cancer cells, suggesting it plays a key role in maintaining ploidy (Nature 2012 482:226-31).

1935

### **Insight into the Coordination of Pole-to-Pole Separation Forces During Spindle Assembly.**

*E. G. Sturgill<sup>1</sup>, R. Ohi<sup>1</sup>; <sup>1</sup>Department of Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN*

The mitotic spindle, a transient bipolar array of microtubules, segregates duplicated chromosomes during cell division. Establishment of proper spindle length and bipolarity are essential for its function and are achieved by a concert of forces that regulate both microtubule organization and dynamics. A largely unexplored problem is how individual force components are integrated to generate a structure of constant shape and size at steady state. For example, the coordination of pole-to-pole separation forces acting on kinetochore-microtubules (KMTs) and non-KMTs is not understood. We found that Kif15, a kinesin-12 believed to act redundantly to kinesin-5/Eg5, localizes specifically to KMTs and enriches at the kinetochore-microtubule interface. Depletion of Kif15 reduces spindle length in a KMT-dependent manner. Live cell imaging of spindle assembly in Kif15-depleted cells shows that spindles initially become abnormally long, and then undergo contraction to their characteristically short steady state length. Contraction requires KMTs, suggesting that instability of KMTs alters the force balance within the spindle of Kif15-depleted cells. Consistent with this notion, Kif15 protects KMTs from cold-induced depolymerization. Since Kif15 concentrates at the outer kinetochore, we speculate that it stabilizes microtubule plus-ends directly and are currently testing this using *in vitro* approaches. Our results suggest that Kif15 promotes spindle bipolarity by mediating kinetochore-generated pushing forces involved in spindle pole separation. Thus, Eg5 and Kif15 cooperate to establish spindle bipolarity by acting in parallel: Eg5 affects non-KMT organization whereas Kif15 regulates KMT plus-end dynamics. Our results also demonstrate that the coordination of KMT length and non-KMT sliding is critical for spindle length homeostasis.

1936

### **Molecular mechanisms governing extrinsic forces in mitotic spindle organization.**

*M. Kwon<sup>1,2</sup>, M. Bagonis<sup>2</sup>, G. Danuser<sup>2</sup>, D. Pellman<sup>1,2</sup>; <sup>1</sup>HHMI, Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA, <sup>2</sup>Cell Biology, Harvard Medical School, Boston, MA*

The presence of supernumerary centrosomes in cancer cells often creates the potential for catastrophic multipolar divisions. However, many cancer cells successfully divide because of mechanisms that suppress multipolar mitoses by clustering their extra centrosomes. Our functional genomic study has previously identified key pathways contributing to centrosome organization in cancer cells. In addition to spindle intrinsic forces, we found that cell adhesion patterns can determine the fate of mitosis whether they divide into two (bipolar) or more (multipolar). Yet, the mechanism by which actin and adhesion-dependent forces to control the fidelity of mitosis remain unclear at the molecular level. One model proposes that sites of strong cell matrix adhesion are imprinted as an actin rich structure called retraction fibers during mitosis, and the retraction fibers serve as cortical cues to concentrate force generators and regulators to pull centrosomes. By imaging cancer cells plated on fibronectin micropatterns, here we demonstrate that Myo10, an unconventional myosin identified from our genome-wide

screen, is an essential component linking retraction fiber-mediated forces to astral microtubules (MTs) during spindle organization. Myo10 specifically localizes along and to the tips of the retraction fibers. When cells with extra centrosomes were plated on Y-shaped fibronectin micropatterns, control cells divide tripolar toward Y-adhesion axis; however, cells depleted of Myo10 undergo bipolar division independent of retraction fiber positions, suggesting that Myo10 is a force coupler from retraction fibers to centrosomes. We have hypothesized that intrinsic properties of MTs adjacent to retraction fibers are altered to favor stable interaction between astral MTs and cell cortex. To uncover heterogeneity of MT dynamics in relation to retraction fibers, we have performed live cell imaging of GFP-EB3 with high spatio-temporal resolution in cells plated on fibronectin micropatterns where retraction fiber positions are precisely manipulated. We have developed a system that quantifies and visualizes MT dynamics in different subregions of cells by an automated computer program capable of tracking GFP-EB3 comets. This approach uncovered heterogeneity of MT dynamics around retraction fiber regions. Interestingly, our analyses have revealed that Myo10 is in part responsible for promoting the long-lived and long distance travelling MTs. Taken together, these results suggest that Myo10 is a key adhesion-dependent regulator that confers heterogeneity of mitotic cortex by coupling cell geometry/adhesion to mitotic fidelity and genome stability.

1937

**The nucleoporin ALADIN is essential for proper mitotic and meiotic spindle function.**

*S. Carvalhal<sup>1</sup>, M. Arocena<sup>1</sup>, E. R. Griffis<sup>1</sup>; <sup>1</sup>Wellcome Trust Centre for Gene Regulation and Expression, University of Dundee, Dundee, United Kingdom*

The nuclear pore complex (NPC) is a large proteinaceous structure composed of multiple copies of 30 proteins termed nucleoporins (Nups). During interphase, the NPC is the sole conduit for the bidirectional transport of soluble molecules between the nucleus and cytoplasm. In higher eukaryotes, entry into mitosis is coincident with nuclear envelope breakdown, NPC disassembly, and dispersion of Nups. Many recent studies have demonstrated that some Nups have functions in mitosis. In order to probe the function of all nucleoporins in mitosis we carried out a comprehensive RNAi screen in S2 cells. We performed automated live and fixed analysis using S2 cells expressing mCherry-tubulin and H2B-GFP. Of the 29 dsRNAs used, 5 showed mitotic index alterations, spindle morphology and/or chromosome alignment defects. We have focused our subsequent studies on ALADIN (a nucleoporin that is mutated in the neurological disorder Allgrove/TripA Syndrome), which caused chromosome alignment and segregation defects and shortened mitotic spindles when it was depleted. In ALADIN depleted cells, the rate of microtubule flux in the mitotic spindle is significantly increased over control cells, Aurora B and the microtubule depolymerizing kinesin Klp10A enrich on aligned chromosomes. Curiously, ALADIN does not localize to the mitotic spindle or kinetochores, although it does localize around centrosomes and the mitotic spindle in human and *Drosophila* cells. In human cells, ALADIN colocalizes nicely with the spindle matrix proteins NuMA and Tpr. Spindles that form in HeLa cells lacking ALADIN are shorter and not cold-stable, and ALADIN depletion delays chromosome alignment after monastrol washout. We've found that pools of Sgo1, NuMA, and Plk1 are mislocalized after ALADIN depletion and Plk1 inhibition produces a similar, but not additive, decrease in spindle length, suggesting that ALADIN may function to regulate Plk1 activity. Intriguingly, female mice that lack ALADIN are sterile. Oocytes from ALADIN <sup>-/-</sup> mice fail to eject a polar body after the first meiotic division and have poorly aligned chromosomes and weak spindles at metaphase of meiosis II. We therefore hypothesize that ALADIN may be more essential in acentrosomal divisions. In support of this hypothesis we find that ALADIN depletion produces no phenotype in *Drosophila* embryos but is synthetically lethal in the early embryo when centrosomes are ablated. Curiously, the ALADIN meiosis phenotype can be rescued by

expressing a version of ALADIN/AAAs that contains a mutation commonly found in human Triple-A syndrome patients, which suggests that failures in mitosis may not underlie many of the phenotypes associated with Triple-A syndrome.

1938

**Aneuploidy causes chromosome mis-segregation and karyotype-dependent phenotypes in cancer cells.**

*J. M. Nicholson<sup>1</sup>, A. Mattingly<sup>1</sup>, D. Wangsa<sup>2</sup>, J. Camps<sup>2</sup>, T. Ried<sup>2</sup>, D. Cimini<sup>1</sup>; <sup>1</sup>Biological Sciences, Virginia Tech, Blacksburg, VA, <sup>2</sup>Genetics Branch, National Cancer Institute, National Institutes of Health, Bethesda, MD*

Cancers display distinct aneuploid karyotypes (i.e., abnormal chromosome numbers) and typically mis-segregate chromosomes at high rates, a phenotype referred to as chromosomal instability (CIN). While it is readily apparent how chromosome mis-segregation can cause aneuploidy, the effect aneuploidy has on chromosome segregation is unclear. To test the effects of aneuploidy on chromosome segregation we utilized the colorectal cancer cell line DLD1 (2n=46) and variants of this line containing defined artificial trisomies for chromosomes 7 and 13 (DLD1+7 and DLD1+13, respectively). We found that DLD1+7 and DLD1+13 exhibited higher rates of chromosome mis-segregation compared to the parental cell line, with higher mis-segregation rates for the aneuploid chromosomes compared to other chromosomes. Further, there was an increase in near-tetraploid DLD1+13 cells, due to an increase in cytokinesis failure rates. Our data indicate that this is due to overexpression of the cytokinesis protein spastic paraplegia 20 (Spartin, or SPG20) located on chromosome 13q13.3. Indeed, overexpression of Spartin in DLD1 cells reproduced the cytokinesis failure phenotype observed in DLD1+13 cells. Conversely, siRNA-mediated Spartin knock down resulted in significant reduction of cytokinesis failure in the DLD1+13 cell line. Overall, our study shows that aneuploidy per se induces chromosome mis-segregation in cancer cells. Moreover, our data indicate that different aneuploidies yield distinct cellular phenotypes.

1939

**Transient mitotic spindle defects as a cause of chromosomal instability in human cancer cells.**

*W. T. Silkworth<sup>1</sup>, I. K. Nard<sup>2</sup>, D. Cimini<sup>1</sup>; <sup>1</sup>Biological Sciences, Virginia Tech, Blacksburg, VA, <sup>2</sup>Department of Molecular Cell and Developmental Biology, University of Virginia, Charlottesville, VA*

Accurate chromosome segregation during mitosis is necessary for stability of the genome in developing organisms, and erroneous chromosome segregation is known to cause miscarriage, birth defects, and cancer in humans. Recent reports in both cancer and non-cancer cells have shown a link between transient abnormal mitotic spindle geometry and the establishment of kinetochore mis-attachments, which in turn cause chromosome mis-segregation in the form of anaphase lagging chromosomes. In particular, two mechanisms have been described, one of which occurs in cells that assemble a multipolar spindle but bipolarize before anaphase onset (transient multipolarity mechanism, TM); and one that is characterized by a delay in centrosome separation (incomplete spindle pole separation mechanism, ISPS), by which the centrosomes are not completely separated at the time of nuclear envelope breakdown (NEB), and instead achieve complete separation after NEB. In this study, we investigated the role that these mechanisms play in cancer cell chromosomal instability (CIN). To this end, we screened a panel of cancer cells from various sites to determine the prevalence of mitotic spindle geometry defects in early mitosis and how such defects correlate to chromosome segregation defects. Our data show that human cancer cells from various sites exhibit one or both of the two

transient mitotic spindle defects that can promote kinetochore mis-attachment and chromosome mis-segregation, thus indicating that transiently abnormal spindle geometry plays an important role in CIN.

1940

**Stabilization of kinetochore-microtubule attachments is sufficient to induce chromosomal instability in human cells.**

*C. D. Laucius<sup>1</sup>, L. Kabeche<sup>1</sup>, D. A. Compton<sup>1</sup>; <sup>1</sup>Biochemistry, Geisel School of Medicine at Dartmouth, Hanover, NH*

Chromosomal instability (CIN) – a high rate of chromosome loss or gain – is common in aneuploid tumor cells. The most common cause of CIN is the persistence of errors in kinetochore-microtubule (kMT) attachments. Proper chromosome segregation requires sufficiently stable kMT attachments for chromosome movement, yet the attachments must be dynamic enough to permit efficient error correction before anaphase onset. To date more than 10 proteins have been demonstrated to regulate kMT attachment stability including stabilizers and destabilizers. We previously demonstrated that overexpression of kMT stabilizers or loss of destabilizers would induce CIN and that overexpression of destabilizing proteins in cancer cells is sufficient to suppress CIN. These data suggest that regardless of what protein is targeted, stabilizing kMT attachments is sufficient to drive chromosome missegregation and CIN. To test this we treated chromosomally stable, diploid cell lines with low doses of the MT stabilizing drug taxol. We show that the frequency of lagging chromosomes in anaphase increases from 1.0% to 8.4% in RPE-1 cells treated with 2nM taxol. Low dose taxol also increases the frequency of multipolar spindles. Moreover, FISH analyses of clonal populations of p53-deficient HCT116 cells show an increase in aneuploid cells from 5.8% to 14.7% following treatment with 2nM taxol. Finally, measurement of kMT attachment stability using photoactivation of GFP-tagged tubulin shows that low dose taxol treatment stabilizes kMT attachments from  $1.8 \pm 0.2$  min to  $2.9 \pm 0.4$  min in prometaphase and from  $3.8 \pm 0.4$  to  $6.0 \pm 0.4$  min in metaphase. These data demonstrate that stabilizing kMT attachments is sufficient to generate CIN in human cells.

1941

**TAO1 maintains genome integrity by mediating the timely maturation of chromosome attachments made to lateral walls of microtubules.**

*R. L. Shrestha<sup>1</sup>, V. M. Draviam<sup>1</sup>; <sup>1</sup>Department of Genetics, University of Cambridge, Cambridge, United Kingdom*

Chromosomes predominantly attach to lateral walls of microtubules and then transform the lateral attachment to ends of microtubules. Pathways that monitor and mediate this transformation process are critical to maintain genome integrity; however, poorly understood. We report TAO1 kinase as a novel regulator of lateral to end-on transformation as laterally attached kinetochore pairs of TAO1 depleted cells remain unresolved and in some cells, missegregate in a laterally attached fashion. Because the resolution of lateral but not syntelic attachments is perturbed following TAO1 depletion, we propose TAO1 as a specific destabilizer of lateral attachments. We show TAO1's role in mitotic microtubule destabilization and mediating anti-poleward movements of laterally attached chromosomes. Using an error-correction assay, we demonstrate the aneuploid nature of unresolved lateral attachments in TAO1 depleted cells and thereby, uncover a previously unrecognized step in kinetochore-microtubule attachment that prevents aneuploidy

1942

**Regulation of microtubule attachment at kinetochores and cell cortex by Cdc42.***E. Vitiello<sup>1</sup>, M. Balda<sup>1</sup>, K. Matter<sup>1</sup>; <sup>1</sup>Cell Biology, UCL Institute of Ophthalmology, London, UK, London, United Kingdom*

Maintenance of epithelial tissue integrity requires correct organization of the polarity plane. This is promoted by assembly of cell-cell junctions, defining distinctive apical and basolateral domains. The establishment of polarity is a key point in tissue organization since it controls the plane in which cells divide. When a cell replicates, it duplicates chromosomes and aligns them before partitioning them evenly between the two daughter cells. Although results from different laboratories indicate a role of cell-cell junctions in the orientation of the mitotic spindle, the coordination between junctions and chromosome capture/alignment is still poorly understood. Previous work suggests that the small Rho GTPase Cdc42 regulates chromosome capture. Cdc42 is also a crucial regulator of cell-cell junction assembly and dynamics. Cell junctions need to remodel during cell division to adapt to the changing cell shape, and allow the condensed chromosomes to be properly aligned. Therefore, we hypothesized that specific regulators of Cdc42 guide the interplay between cell junctions and the mitotic machinery. Using a siRNA approach, we identified a GTPase Activating Protein (GAP) that associates with cell-cell contacts and mitotic spindles, and regulates junctional integrity and chromosome alignment during mitosis. Upon depletion of the GAP in epithelial cells, the normally continuous immunofluorescence staining of junctional markers was disrupted in mitotic cells, and chromosomes were misaligned in metaphase. The orientation of mitotic spindles relative to the substrate was not affected, suggesting that the defect was not due to a loss of polarity. Depletion of the GAP led to increased levels of GTP-bound Cdc42, indicating that deregulation of Cdc42 contributed to the observed phenotypes. Indeed, transfection of dominant negative Cdc42 and partial depletion of Cdc42 by RNA interference rescued the phenotype induced by depletion of the GAP. Live cell imaging revealed that depletion of the GAP led to an extension of prometaphase/metaphase and that the defect in chromosome alignment coincided with a loss in chromosome oscillations. We also found that the GAP associates with the microtubule motor Kif1B, a kinesin-3 family member, and that depletion of Kif1B resulted in a similar phenotype as depletion of the GAP. Based on our observations, we speculate that the GAP regulates Cdc42 to guide association of microtubules with the cell cortex and the kinetochores and to regulate forces they exert at these sites.

1943

**Towards Exploring the 3D Supramolecular Architecture of Centrosomes *in situ*.***J. Mahamid<sup>1</sup>, A. Hyman<sup>2</sup>, W. Baumeister<sup>1</sup>; <sup>1</sup>Department of Molecular Structural Biology, Max-Planck Institute of Biochemistry, Martinsried, Germany, <sup>2</sup>Max-Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany*

Centrosomes are the major microtubule organizing centers in most eukaryotic cells. Recent work characterized the structure of centrioles in some detail, however details on the organization of the pericentriolar matrix (PCM) at the molecular level are lacking, leaving the mechanism by which centrosomes nucleate, orient, and anchor microtubules largely obscure. The PCM represents an unusual protein assembly from a structural biology view-point. Its 3D structure is not solely governed by stereospecific interactions between a defined number of protein subunits. It rather assembles as an intracellular matrix formed at the scale of cellular organelles, with local order and substantial amount of disorder. As such, the PCM cannot simply be isolated and studied by the established methods of structural biology, and must therefore be studied within the cellular context.

Cryogenic-electron tomography (CET) in conjunction with pattern recognition methods has the unique potential to visualize the cellular proteome *in situ*, providing 3D images which are interpretable in molecular terms. Here it is applied to a first *in situ* ultrastructural analysis of centrosomes in *Caenorhabditis elegans* embryos and mammalian cell culture.

The application of CET to the investigation of centrosomes within the cell requires the development of novel approaches in sample preparation, primarily due the large dimensions of the specimen and secondly due to the low copy existence of the centrosome within the cell. Correlative Cryo-fluorescence measurements are essential to localize the centrosomes within the large cells and to identify target areas of interest for focused ion-beam (FIB) milling for the production of electron-transparent windows into the cell. CET on these preparations provides 3D view of centrosome organization at molecular resolution. These high resolution structural data are crucial to gain novel insights into the structure and function of centrosomes and of the yet poorly characterized PCM in particular.

1944

**Functional genomic screen in human cells reveals novel regulators of centriole number.**

*F. Balestra<sup>1</sup>, P. Strnad<sup>1</sup>, I. Fluckiger<sup>1</sup>, P. Gönczy<sup>1</sup>; <sup>1</sup>Swiss Institute for Experimental Cancer Research (ISREC) School of Life Sciences, Swiss Federal Institute of Technology (EPFL), Lausanne, Switzerland*

Centrioles are crucial notably for the formation of cilia and flagella, as well as for robust spindle assembly in many cell types. It is critical that cells harbor the correct number of centrioles. The mechanism regulating centriole number are incompletely understood, despite the fact that genetic and genomic approaches have led to the identification of components required for centriole assembly in several organisms. However, no comprehensive functional genomic screen has been reported for mammalian systems, in which centriole assembly may be orchestrated in a more complex manner than in unicellular or invertebrate systems. Therefore, we have developed and executed a genome-wide siRNA-based screen in human cells for genes required for proper centriole number. We used a cell line stably expressing the centriolar component Centrin1 fused to GFP to monitor centrosome number and analyzed the impact of 76138 distinct siRNAs targeting 19593 genes, using a 96-well-based platform. Cells were incubated with siRNAs for 72 hours before fixation, DNA counterstaining and image acquisition. We developed a MATLAB-based algorithm for the automatic counting of centrosomes in each cell, which lead to the preselection of a number of candidate genes. Several subsequent confirmatory steps led to the identification of a final number of 31 new candidates genes required for promoting centriole assembly and of 13 new candidates required for negatively regulating this process. We are in the process of further characterizing the role of a subset of these genes in the centriole duplication cycle.

1945

**sas-1 maintains centriole integrity during spermatogenesis in *C. elegans*.**

*L. von Tobel<sup>1</sup>, T. Mikeladze-Dvali<sup>1</sup>, M. Delattre<sup>1</sup>, P. Gönczy<sup>1</sup>; <sup>1</sup>ISREC, EPFL, Lausanne, Switzerland*

Centrosomes, the primary microtubule organizing centers of animal cells, usually consist of a pair of centrioles surrounded by pericentriolar material (PCM). Centrosome number must be strictly regulated both in the soma and the germline. The single centrosome present at the onset of the cell cycle in somatic tissues duplicates to give rise to two entities, one of which is ultimately inherited by each daughter cell. Gametogenesis poses a unique challenge to this

general pattern of centrosome inheritance because one of the parental centrosomes must be eliminated so that only one centrosome is inherited by the zygote. In most metazoan organisms, including *C. elegans* and *H. sapiens*, centrioles are eliminated during oogenesis and maintained during spermatogenesis, such that the correct number of centrioles is restored in the zygote upon fertilization. The mechanisms controlling such differential centriole inheritance in the female and male germline, though fundamental for development, are not understood. We use *C. elegans* as a model system to tackle this question. In a screen of paternal-effect embryonic lethal mutations, we identified two alleles of a locus we named *sas-1*. Embryos derived from homozygous mutant animals assemble a monopolar spindle during the first mitotic division. We found that fertilization of wild type oocytes by *sas-1* mutant sperm also confers this phenotype in one-cell stage embryos, whereas wild type sperm can rescue *sas-1* mutant oocytes during early embryogenesis. Serial-section EM analysis suggests that centrioles are abnormal in *sas-1* mutant sperm. Accordingly, centrioles endowed from *sas-1* mutant sperm are not stable and become structurally unrecognizable in the early embryo. Nevertheless, maternal SAS-4 and SAS-6 are recruited in the vicinity of these seemingly defective *sas-1* paternal centrioles. Furthermore, we find that SAS-1 is also required maternally for proper development. Through SNP mapping, whole genome sequencing and subsequent analysis, we uncovered that SAS-1 is a C2 domain-containing protein that localizes to centrioles. Consistent with a role at centrosomes, mutant SAS-1 proteins do not localize efficiently to centrioles. Finally, we show that SAS-1 does not exchange rapidly at the centriole, but instead seems to be recruited during centriole formation and hardly exchanges with the cytoplasmic pool thereafter.

1947

#### Measurements of forces produced by the mitotic spindle using optical tweezers.

J. Ferraro-Gideon<sup>1</sup>, R. Sheykhan<sup>1</sup>, Q. Zhu<sup>2</sup>, M. Duquette<sup>2</sup>, M. W. Berns<sup>2,3</sup>, A. Forer<sup>1</sup>; <sup>1</sup>Biology, York University, Toronto, ON, Canada, <sup>2</sup>Biomedical Engineering, University of California, San Diego, San Diego, CA, <sup>3</sup>Beckman Laser Institute and Biomedical Engineering, University of California, Irvine, Irvine, CA

We used an optical trapping laser (optical tweezers) to measure the forces needed to stop chromosome movement in *Mesostoma* spermatocytes and crane-fly spermatocytes as well as the inward movement of poles in PtK2 cells after cutting across the spindle. We primarily used *Mesostoma* spermatocytes for these experiments because their kinetochores oscillate to and away from the spindle pole for a period of 1 to 2 hours during prometaphase/metaphase; thus we could trap different kinetochores multiple times in the same spermatocyte. We focussed a Nd:YVO4 continuous wave 1064 nm wavelength laser using a 63x oil immersion objective to a single point [Shi et al Microsc Res Tech 69 (2006) 894] in order to trap kinetochores that moved to or away from their poles. When a trap power of 15 mW to 23 mW was applied to the kinetochore, kinetochore movement stopped or the amplitude of the oscillations decreased, and kinetochore oscillations recovered when the trap was released. In crane-fly spermatocytes, less extensive experiments indicated that a trap power of 28 mW to 65 mW could stop or slow poleward chromosome movement. In PtK2 cells a trap power of about 8mW applied to the spindle pole stopped the spindle pole of the irradiated half-spindle from moving in following laser microbeam irradiations across the metaphase spindle. Using the equation  $F=QP/c$ , with Q coefficients of 0.09 for PtK spindle poles and 0.06 for chromosomes, P = power, c= speed of light, the force to stop PtK2 pole movements was 2.3 pN and the forces to stop chromosome movements in *Mesostoma* spermatocytes and crane-fly spermatocytes were 3 pN to 13 pN. These forces are two orders of magnitude lower than the force to move grasshopper

spermatocyte chromosomes measured via micromanipulation [Nicklas J Cell Bio 97 (1983) 542].

1948

**Drosophila mech is Required for Cilium Formation.**

*M. Basiri<sup>1</sup>, A. Chadha<sup>2</sup>, B. Cook<sup>2</sup>, T. Avidor-Reiss<sup>1</sup>; <sup>1</sup>Department of Biological Sciences, University of Toledo, Toledo, OH, <sup>2</sup>Department of Cell Biology, The Scripps Research Institute, La Jolla, CA*

Cilia are conserved eukaryotic organelles that extend from cell surfaces to mediate motility and sensory functions. During ciliogenesis, centrioles elongate and migrate from the centrosome to the cell membrane to initiate axoneme formation, where they are called basal bodies. The region that lies at the interface of the basal body and the axoneme is termed the transition zone and is essential for proper cilium formation. We have identified mech, a *Drosophila* loss-of-function mutant that abolishes cilium formation. Interestingly, mech localizes to the ciliary transition zone. Using hidden Markov modeling, we have identified a highly conserved domain of mech. Mutation of this domain fails to rescue the mech phenotype, suggesting that this region is essential for mech function. We are currently examining the role of this domain in the context of mech function during ciliogenesis.

1949

**Matrix stiffness affects mitotic spindle orientation.**

*S. Ou<sup>1</sup>, P. Utomo<sup>1</sup>, C-G. Koh<sup>1</sup>; <sup>1</sup>School of Biological Sciences, Nanyang Technological University, Singapore, Singapore*

The extra-cellular matrix (ECM) provides cells with a complex array of biochemical and mechanical stimuli. Mechanical stimuli (stiffness of the ECM) can influence many cellular biochemical pathways that regulate cell proliferation, morphology, and differentiation. The signaling network regulating ECM-cell adhesion and cellular cytoskeleton dynamics help the cells to sense the stiffness of the ECM and transduce these mechanical stimuli into biochemical responses. While the influence of ECM stiffness on cell proliferation and morphology has been widely studied, the influence of micro-environment stiffness on mitosis remains poorly understood. In this study, we investigate how matrix stiffness affects the mitotic spindle apparatus. We found that matrix stiffness influences interphase actin cytoskeleton organization and cell morphology. In addition, matrix stiffness influences cortical actin organization in mitotic cells, which in turn could affect proper mitotic spindle orientation.

1950

**Chromosome Biorientation by the Chromosomal Passenger Complex is Separable from Its Localization to the Inner Centromere.**

*C. Campbell<sup>1</sup>, A. Desai<sup>1</sup>; <sup>1</sup>University of California, San Diego, La Jolla, CA*

Accurate segregation of the replicated genome requires biorientation of chromosomes on the metaphase spindle, which is ensured by the kinase Aurora B/Ipl1, a member of the 4-subunit chromosomal passenger complex (CPC). Aurora B localization between sister kinetochores at the inner centromere, which depends on the CPC subunit Survivin, is thought to promote biorientation by eliminating incorrect kinetochore-spindle attachments not under tension. We engineered a truncation of the INCENP/Sli15 subunit of budding yeast CPC that eliminates association with Survivin/Bir1 but nevertheless supports proper chromosome segregation during both mitosis and meiosis. The truncated Sli15 fully rescues inviability of Bir1 and Borealin/Nbl1

deletion mutants, and suppresses deletion phenotypes of Bub1 and Sgo1, components responsible for targeting the CPC to the inner centromere via Bir1. This Sli15 mutant no longer localizes in between the sister kinetochores, indicating that the inner-centromeric pool of the CPC is dispensable for accurate chromosome segregation. Truncated Sli15 localizes to pre-anaphase spindle microtubules, suggesting that Aurora B/Ipl1 activation by clustering on microtubules is sufficient for biorientation. Consistent with this, premature targeting of Sli15 to microtubules by preventing Cdk1 phosphorylation partially suppresses the loss of Bir1. These findings suggest that tension-based discrimination of correct versus incorrect attachments occurs within the kinetochore, as opposed to relying on Survivin-dependent localization of the CPC between sister kinetochores. We propose that clustering-based activation of Aurora B/Ipl1 on either chromatin or on microtubules, coupled to kinetochore-intrinsic sensing of tension, is sufficient for chromosome biorientation.

1951

**KNL1 mediates recruitment of Aurora B kinase to the kinetochore to regulate microtubule stability.**

*G. V. Caldas<sup>1</sup>, K. F. DeLuca<sup>1</sup>, J. G. DeLuca<sup>1</sup>; <sup>1</sup>Biochemistry, Colorado State University, Fort Collins, CO*

Accurate chromosome segregation during mitosis depends on the correct attachment of kinetochores to spindle microtubules. Aurora B kinase destabilizes incorrect attachments by phosphorylating kinetochore substrates that directly interact with microtubules and it has been proposed that such phosphorylation depends on the distance of the substrates from an inner centromeric pool of the kinase. Here, we show that the kinetochore protein KNL1 mediates recruitment of active Aurora B to the outer kinetochore and this recruitment is required for the phosphorylation of Hec1, an Aurora B substrate involved in kinetochore-microtubule attachment regulation. We identify a region in KNL1 sufficient to rescue both active Aurora B localization and Hec1 phosphorylation in KNL1-depleted cells. A portion of this domain is also sufficient for the kinetochore recruitment of the checkpoint protein Bub1, which has been previously implicated in the regulation of Aurora B kinase activity. We find that Bub1 depletion partially inhibits outer kinetochore Aurora B binding and Hec1 phosphorylation, indicating that both Bub1 and KNL1 are crucial factors for optimal kinetochore Aurora B targeting. Our findings suggest that kinetochore-microtubule attachment stability is regulated by direct recruitment of Aurora B to the outer kinetochore rather than a concentration gradient of a spatially distant centromeric Aurora B population.

1952

**Cep192/Aurora A/Plx1 pericentriolar material-recruiting complex is a key mediator of centrosome maturation.**

*V. Joukov<sup>1</sup>, J. C. Walter<sup>2</sup>, A. De Nicolo<sup>1</sup>; <sup>1</sup>Department of Cancer Biology, Dana-Farber Cancer Institute, Boston, MA, <sup>2</sup>Department of Biological Chemistry and Molecular Pharmacology, Harvard Medical School, Boston, MA*

Centrosomes are the primary microtubule (MT)-organizing centers (MTOCs) and play an important role in cell division, polarity, and spindle assembly. They consist of a pair of centrioles and pericentriolar material (PCM), the amount and composition of which determine centrosome function. The role of centrosomes as MTOCs of the mitotic spindle relies on extensive recruitment, at mitosis onset, of additional PCM. This process, termed centrosome maturation, critically depends on the mitotic serine/threonine kinases Aurora A (AurA) and Plk1 and on several centrosomal proteins, including the key regulator of centrosome biogenesis,

Cep192/Spd-2. How these proteins interact at the molecular level to form a functional MTOC has been elusive.

To dissect the mechanisms underlying centrosome maturation, we have devised a set of assays that recapitulate basic aspects of this process in *Xenopus* egg extract. We found that Cep192 targets Aurora A (AurA) and Plx1 (*Xenopus* ortholog of Plk1) to centrosomes, where it assembles these protein kinases into a two-tiered cascade that drives centrosome maturation. Specifically, the Cep192-bound, T-loop-phosphorylated, AurA, phosphorylates Plx1 at its T-loop-located T201 (equivalent of T210 in human Plk1), thereby facilitating Plx1 self-priming and binding to a conserved threonine in Cep192. The active Plx1 then phosphorylates Cep192, at several serine residues located in regions flanking the AurA-interacting domain, to generate the attachment sites for the  $\gamma$ -tubulin ring complex ( $\gamma$ -TuRC) and, possibly, other PCM components. This set of events is essential for centrosome maturation and for the MT-organizing function of a recombinant N-terminal Cep192 fragment that binds AurA, Plx1, and  $\gamma$ -TuRC. Our study reveals a critical mechanism underlying centrosome maturation and identifies the tripartite Cep192/AurA/Plx1 complex, which we denote Pericentriolar Material-Recruiting Complex (PMRC), as a key mediator of this process.

1953

### Evolution of GPR regulation in the control of spindle positioning for two *Caenorhabditis* species embryos.

S. Riche<sup>1</sup>, F. Argouf<sup>2</sup>, M. Zouak<sup>1</sup>, A. Arneodo<sup>2</sup>, J. Pecreaux<sup>3</sup>, M. Delattre<sup>1</sup>; <sup>1</sup>Laboratory of Molecular Biology of the Cell, Lyon, France, <sup>2</sup>Laboratory Joliot-Curie, Lyon, France, <sup>3</sup>Institute of Genetics and Developmental biology of Rennes, Rennes, France

Asymmetric cell division relies on the proper positioning of the mitotic spindle. However, it is unclear whether genetic networks that control such a highly conserved cellular processes contain cryptic genetic variability. To address this question, we analyzed such a division within nematodes, which represents an evolutionary conserved phenotype. In *C. elegans*, this process occurs in two steps. First, the nuclei/centrosome complex (NCC) is centered and aligned along the anterior/posterior axis. Second, unbalance pulling forces displace the spindle toward the posterior pole of the cell and cause transverse spindle oscillations. By comparisons with *C. elegans* embryos, the NCC of *C. briggsae* embryos was shifted toward the anterior pole during prophase. In addition, *C. briggsae* spindle oscillations were delayed, shorter in duration, and lower in amplitude. The “tug-of-war” model proposes that oscillations – and thus pulling forces contributing to posterior displacement and spindle elongation – are driven by force generators processivity. We extended this model to account for interspecies phenotypic differences by including the dynamics of astral microtubules and found that centrosome needs to reach a posterior enough position to undergo oscillations. The interspecies differences could be explained by changes in levels and localization of the essential G protein regulator GPR. Importantly, localization of GPR to the posterior cortex was conserved between these species, which established a common positional switch for the onset of spindle oscillation. Oscillation onset and the final spindle position are robust to changes in cell size/shape, the initial position of the spindle, and levels of GPR within the active region. This model fully accounts for the phenotypic differences between both species and suggest that the posterior pulling forces are under the double control of processivity – putatively driven by cell cycle –and position of the spindle. We also uncovered cryptic genetic changes underlying an essential cellular process. Whereas the posterior localization of GPR represented a highly constrained parameter of this asymmetric cell division, variations in other aspects of GPR localization were clear manifestations of these cryptic changes.

**A tethered Dam1 ring suffices for a minimal force-bearing unit of a kinetochore.**

V. A. Volkov<sup>1,2</sup>, A. V. Zaytsev<sup>3</sup>, N. Gudimchuk<sup>3</sup>, P. M. Grissom<sup>2</sup>, F. I. Ataulakhanov<sup>1,4</sup>, J. McIntosh<sup>2</sup>, E. L. Grishchuk<sup>3</sup>; <sup>1</sup>Center for Theoretical Problems of Physico chemical Pharmacology, Russian Academy of Sciences, Moscow, Russia, <sup>2</sup>Department of Molecular, Cellular and Developmental Biology, University of Colorado, Boulder, CO, <sup>3</sup>Physiology Department, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, <sup>4</sup>Physics Department, Moscow State University, Moscow, Russia

During mitosis the sister chromatids must segregate properly into the daughter cells. Two principal components are responsible for this task: the microtubules (MTs) and kinetochores, multi-protein chromosomal specializations. Dynamic MTs are thought to be the main anaphase force-generators, but the mechanism that couples such forces to chromosome movement is still unknown. Recent studies both in budding yeasts and *in vitro* using recombinant kinetochore complexes have identified the ring-shaped Dam1 complex as one of the most energy-efficient couplers which can transduce MT depolymerization into cargo movement. However, microbeads carrying this complex on their surface could capture no more than 5 pN from MT disassembly. On the other hand, a single MT is predicted to generate up to 75 pN (Molodtsov et al., 2005), and the force acting on the chromosomes in live cells is about 45 pN per MT (Nicklas, 1983). A plausible explanation for this poor force-transduction by Dam1 complex is that *in vitro* it is likely to promote lateral attachment of microbeads to MT walls. This geometry of a cargo attachment is significantly different from the end-on MT attachment of metaphase and anaphase kinetochores *in vivo*. Here we show that tethering Dam1 oligomers to the beads with non-kinetochore linker proteins allows formation of the end-on MT-bead attachment and increases the measured force up to 29 pN. Beads with tethered Dam1 show 4-fold increase in force amplitude and 3-fold increase in force duration compared to the control beads that carry Dam1 complexes at their surface with no linker proteins. We also show that beads with tethered Dam1 move under tension with velocities similar to those reported for beads attached to isolated budding yeast kinetochores (Akiyoshi et al., 2010). Beads with tethered Dam1 can move processively under tension up to 30 pN, implying that Dam1 oligomers are bound strongly to the MT wall. Indeed, our direct measurement of Dam1 complex diffusion along MTs estimates a single Dam1 monomer-MT bond strength at 8-10  $k_B T$ . Further, the force amplitudes obtained for tethered Dam1 beads are strikingly similar to the rupture forces measured for wild-type kinetochore particles, while the control beads resemble kinetochores isolated from *dad1-1* mutants (Akiyoshi et al., 2010). These results lead to the conclusion that tethered Dam1 complexes reconstitute the force-bearing unit of a budding yeast kinetochore.

**Cracking the *C. elegans* Eggshell.**

S. Olson<sup>1</sup>, T. Muller-Reichert<sup>2</sup>, K. Oegema<sup>3</sup>; <sup>1</sup>Biology, Pomona College, Claremont, CA, <sup>2</sup>Medical Theoretical Center, Dresden University of Technology, Dresden, Germany, <sup>3</sup>Department of Cellular and Molecular Medicine, Ludwig Institute for Cancer Research, UC San Diego, La Jolla, CA

Metazoan oocytes have an extracellular coating that governs fertilization. Following fertilization, this covering is altered to prevent polyspermy and protect the developing embryo. In *C. elegans*, a vitelline layer covers oocytes prior to fertilization. Fertilization initiates conversion of

the vitelline layer into a trilaminar eggshell consisting of an outer vitelline layer, a middle chitin-containing layer, and an inner layer proposed to serve as a permeability barrier. Here, we characterize CPG-1 and CPG-2, functionally redundant chondroitin proteoglycans that are the first described protein eggshell components. We show that CPG-1 and CPG-2 are delivered to the extracellular space after formation of the chitin layer by cortical granule exocytosis during meiosis I. Although they contain multiple chitin binding domains, CPG-1 and CPG-2 localize to the inner eggshell layer, whereas chitin is confined to the middle layer. We show that the inner eggshell layer is not the permeability barrier for small molecular weight solutes. Instead, this function resides in a previously undescribed layer that assembles between the eggshell and the plasma membrane following meiosis II. Disruption of the permeability barrier leads to solute permeability and osmotic stress. Disruption of the inner CPG-1/2 eggshell layer causes these phenotypes, as well as adhesion of the embryonic plasma membrane to the eggshell and cytokinesis failure. Interfering with chitin layer assembly results in the inner layer phenotypes, plus polyspermy and catastrophic eggshell rupture. We conclude that the eggshell layers and permeability barrier are laid down in a step-wise and cell cycle-dependent fashion, with later assembly events requiring successful completion of previous ones. To build on this work, we conducted an RNAi screen to identify additional genes that regulate eggshell and permeability barrier assembly. Several screen hits rendered the eggshell permeable, with minimal deleterious effects on early embryonic development. We therefore developed a reliable method to permeabilize and immobilize embryos to allow acute drug/inhibitor treatment to study early embryonic processes with live imaging

**Identification and characterization of *mel-43*, a gene required for early embryonic development in *C. elegans*.**

M. Ataeian<sup>1</sup>, M. Srayko<sup>1</sup>; <sup>1</sup>Department of Biological Sciences, University of Alberta, Edmonton, AB, Canada

The segregation of chromatin during meiotic and mitotic divisions in the embryo occurs via a bipolar microtubule-based structure called the spindle. The female meiotic spindle forms around chromatin without the contribution of centrosomes, even though the centriole pair is introduced into the oocyte cytoplasm with the sperm upon fertilization. The centrosomes mature and nucleate microtubules for mitotic spindle assembly only after the female meiotic divisions are complete (about 40 minutes after fertilization). Therefore, coordination of all cellular events during the meiosis-to-mitosis transition ensures that these two types of spindles do not form at the same time in the newly fertilized embryo. *mel-43* (*sb41*) is a dominant, temperature-sensitive, maternal-effect mutation that is required for early embryonic viability<sup>1</sup>. These mutants exhibit cytoskeleton defects at the end of meiosis II and multiple defects during the first mitotic cell division including cytokinesis, microtubule organization and cell polarity. From our imaging of meiosis *in utero*, the mutant embryos displayed defects in chromatin segregation in anaphase II and failure to extrude the second polar body. Similar to wild type, we found cyclin B1 and katanin levels decreased in the *mel-43*(*sb41*) embryos at the end of meiosis, suggesting that the cell cycle machinery was not grossly affected. These embryos revealed extensive cytoplasmic blebbing as well as improper polarity establishment; however, centrosome maturation occurred normally. Genetic duplication analysis showed that *mel-43*(*sb41*) is a hypermorphic gain-of-function mutation. Sequencing revealed a missense mutation in the coding region of *sb41* worms, and RNAi against *mel-43* rescued this mutant phenotype. *mel-43* is predicted to encode a novel protein, with two highly similar paralogues in *C. elegans*. *mel-43*(RNAi) did not exhibit any obvious phenotype, however, RNAi directed against all paralogues resulted in defects in polar body extrusion at the end of meiosis I. These embryos proceeded directly into mitosis

without forming a meiosis II spindle, suggesting a role for *mel-43* and paralogues in promoting meiosis II-specific events.

**Uncovering the Role of Condensin I during *C. elegans* Meiosis.**

*M. H. Sifuentes<sup>1</sup>, K. Collette<sup>1</sup>, G. Csankovszki<sup>1</sup>; <sup>1</sup>Molecular, Cellular, & Developmental Biology, University of Michigan, Ann Arbor, MI*

Condensin complexes are key determinants of higher-order chromatin structure during meiosis and mitosis in eukaryotes. However the different roles of condensins I and II in meiosis are poorly understood and have yet to be elucidated in higher eukaryotes. Interestingly, analysis of condensin I in *C. elegans*, demonstrates it localizes to a ring shaped domain between chromosomes at the midbivalent during metaphase and to the meiotic spindle between separating chromosomes during anaphase. Other proteins such as the Chromosomal Passenger Complex, BUB-1, KLP-19, HCP-1/2, and CLS-2 also localize to the midbivalent, suggesting that condensin I may function with proteins at the ring shaped domain to promote chromosome orientation, alignment, and separation.

Depletion of condensin I by RNAi interference leads to gross meiotic spindle defects and abnormal chromosome organization. Our data suggests that condensin I supports orientation and movement of chromosomes throughout meiosis. Additionally, condensin I depletion prevents successful chromosome resolution at anaphase.

Future studies will determine how condensin I functions together with other proteins at the midbivalent to influence chromosomal orientation during meiotic congression and segregation in *C. elegans*.

1958

**Non-random segregation of unpaired X chromosomes in *C. elegans* female meiosis.**

*D. B. Cortes<sup>1</sup>, F. McNally<sup>1</sup>; <sup>1</sup>BMCDDB, UC Davis, Davis, CA*

Attachment between homologous chromosomes during meiosis I is essential for accurate segregation of chromosomes. Surprisingly, humans with three X chromosomes (triploX) have normal fertility and give birth predominantly to children with a normal chromosome complement (Neri, 1984. *American Journal of Medical Genetics* 18:357). If the unpaired X segregated randomly at anaphase I, triploX mothers would produce 50% eggs with one X and 50% eggs with two X chromosomes. The low frequency of XXX offspring observed suggests that human female meiosis possesses a mechanism that prevents the inheritance of unpaired X chromosomes. In the *C. elegans* *him-8* mutant, which possesses two unpaired univalent X chromosomes at metaphase I, a similar situation occurs. If the two univalent X chromosomes segregated randomly at anaphase I, *him-8* mutants should produce 25% XO male, 50% XX hermaphrodite and 25% XXX progeny. Instead 38% XO male, 56% XX hermaphrodite and 8% XXX progeny are seen, suggesting that female meiosis in *C. elegans* also possesses a mechanism of selective removal of unpaired X chromosomes (Hodgkin et al., 1979. *Genetics* 91(1):67-94).

We are currently testing the hypothesis that univalent X chromosomes are selectively extruded into the first polar body. Using live imaging and fixed immunofluorescence, we found that 95% of *him-8* metaphase I spindles have 7 chromosomes at metaphase I whereas 100% of wild-type metaphase I spindles have 6 chromosomes. This result demonstrates that both univalent X chromosomes in *him-8* worms are still present during metaphase I. 100% of wild-type

metaphase II spindles have 6 chromosomes whereas 40% of him-8 metaphase II spindles have 5 chromosomes, 55% have 6 chromosomes and 5% have 7 chromosomes. These numbers suggest that univalent chromosomes are lost between metaphase I and metaphase II.

Interestingly, 88% of him-8 anaphase I spindles have 1 or 2 lagging chromosomes, something seen in only 2% of wild-type, suggesting that univalents lag during anaphase I. Quantification of the fates of lagging chromosomes revealed that 63% of these are expelled into the polar body and 37% of them are retained in the embryo. Fixed immunofluorescence of him-8 worms with REC-8 antibody revealed univalent chromosomes that biorient at metaphase I. During anaphase I, lagging univalents were also bioriented. H3K9-trimethylation staining of repetitive DNA arrays specifically integrated on the X chromosomes, suggested that both chromosomes lost in embryos with 5 chromosomes at metaphase II are univalent X chromosomes. Our results are consistent with a model in which univalent X chromosomes biorient at metaphase I but lag at anaphase I because cohesin between sister chromatids is not cleaved. The delayed, poleward movement of these bioriented univalents is biased toward the polar body end of the spindle. Preliminary data suggest that contractile ring activity is necessary for the bias seen in expulsion of lagging chromosomes. Our results reveal a cellular process that might allow production of a euploid embryo from a trisomic oocyte.

1959

**The role of CDK-1 dependent phosphorylation of Dynactin in meiotic spindle rotation in *C. elegans*.**

*J. Flynn<sup>1</sup>, M. Ellefson<sup>1</sup>, A. Andaya<sup>1</sup>, J. Leary<sup>1</sup>, F. McNally<sup>1</sup>; <sup>1</sup>University of California, Davis, Davis, CA*

Meiosis is a specialized cell division required for sexual reproduction characterized by a single round of DNA replication followed by two rounds of chromosome segregation. The molecular machine responsible for accurately segregating chromosomes is the meiotic spindle. In female meiosis, to properly segregate chromosomes the spindle must correctly orient its pole-to-pole axis perpendicular to the cell cortex. In *C. elegans*, this perpendicular orientation is dependent on activation of the anaphase promoting complex (APC), the molecular motor dynein, and the dynein modulator dynactin (Ellefson and McNally, *Mol. Biol. Cell*, 20: 2722). Furthermore, dynein/dynactin dependent rotation was found to be inhibited by CDK-1 (Ellefson and McNally, *J. Cell Biol.* 193: 1229). These results suggested that phosphorylation of a CDK-1 target inhibits dynein-dependent spindle rotation. Analysis of the *C. elegans* phosphoproteome (phosida.com; phosphopep.org) revealed 7 *in vivo* phosphorylation sites within the basic domain of p150 dynactin. We hypothesize that CDK-1-dependent phosphorylation of the p150 basic domain inhibits dynactin from binding microtubules and thus inhibits recruitment of dynein to the spindle during meiotic metaphase. Furthermore, APC-dependent inactivation of CDK-1 would result in dephosphorylation of the basic domain, which would increase binding of dynactin to spindle microtubules and allow spindle rotation. Mutation of all 7 phosphorylation sites to alanine resulted in increased spindle association by the CAP-Gly + basic domains of *C. elegans* p150 dynactin in transfected *Xenopus* A6 cells. Mutation of all 7 sites to glutamate caused reduced spindle association in transfected cells. Because the *C. elegans* phosphoproteome was generated from mixed stage worms, we then attempted to determine the sites within the p150 basic domain that are phosphorylated in a CDK-1-dependent manner during metaphase of meiosis. We found that metaphase extract isolated from *Spisula solidissima* oocytes is able to phosphorylate *C. elegans* dynactin on 4 residues in the basic domain and 3 of these phosphorylations are prevented by the CDK-1 inhibitor, purvalanol A. In the future we will test these sites for their involvement in regulating dynactin microtubule association in both transfected A6 cells and *C. elegans* meiotic embryos.

1960

**Katanin is required continuously during meiotic metaphase to maintain chromosome position and spindle pole structure.**

K. P. McNally<sup>1</sup>, F. McNally<sup>1</sup>; <sup>1</sup>Molecular and Cellular Biology, University of California, Davis, Davis, CA

Katanin is a heterodimeric microtubule-severing ATPase (McNally and Vale, Cell 75:419). In *C. elegans*, the catalytic subunit (MEI-1) and the regulatory subunit (MEI-2) are both required specifically for assembly of female meiotic spindles (Srayko et al. Genes Dev. 14:1072). The P225L mutation in MEI-1 is representative of a class of mutants that assemble meiotic spindles with no ASPM-1 positive poles and produce only dead embryos. The A338S mutation of MEI-1 is representative of a class of mutations that assemble unusually long but fully functional meiotic spindles with two ASPM-1 positive poles. Wild-type MEI-1 but not MEI-1(A338S) or MEI-1(P225L) caused microtubule disassembly when co-expressed with MEI-2 in *Xenopus* A6 cells (McNally and McNally, Mol. Biol. Cell 22:1550). This led to the hypothesis that MEI-1(A338S) lacks microtubule-severing activity but retains a discrete second activity that is required for spindle pole assembly. In this hypothesis, microtubule-severing activity is required only for controlling spindle length and MEI-1(P225L) lacks both severing and pole-forming activities. To further test this hypothesis, we developed methods for purifying active stoichiometric complexes of MEI-1 and MEI-2 from *E. coli*. In vitro microtubule-severing assays revealed that at 0.5 uM MEI-1/MEI-2 completely disassembled microtubules in 4 min whereas MEI-1(A338S)/MEI-2 exhibited no microtubule disassembly. In contrast, at 1.0 uM, MEI-1(A338S)/MEI-2 exhibited microtubule severing that was just kinetically slower than that of wild type. MEI-1(P225L)/MEI-2 showed no microtubule disassembly activity at concentrations up to 2.0 uM. Wild-type MEI-1 in the absence of MEI-2 severed microtubules but only at concentration of 3 to 4 uM. To elucidate whether microtubule severing is likely occurring in meiotic embryos of MEI-1(A338S) or MEI-2(null) mutants, we are currently determining the in vivo concentration of MEI-1 and MEI-2. As a second approach to understanding the relationship between katanin-dependent spindle length control and katanin-dependent spindle pole assembly, we have begun analysis of a fast-acting temperature sensitive mutation in MEI-1 (O'Rourke et al. PlosOne, 6: e16644 ). We depleted worms of the anaphase promoting complex subunit, MAT-1, by RNAi at permissive temperature to allow accumulation of embryos with pre-formed metaphase I spindles. We then used both live spinning disk confocal microscopy and fixed immunofluorescence to determine the fate of the spindle immediately after shifting to non-permissive temperature. The earliest and most surprising phenotype observed was movement of metaphase chromosomes to the poles. Spindles then elongated and then became disorganized. Fixed immunofluorescence indicated that ASPM-1 moved from the poles onto the spindle microtubules before dissociating. These results show for the first time that katanin activity is required after initial spindle assembly for maintenance of chromosome position, spindle length and spindle pole structure.

1961

**Spire-type actin nucleators cooperate with Formin-2 to drive asymmetric oocyte division.**

S. Pfender<sup>1</sup>, V. Kuznetsov<sup>1</sup>, S. Pleiser<sup>2</sup>, E. Kerkhoff<sup>2</sup>, M. Schuh<sup>1</sup>; <sup>1</sup>Medical Research Council-Laboratory of Molecular Biology, Cambridge, United Kingdom, <sup>2</sup>University Hospital Regensburg, Regensburg, Germany

Oocytes mature into eggs by extruding half of their chromosomes in a small cell termed the polar body. Asymmetric oocyte division is essential for fertility, but despite its importance, little is known about its mechanism. In mammals, the meiotic spindle initially forms close to the centre of the oocyte. Thus, two steps are required for asymmetric meiotic division, first, asymmetric

spindle positioning, and second, polar body extrusion. Here, we identify Spire1 and Spire2 as new key factors in asymmetric division of mouse oocytes. Spire proteins are novel types of actin nucleators that drive nucleation of actin filaments with their four WH2 actin binding domains. We show that Spire1 and Spire2 first mediate asymmetric spindle positioning by assembling an actin network that serves as a substrate for spindle movement. Second, they drive polar body extrusion by promoting assembly of the cleavage furrow. Our data suggest that Spire1 and Spire2 cooperate with Formin-2 to nucleate actin filaments and that both types of nucleators act as a functional unit. This study not only reveals how Spire1 and Spire2 drive two critical steps of asymmetric oocyte division, but it also uncovers the first physiological function of Spire-type actin nucleators in vertebrates.

1962

**Meiotic HORMA domain proteins prevent untimely centriole disengagement during male meiosis.**

M. Schvarzstein<sup>1</sup>, D. Pattabiraman<sup>1</sup>, J. Bembene<sup>2</sup>, A. Villeneuve<sup>1</sup>; <sup>1</sup>Stanford Medical School, Stanford, CA, <sup>2</sup>University of Tennessee, Knoxville, TN

Successful embryonic development requires that at fertilization each gamete provide complementary components the zygote. One such component is the centrosome, which influence the organization of the microtubule arrays within the cell. Centrosomes are formed by either one or two cylindrical microtubule structures called centriole(s) that recruit pericentriolar proteinaceous material. In species where oocytes lack centrosomes, sperm must contribute both haploid genome and centrioles to the zygote. Correct centriole organization during male meiosis is critical to ensure normal bipolar mitotic spindle in the zygote. We identified a new role for *C. elegans* meiosis HORMA domain proteins, HIM-3, HTP-1 and HTP-2, in regulating centriole dynamics during spermatocyte meiosis. In *C. elegans*, centrioles undergo two rounds of duplication during male meiosis, resulting in haploid sperm each containing a single tightly engaged centriole pair. Since centriole disengagement can license centriole duplication, spermatocytes must tightly regulate centriole disengagement to ensure that sperm inherit a single centriole pair. In the horma mutants, we observe inappropriate separation of centrioles during meiosis II, resulting in separated centrioles in sperm. Further, an extra pair of centrosomes is detected in a subset of zygotes, reflecting a single additional round of centriole duplication that was enabled by aberrant centriole disengagement in the spermatocytes. These and other data implicate meiotic HORMA proteins in preventing centriole disengagement in meiosis II. We showed previously that HTP-1/2 associates with chromosomes and prevents premature loss of sister chromatid cohesion during the meiotic divisions by inhibiting removal of the REC-8 meiosis-specific cohesin subunit. We find that *rec-8* cohesin mutant spermatocytes have similar inappropriate centriole separation phenotypes to those observed in *htp-1/2* mutants. Further, a mutant form of separase that exhibits elevated concentration at meiosis II spindle poles and in budding spermatids likewise promotes inappropriate centriole separation, consistent with HORMA proteins preventing centriole disengagement by antagonizing separase-dependent cohesin removal. Our data suggest that the same specialized meiotic mechanisms that prevent premature release of sister chromatid cohesion during meiosis I also function to inhibit centriole disengagement at meiosis II, thereby ensuring that the zygote inherits the appropriate complement of chromosomes and centrioles.

Here we will also report our current investigation on both the molecular mechanisms preventing untimely separation of centrioles and on the role of other proteins in centrosome inheritance during gametogenesis.

1963

**Sub-optimal APC activity following SAC satisfaction reduces aneuploidy in mouse oocytes.**S. I. Lane<sup>1</sup>, K. T. Jones<sup>1</sup>; <sup>1</sup>University of Newcastle, Newcastle, Australia

It has long been established that oocytes have a poor ability to divide their chromosomes faithfully during the first meiotic division, resulting in the generation of aneuploid embryos. This is in contrast to the high fidelity of chromosome segregation in somatic cells. Recently we, and others, have demonstrated in oocytes that Spindle Assembly Checkpoint (SAC) satisfaction is coupled to a majority kinetochore-microtubule attachment, but chromosomes neither have to be congressed on the metaphase plate nor bi-oriented, thus creating the potential for aneuploidy. Additionally, exit from meiosis I is characterised by a long period of APC mediated cyclin B1 and securin destruction culminating in anaphase. We hypothesise therefore that in oocytes, this delayed exit from meiosis I following SAC satisfaction helps to prevent aneuploidy.

To examine this idea further we added flavopiridol, a CDK1 inhibitor, to mouse oocytes maturing in culture, at a time following APC activation (observed by the degradation of cyclin B1-GFP during timelapse microscopy). CDK1 inhibition significantly increased APC activity, bringing forward anaphase-onset by >1 hour, and also raising aneuploidy rates. Furthermore, addition of reversine, an Mps1 inhibitor, or ZM447439, an Aurora kinase inhibitor, or microinjection of Mad2 antibody, all increased APC activity. Given these latter interventions are predicted to ameliorate SAC activity, we propose that the APC in oocytes, although active in degrading cyclin B1, continues to be negatively regulated by the SAC and CDK1 activity throughout meiosis I. The delay caused by this restriction of APC activity may allow oocyte aneuploidy to be significantly lowered in a system where attachment errors cannot generate a signal capable of full APC inhibition.

1964

**Determining the mechanism of zinc transporters in zinc accrual during meiosis in the mammalian oocyte.**B. Y. Kong<sup>1</sup>, F. E. Duncan<sup>1</sup>, T. O'Halloran<sup>2,3</sup>, T. K. Woodruff<sup>1,3</sup>; <sup>1</sup>Department of Obstetrics and Gynecology, Northwestern University, Chicago, IL, <sup>2</sup>Department of Chemistry, Northwestern University, Evanston, IL, <sup>3</sup>Department of Molecular Biosciences, Northwestern University, Evanston, IL

Zinc is a biologically essential transition metal with well-established roles in many molecular and cellular processes. Recently, we demonstrated that zinc regulates meiosis in the mammalian oocyte. Based on synchrotron x-ray fluorescence microscopy, the total intracellular zinc content in mouse oocytes is nearly a magnitude higher than copper or iron, and increases by over 50% during meiotic maturation which occurs over approximately 14 hours. This increase is required for proper meiotic progression as limiting intracellular zinc availability results in premature arrest at telophase I. Although this accumulation of total zinc is necessary, it is not known how labile zinc changes during meiotic maturation or how zinc levels are modulated. We performed in vitro maturation to obtain oocytes at prophase I, metaphase I, and metaphase II. Using a novel zinc-specific fluorophore, we tracked labile zinc using live imaging at these stages of meiosis. Following zinc imaging, cells were fixed and stained for cortical granules, secretory vesicles required for modification of the zona pellucida at fertilization. Zinc localized to discrete vesicle-like structures that were symmetrically distributed in the cortex during prophase I but was highly polarized at metaphase II. Zinc appeared to have a similar localization as cortical granules. To determine how intracellular zinc levels may be regulated during meiosis, we examined the role of zinc transporters. Of the 14 known mammalian zinc transporters that increase intra-

cytoplasmic zinc levels, zip10 had the highest mRNA levels in the oocyte compared to over 60 other mammalian tissues as determined by microarray analysis. We generated a ZIP10-specific antibody; immunostaining of ZIP10 protein in the oocyte revealed a predominantly cortical distribution with a polarized pattern in the prophase I, metaphase I and metaphase II staged oocytes. ZIP10 localization was thus similar to that of both labile zinc and cortical granules. These results suggest that ZIP10 may be the regulatory pathway by which the oocyte acquires zinc from the extracellular environment during meiosis. Current experiments are focused on determining how zinc insufficiency affects ZIP localization and function and how meiotic progression is affected by disruption of ZIP10 expression. Supported by NIH Grant P01 HD021921 and the W. M. Keck Foundation Medical Research Award. B.Y. Kong is a recipient of the American Association of University Women award.

1965

### **Effects of taxol on chromosome movements in *Mesostoma* spermatocytes.**

C. Hoang<sup>1</sup>, A. Forer<sup>1</sup>; <sup>1</sup>Biology, York University, Toronto, ON, Canada

Dividing *Mesostoma ehrenbergii* spermatocytes have 3 bivalent chromosomes that oscillate 4-6µm to and from the poles throughout prometaphase/metaphase and 4 univalent chromosomes that sit at the poles. Notably, univalents sometimes move from one pole to another to achieve correct segregation. We added various concentrations of taxol to dividing spermatocytes and found that 10nM taxol was the minimum concentration needed to stop bivalent oscillations. Oscillations resumed 24-42 minutes after the taxol was washed out, with normal velocities but reduced amplitudes. In 10nM taxol, most kinetochores stopped their oscillations toward the poleward side of their normal oscillation cycle, not toward the equator. Cells in taxol with stopped bivalents entered anaphase nonetheless, with chromosome velocities approximately 58% of those in control cells. Univalent movements also occurred in taxol while bivalents were stopped. Assuming that at this low concentration of taxol microtubules (MTs) were stabilized by reducing MT dynamics at the kinetochore (plus) end (Derry et al. 1995), our data suggest that during bivalent oscillations, movements towards the pole require depolymerization of kinetochore MTs at the pole and movements away from the pole require polymerization of kinetochore MTs at the kinetochores. Oscillations are blocked with kinetochores toward the pole because movements away from the pole are blocked when kinetochore MT plus ends are stabilized. We hypothesize that anaphase takes place in the presence of taxol as a result of MT depolymerizing or MT severing enzymes described by Rath and Sharp (2011) increasing their activity at the onset of anaphase.

1966

### **Cdk1-Cyclin B Activity Regulates the Timing of Formation of Stable Kinetochore-Microtubule Attachments in Meiosis I.**

O. Davydenko<sup>1</sup>, R. M. Schultz<sup>1</sup>, M. A. Lampson<sup>1</sup>; <sup>1</sup>Department of Biology, University of Pennsylvania, Philadelphia, PA

Chromosome segregation during cell division depends on stable attachment of kinetochores to spindle microtubules. Mitotic spindle formation and kinetochore-microtubule capture typically occur within ~30 min. In contrast, in meiosis I in mouse oocytes, the bipolar spindle forms within 3-4 hours, but formation of stable kinetochore-microtubule attachments is delayed for an additional 3-4 hours. The mechanism underlying this delay, which likely prevents attachment errors during spindle formation, is unknown. Cdk1-Cyclin B activity increases rapidly at mitotic entry and then remains stable, whereas in meiosis I Cyclin B protein levels and Cdk1 activity increase slowly over a period of ~6 hours. This difference suggests that levels of Cdk1 activity may control the timing of formation of stable kinetochore-microtubules. To test this hypothesis

we manipulated Cdk1 activity in mouse oocytes in two ways. First, reducing Cdk1 activity using low levels of an inhibitor led to delayed formation of stable attachments and late anaphase I onset. Second, over-expression of Cyclin B led to a faster increase in Cdk1 activity and early formation of stable attachments. These results indicate that the slow increase in Cdk1 activity in meiosis I acts as a timing mechanism to control kinetochore-microtubule interactions. We also tested whether inter-kinetochore tension and Aurora B kinase, known regulators of attachment stability, also contribute in meiosis I. We show that disrupting tension by premature loss of cohesion prevents full stabilization of attachments, while Aurora kinase inhibition leads to hyper-stability. We conclude that formation of stable kinetochore-microtubule attachments in meiosis I depends on both established mechanisms and high levels of Cdk1-Cyclin B activity that are reached late in metaphase I.

1967

**Protein 14-3-3 eta (YWHAH) is essential for normal meiotic spindle assembly during *in vitro* maturation of mouse oocytes.**

S. De<sup>1</sup>, S. Davis<sup>1</sup>, D. Letwin<sup>1</sup>, C. Mozena<sup>1</sup>, D. Kline<sup>1</sup>; <sup>1</sup>Biological Sciences, Kent State University, Kent, OH

The 14-3-3 (YWHA) proteins are known to be central mediators in various cellular signaling pathways regulating development and growth including cell cycle regulation. We previously found that all seven mammalian 14-3-3 isoforms are expressed in mouse oocytes and eggs, and that 14-3-3 eta (YWHAH) accumulates and co-localizes in the region of meiotic spindle in mouse eggs matured *in vivo* [De, S. et al., 2012, BMC Res Notes. 5(1), 57]. Examination of oocytes matured *in vitro* demonstrated that 14-3-3 eta accumulates in both meiosis I and II spindles. To examine the role of 14-3-3 eta in meiotic spindle formation, we microinjected mouse oocytes with a ~0.1mM translation-blocking morpholino oligonucleotide against 14-3-3 eta mRNA. The morpholino-injected oocytes were held in prophase I arrest for 24 hours to allow reduction of existing 14-3-3 eta protein and then allowed to mature *in vitro*. Meiotic spindles in those cells were examined by immunofluorescence staining of 14-3-3 eta and alpha-tubulin along with observation of chromosomes stained with Hoechst dye. Following injection of the morpholino, the spindle was often found to be absent or abnormally formed along with no or reduced accumulation of 14-3-3 eta. In those cells, chromosomes were clumped or disorganized and first polar body formation was absent. Immunofluorescence staining of 14-3-3 eta and alpha-tubulin in control eggs matured *in vitro* from uninjected oocytes and oocytes microinjected with the ineffective, inverted form of a morpholino against 14-3-3 eta, a morpholino against 14-3-3 gamma or deionized water showed normal, bipolar meiosis II spindle assemblies. To further examine the interaction of 14-3-3 eta with alpha-tubulin in meiotic spindles, we performed an *in situ* proximity ligation assay (Duolink In-cell Co-IP; Olink Bioscience) that can detect protein-protein interactions at the single molecule level directly in cells and allows visualization of the actual sites of the interactions. In control eggs, the proximity ligation assay revealed an accumulation of sites of interaction between 14-3-3 eta and alpha-tubulin at the normal meiotic spindles and in the cell cortices adjacent to the spindles, confirming the co-immunofluorescence finding we reported before. However, in cells matured *in vitro* from oocytes microinjected with the morpholino against 14-3-3 eta, there was a marked reduction in the interaction sites for 14-3-3 eta and alpha-tubulin in the regions of the disrupted spindles. These results suggest that 14-3-3 eta is essential for formation of the normal meiotic spindle during *in vitro* maturation of mouse oocytes, in part by interacting with alpha-tubulin.

**RNA activates Aurora B kinase to promote meiotic spindle assembly.**

A. Jambhekar<sup>1</sup>, S. Nadarajan<sup>2</sup>, M. Colaiacovo<sup>2</sup>, M. Blower<sup>1</sup>; <sup>1</sup>Molecular Biology, Massachusetts General Hospital, Boston, MA, <sup>2</sup>Genetics, Harvard Medical School, Boston, MA

Spindle assembly during cell divisions is a highly controlled process that is regulated by many proteins encompassing a wide range of activities. Our group has shown that, in addition to protein factors, RNA functions in a translation-independent manner to promote spindle assembly. However, the mechanisms by which RNA operates have been unclear. We have now found that one role of RNA is to regulate the kinase Aurora B. Aurora B, the catalytic subunit of the chromosome passenger complex (CPC), plays an important role in aligning chromosomes at metaphase and ensuring their segregation at anaphase and telophase. Its localization and activity are regulated by the other members of the CPC, which stimulate kinase activity and localize it to the inner centromere during metaphase. We have found that RNA is required for maximal Aurora B kinase activity and localization to inner centromeres. One of the main functions of Aurora B during metaphase in *Xenopus* egg extracts is to phosphorylate and inactivate the microtubule depolymerizing kinesin MCAK. Accordingly, inhibiting MCAK largely restores spindle formation in the absence of RNA. Aurora B can be detected in a large RNA-dependent complex, and many of the associated proteins are classified as RNA-binding proteins. Analyzing the transcripts bound to Aurora B revealed that the RNA-binding profile varies between cell-cycle stages, and that some transcripts are specifically bound to Aurora B upon activation by chromatin or microtubules. Finally, we have shown an unprecedented function for one of the associated RNA-binding proteins in localizing Aurora B to meiotic chromosomes in *C. elegans*. These results elucidate a molecular pathway by which RNA influences spindle assembly by serving as a scaffold for protein complex assembly, and suggest a novel mechanism for regulating enzyme functions.

**Characteristics of DNA in meiotic recombination hotspots.**

O. Miura<sup>1</sup>, H. Kimura<sup>1</sup>, T. Ogake<sup>1</sup>, T. Ohyama<sup>1</sup>; <sup>1</sup>Biology, Waseda Univ, Tokyo, Japan

Based on Oxford Dictionary of Biochemistry and Molecular Biology, "genetic information" is defined as "the information carried in a sequence of nucleotides in a molecule of DNA or RNA". Indeed, the genetic code is 'written' in a sequence of nucleotides. Then, is the genetic information carried only in the sequence of nucleotides? The answer is "No". It is also carried in conformation and physical properties of DNA, histones or chromatin. Deciphering the veiled 'code' carried in them is one of the key issues in the current era of epigenetics. We are studying this challenging issue with focusing on the meiotic recombination hotspots.

The current study focused on the genetic background that generates recombination hotspots at meiosis. These sites do not have any consensus sequence. Thus, using the genome databases of *Saccharomyces cerevisiae* and *Mus musculus*, we examined characteristics of the mechanical properties of the hotspots. When averaged, a common distinctive mechanical property was clearly detected at the center region of the hotspots for both organisms. However, very interestingly, the properties themselves were opposite between *S. cerevisiae* and *M. musculus*: i.e., the center region is very rigid in the former while very flexible in the latter. We are now analyzing how these differences are reflected in the conformations of hotspots using atomic force microscopy.

1970

### Characterizing Genetic Variation in PRDM9 and its Association with Altered Patterns of Recombination Linked to Chromosome 21 Nondisjunction.

T. R. Oliver<sup>1</sup>, A. Harden<sup>1</sup>, C. Walker<sup>1</sup>, S. Sherman<sup>2</sup>; <sup>1</sup>Department of Biology, Spelman College, Atlanta, GA, <sup>2</sup>Department of Human Genetics, Emory University, Atlanta, GA

Nondisjunction (NDJ) of chromosome 21 is the leading cause of trisomy 21, a condition characterized by severe intellectual disability, more commonly known as Down syndrome. Altered patterns of recombination on 21q have long been identified as risk factors for chromosome 21 NDJ. Interestingly, recent studies have shown that variation in the Zinc Finger Binding Domain (ZFBD) of the protein Proline Rich Domain Containing 9 (PRDM9) is associated with altered patterns of recombination. As PRDM9 is a major determinant of the placement of recombination, we hypothesize that variation in the ZFBD of PRDM9 promotes the altered patterns of recombination that predispose chromosome 21 to nondisjoin. We are currently sequencing the ZFBD of DNA collected from over 400 parents who had a chromosome 21 NDJ error leading to an offspring with trisomy 21 (100 paternal cases, 300 maternal cases). If our hypothesis is correct, the distribution of ZFBD alleles identified in the cases should vary from that of the normal population and be correlated with the altered placement of recombination on chromosome 21. These findings may help identify genetic factors that predispose to nondisjunction and refine the risk of having a child with trisomy 21.

1971

### Regulation of glucose metabolism and cytoplasmic streaming by *Txnip* during oocyte maturation.

S-Y. Lee<sup>1</sup>, H-S. Lee<sup>1</sup>, E-Y. Kim<sup>1</sup>, K-A. Lee<sup>1</sup>; <sup>1</sup>Department of Biomedical Science, CHA university, Seoul, Korea

Previously, we found higher *Txnip* mRNA expression in germinal vesicle (GV) compared to metaphase II (MII) oocytes. *Thioredoxin interacting protein (Txnip)* binds to *Thioredoxin (Trx)* and regulates intracellular redox state. In addition, via *Trx*-independent mechanism, *Txnip* regulates glucose metabolism for maintaining intracellular glucose concentration. However, *Txnip* function in mouse oocytes was not yet known. Therefore, the objective of present study was to determine the function of *Txnip* during mouse oocyte maturation using RNAi.

For *Txnip* RNAi, we performed microinjection of *Txnip* dsRNA into the cytoplasm of GV oocytes. By *Txnip* RNAi, most of oocytes (79.5%) were arrested at metaphase I (MI) stage whereas control (81.25%) or buffer-injected (76.3%) oocytes normally progressed to MII stage. When we used time lapse video microscopy to observe phenotypic changes during oocyte maturation, formation of granules in the oocyte cytoplasm increased after *Txnip* RNAi concurrent with the retarded cytoplasmic streaming. We supposed that these granules were glycogen molecules formed by upregulated lactate production via gluconeogenic pathway following increased glucose uptake by *Txnip* RNAi. For monitoring glucose uptake, oocytes were treated with 2-(N-(7-Nitrobenz-2-oxa-1,3-diazol-4-yl)Amino)-2-Deoxyglucose (2-NBDG), a fluorescent glucose analog and lactate production was measured using the lactate colorimetric assay kit. After *Txnip* RNAi, not only glucose uptake but also lactate production increased in *Txnip* RNAi-treated oocytes compared to control oocytes. When oocytes were incubated in high lactate-supplemented medium, we observed increased granule formations and retarded cytoplasmic streaming similar to the phenotypic changes observed in *Txnip* RNAi-treated oocytes. Thus, we concluded that *Txnip* RNAi increased lactate production and glucose uptake, and resulted in formation of cytoplasmic glycogen granules. In addition, using immunofluorescence staining, we

observed scattered microtubules and aggregated chromosomes in *Txnip* RNAi-treated oocytes. These results indicate that actin networking was disturbed and thus cytoplasmic streaming was retarded by *Txnip* RNAi.

This study was supported by a grant of the Korea Healthcare Technology R&D Project, Ministry for Health, Welfare & Family Affairs, Republic of Korea (A084923), and by Priority Research Centers Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education, Science and Technology (2009-0093821).

1972

**Mitochondria are inherited asymmetrically during the first meiotic division.**

*C. M. Dalton<sup>1</sup>, J. Carroll<sup>1</sup>; <sup>1</sup>Cell and Developmental Biology, UCL, London, United Kingdom*

Most cell divisions result in the production of two equally sized daughter cells each of which inherit half of the DNA and an equal proportion of cellular organelles. The highly asymmetric cell divisions of female meiosis provide a different challenge because one of the daughters, the polar body, is destined to degenerate, putting at risk essential maternally-inherited organelles such as mitochondria. Whilst the division of DNA during this cytokinesis must be equal, the loss of important cellular organelles to the polar body could be detrimental to oocyte health. This may be particularly relevant in the case of mitochondria which provide the primary source of ATP during oocyte maturation and early embryogenesis due to a block in glycolytic activity that lasts until the blastocyst stage. Furthermore, mitochondrial replication is suppressed in the fully grown oocyte and does not resume until after implantation, such that the mitochondrial complement contained within the oocyte must be capable of sustaining the early stages of mammalian development. However, little is known about how cytoplasmic organelles are organised and distributed during this time.

We find that during oocyte maturation, 42% of mitochondria aggregate around the first meiotic spindle. Disruption of dynein activity using the function-blocking antibody 70.1 decreases the extent of mitochondrial aggregation to 26%, ( $p < 0.001$ ), indicating a role for dynein in this process. Conversely, inhibition of kinesin-1 activity using the function-blocking antibody SUK4 increases mitochondrial aggregation to 54%, ( $p < 0.005$ ) implying a role for kinesin-1 in regulating the extent of mitochondrial association with the spindle.

The arrangement of mitochondria around the spindle places them in an ideal position to be equally segregated between oocyte and polar body, with a resulting loss of ATP generating capacity in the oocyte and early embryo. However, we show that at cell division there is a profound reorganisation of mitochondria into an asymmetrical arrangement. Mitochondria are anchored in the cytoplasm of the oocyte and largely excluded from the polar body, with the result that the percentage area occupied by mitochondria in the oocyte is significantly higher than that in the polar body ( $23.7\% \pm 1\%$  vs  $4.8\% \pm 1\%$ ,  $p < 0.0001$ ). Using live cell imaging we show that this rearrangement is initiated around the time of anaphase, and is inversely correlated with the spindle-cortex distance. By inhibiting spindle migration we show that asymmetrical mitochondrial inheritance requires spindle-cortex proximity but find that this alone is not sufficient to initiate asymmetry. Arresting the cell cycle at metaphase with the spindle positioned at the cortex reveals that cell cycle progression is also a requirement for asymmetrical mitochondrial inheritance.

Thus, oocyte-biased inheritance of mitochondria is a variation on rules that normally govern cell division and ensures that essential maternally inherited mitochondria are retained to provide ATP for early mammalian development.

### Molecular mechanisms of axon pruning in the CNS.

B. S. McAdory<sup>1</sup>, M. M. Riccomagno<sup>2</sup>, J. G. Macopson<sup>2</sup>, J. Shinn<sup>2</sup>, M. G. Kazanietz<sup>2</sup>, A. L. Kolodkin<sup>2</sup>; <sup>1</sup>Biological Sciences, Tennessee State University, Nashville, TN, <sup>2</sup>Neuroscience, Johns Hopkins Medical Institute, Baltimore, MD

Axon pruning and synapse elimination are critical for both the establishment of neural connectivity and synaptic plasticity. Axon pruning involves removal of ectopic, or misguided, axonal branches that have already formed synaptic connections, thus synapse elimination usually precedes pruning. Stereotyped pruning of axons that originate in the hippocampal dentate gyrus (DG) and extend in the infrapyramidal tract (IPT) occurs during postnatal murine development by neurite retraction and superficially resembles axon repulsion. The chemorepellent Sema3F and its holoreceptor complex neuropilin-2 (Npn-2)/plexinA3 (PlexA3) are required for IPT axon pruning, in addition to dendritic spine remodeling and repulsion of DG axons. The objective of our study was to determine the signaling events that act downstream of Sema3F to regulate IPT axon pruning. Consequently, we uncovered a novel role for Sema3F-mediated activation of the Rac-GAP  $\beta$ 2 chimaerin (Chn) in stereotyped IPT axon pruning and synapse elimination.  $\beta$ 2Chn is required for axon pruning, but not for Sema3F-mediated axon guidance or dendritic spine constraint. Therefore, this selective requirement for  $\beta$ 2Chn defines a mechanistic distinction among axon pruning, repulsion, and dendritic spine remodeling, all of which are mediated by Sema3F. Here, we conducted structure-function analyses *in vitro* and *in vivo* that shed new light onto these signaling events using biochemical and molecular genetic approaches. We first asked whether the lipid binding and the SH2 domains of  $\beta$ Chn are required for Npn2 binding *in vitro*, given the known requirement for these domains in a closely related protein,  $\alpha$ Chn, for Ephrin-dependent motor circuit assembly. To test the importance of these domains for IPT pruning *in vivo*, we performed rescue experiments employing stereotactic injection of viral vectors containing WT,  $\Delta$ SH2 or C246A (lipid-binding deficient)  $\beta$ Chn. We also analyzed other CNS tracts that are dependent on neuropilin/plexin signaling for axon pruning, including the hippocampo-septal (HST) and visual corticospinal (vCST) tracts by performing *in vivo* tracing experiments in WT and Chn2<sup>-/-</sup> mice. In conclusion, these experiments unveil the critical molecular events that mediate axon pruning, and they also lend insight into the differences and similarities between axon guidance and axon pruning during neural development.

1974

### Ribosomal transport in Schwann cells: a role for myelination in peripheral nervous system regeneration.

J. M. Love<sup>1</sup>, S. B. Shah<sup>2</sup>; <sup>1</sup>Bioengineering, University of Maryland, College Park, College Park, MD, <sup>2</sup>Orthopaedic Surgery, University of California, San Diego, La Jolla, CA

Local protein synthesis within the axon is known to play a significant role in its regeneration following injury. Schwann cells have also been noted to enhance regeneration but generally are

considered in the capacity of guiding outgrowth and providing trophic factors. Recent evidence has shown ribosomes are transferred *in vivo* from Schwann cells to neurons following axonal injury. Much of this phenomenon has yet to be identified including the underlying mechanisms initiating and driving this process, the development of transferrable ribosomal populations within Schwann cells, and the coupling of this process with that of axonal regeneration. We have developed an *in vitro* myelination system to test several aspects of this process. In this study, we examined the recruitment of ribosomal populations to the SC-neuron boundary through transport during myelination and following injury, and the role that myelination plays in axonal regeneration. Embryonic rat DRG cultures purified for two weeks were supplemented with P2 Schwann cells from sciatic nerves and induced to myelinate through the addition of 50  $\mu\text{g/ml}$  ascorbic acid (AA) to culture media. Schwann cells were transfected with a plasmid encoding the ribosomal subunit L4 tagged with GFP to track ribosomal transport and distribution within Schwann cells. Transport of ribosomes was tracked by time-lapse confocal fluorescence imaging with observations made prior to myelination, during early myelination (3 days post-AA), and late myelination (10+ days post-AA). Corresponding experiments were performed in which either unmyelinated or myelinated axons were severed and allowed to regrow for 3 hours. Images were taken every 10 minutes and axonal lengths measured. Rates of transport within Schwann cells reflected a decrease between initial transfection (.976  $\mu\text{m/s}$ ) and early myelination (.369  $\mu\text{m/s}$ ), suggesting a development of residual gradients within projections. Additionally, punctate ribosomal populations were observed on the order of every 30  $\mu\text{m}$ . This value was similar to the known distribution of Schmidt-Lanterman incisures, major candidates for sites of ribosomal transfer. Preliminary data fails to identify a statistically significant difference between axonal regrowth following injury in myelinated (21.27  $\mu\text{m/hr}$ ) and unmyelinated (18.06  $\mu\text{m/hr}$ ) cultures ( $p > .05$ , student's t-test). It is possible that at early time points, myelination physically bars axonal elongation, with positive effects not seen till later time points. In the future it is our desire to investigate the role of axo-glia signaling in this process through the manipulation of calcium and ATP.

1975

#### **A role of the Rac1-TC10 axis in neurite outgrowth.**

*T. Nakamura<sup>1</sup>, A. Fujita<sup>1</sup>, S. Yasuda<sup>1</sup>, S. Koinuma<sup>1,2</sup>, H. Nagai<sup>1</sup>, N. Wada<sup>2</sup>; <sup>1</sup>Research Institute for Biomedical Sciences, Tokyo University of Science, Noda, Japan, <sup>2</sup>Faculty of Science and Technology, Tokyo University of Science, Noda, Japan*

Neurite outgrowth is essential for both the initial wiring of neuronal networks during development and regeneration. We have previously shown that Rac1 is locally activated at neurite tips in a variety of neuritogenic processes although the mechanisms of Rac1 activation vary widely. It is well known that the promoting effect of Rac1 on neuritogenesis is mainly through cytoskeletal reorganization. However, neurite outgrowth also requires a local increase in the surface area, which relies on anterograde transport of membrane vesicles. Recently, TC10, which is a Rho family GTPase and located to vesicles and the plasma membrane, has been shown to be required for axonal growth. We are pursuing the possibility that the Rac1-TC10 axis contributes to neurite outgrowth through the membrane addition to neurite tips. In EGF-treated HeLa cells, we previously found that TC10 activity at tethered vesicles dropped immediately before the fusion to the plasma membrane through the Rac1-mediated pathway. In combination with other functional assays, we have proposed that GTP hydrolysis by TC10 is a critical step in vesicle fusion. By using TC10 FRET sensors, here we have shown that TC10 activity decreased on the plasma membrane in parallel with the extension of cell periphery in a range of neuronal cells including hippocampal neurons. In PC12 cells, NGF or dbcAMP treatment rapidly decreased the level of GTP-TC10. This down-regulation was mediated by Rac1 and ROS generation. We found that TC10 activity at the vesicles was markedly higher than that at the plasma membrane

in NGF-treated PC12 cells. We note that TC10 frequently resided on the vesicles containing Rab11, which is a key regulator of recycling endosomal pathways and has been shown to play a role in neurite outgrowth as well as TC10. We think that the role of GTP hydrolysis by TC10 in membrane fusion might be applicable to neurite outgrowth.

1976

**Real-time dynamics of autophagosome assembly in primary neurons indicate biogenesis proceeds via a conserved but spatially regulated mechanism.**

*S. Maday<sup>1</sup>, E. L. Holzbaur<sup>1</sup>; <sup>1</sup>Department of Physiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA*

Neurons are post-mitotic and thus particularly dependent on efficient degradative pathways such as autophagy to maintain neuronal homeostasis. In fact, neuron-specific depletion of genes required for autophagy is sufficient to cause neuronal cell death. Further, multiple neurodegenerative diseases characterized by excessive protein aggregation exhibit pronounced defects in autophagy. Despite the clear implication of defective autophagy in disease, little is known about the basic mechanisms driving autophagy in neurons. Using live-cell imaging, we investigated autophagosome biogenesis and maturation in primary dorsal root ganglion neurons expressing the autophagosome marker GFP-LC3. We have previously shown that autophagosomes are robustly transported along the axon toward the cell soma in primary neurons. As they move distally to proximally, they undergo maturation into compartments that may more effectively catalyze the degradation of cargo. To determine the source of these retrogradely moving autophagosomes, we imaged the neurite tip and observed constitutive and preferential generation of autophagosomes in the distal axon. Autophagosome formation is initiated with the ordered appearance of Atg13 and Atg5. Atg13 has been previously shown to function in the initial steps of biogenesis by regulating the induction of autophagy, while Atg5 is important for the recruitment of LC3 to the nascent autophagosome structure. We observed de novo appearance of puncta positive for Atg13 and Atg5 that grow progressively in size, followed by recruitment of GFP-LC3. Atg13 and Atg5 then disassemble from the nascent autophagosome leaving the GFP-LC3-positive puncta to grow progressively into ring structures ~800 nm in diameter. These developing autophagosomes are generated in close apposition to the endoplasmic reticulum (ER). Atg13 puncta appear on or near ER structures and often co-migrate with the ER in the distal axon. Further, autophagosomes are enriched in luminal and membraneous components of the ER that persist during transport along the axon toward the cell soma. Taken together, autophagosome formation in primary neurons involves an ordered recruitment of autophagosome assembly factors and a proximal relationship with the ER. Thus, the pathway of autophagosome biogenesis in primary neurons appears to be conserved from yeast and nonpolarized mammalian cells, however, the spatial restriction of autophagosome formation to the distal axon is distinct. Supported by NIH NS060698 to EH.

1977

**Slow axonal transport driven by directional actin treadmilling.**

*H. Katsuno<sup>1</sup>, M. Toiyama<sup>1</sup>, Y. Sakumura<sup>1,2</sup>, K. Ikeda<sup>1</sup>, K. Mizuno<sup>3</sup>, N. Inagaki<sup>1</sup>; <sup>1</sup>Nara Institute Science and Technology, Ikoma, Japan, <sup>2</sup>Aichi Prefectural University, Nagakute-cho, Aichi-gun, Japan, <sup>3</sup>Tohoku University, Sendai, Japan*

Axonal transport is essential for the growth, maintenance and regeneration of axons, and categorized into the fast component (2-5  $\mu\text{m/s}$ ), slow component a (0.002-0.01  $\mu\text{m/s}$ ) and slow component b (0.02-0.09  $\mu\text{m/s}$ ). Slow component b conveys more than 200 proteins including actin and actin binding proteins. The fast component and slow component a are thought to be transported by kinesins and dyneins along microtubules, however the mechanism for slow

component b has been not well known since it was first reported more than 30 years ago. Previous report showed that an actin rich structure called wave h moves along the axonal shaft at the rate of slow component b, thereby suggesting that the wave transports slow component b (Ruthel & Banker, *Cell Motil. Cytoskeleton*, 1998; Flynn et al., *Dev. Neurobiol.*, 2009).

Here we show that assemblies of actin filaments in wave move anterogradely along the axonal shaft at the rate of slow component b, depending on their directional polymerization/depolymerization, the process called treadmilling, and their anchoring to the substrate.

We found that mass of actin filaments in waves undergo treadmilling in which the polymerizing ends are orientated toward the neurite tip. Inhibition of actin polymerization by cytochalasin B led to a decrease in the velocity of wave movement. Enhancement of the actin polymerization by promoting the cofilin activity led to an increase in the velocity of wave movement. We also found that the treadmilling F-actins are anchored to the substrate, through a clutch protein shootin1 and cell adhesion molecule L1-CAM. Inhibition of the interaction between F-actins and the substrate induced a slippage of treadmilling F-actins. Importantly, this slippage decreased the velocity of wave movement. We also confirmed the actin transport with the wave in vivo.

We propose a novel type of axonal transport system driven by directional F-actin treadmilling anchored to the substrate; this mechanism is consistent with the data that the subaxolemmal region is enriched with slow component b proteins (Heriot et al., *J. Cell. Biol.*, 1985) and appear to explain apparently discrepant previous observations that axonal actin is transported as dynamic and polymeric forms (Tashiro & Komiyta, *J. Neurosci.*, 1989; Okabe & Hirokawa, *Nature*, 1990; Vallee & Bloom, *Ann. Rev. Neurosci.*, 1991).

1978

### **JIP1 Sustains Long Distance Anterograde Transport via Direct Regulation of Kinesin Autoinhibition and Coordination of Retrograde Motor Association.**

M-M. Fu<sup>1</sup>, E. Holzbaur<sup>1</sup>; <sup>1</sup>Department of Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

Axonal cargos are transported distances of up to one meter in human neurons. Analysis of the highly processive vesicular cargo APP (amyloid precursor protein) in primary mammalian neurons shows transport characterized by long run lengths with few pauses or directional switches. In order to elucidate the molecular mechanism for sustaining long-distance processive motility, we depleted the adaptor protein JIP1, which directly binds to APP, and observed significant defects in both anterograde and retrograde APP transport. While JIP1 was previously shown to bind kinesin light chain (KLC), we now identify a novel KLC-independent interaction between JIP1 and kinesin heavy chain (KHC) via distinct binding sites in both KHC stalk and tail. Using in vitro TIRF motility assays with single molecule resolution, we found that addition of JIP1 relieves auto-inhibition of KHC and activates motility. In the presence of JIP1, KHC exhibits a ~7-fold increase in run frequency, a ~2-fold increase in run length and ~25% increase in speed. Interestingly, fragments of JIP1 that only bind KHC stalk or KHC tail are sufficient to initiate processive runs, but cannot fully recapitulate the enhancement of KHC speed and sustained processivity seen with full-length JIP1. In addition, JIP1 can coordinate both kinesin- and dynein-driven motility, as we identify a novel interaction between JIP1 and the p150<sup>Glued</sup> subunit of dynactin. Both in vitro and in primary neurons, addition of the JIP1-binding region of p150<sup>Glued</sup> competitively inhibits JIP1-mediated enhancement of KHC processivity. In contrast to a stochastic tug-of-war model, our data suggest that JIP1 can coordinate the formation of two distinct motile complexes - an anterograde complex that binds directly to KHC and a retrograde complex via its interaction with dynactin. Finally, analysis of JIP1 mutants

suggests that JIP1 phosphorylation regulates switching between anterograde and retrograde JIP1 complexes by altering KHC tail binding affinity. Together, our data support a model whereby the vesicle-associated adaptor protein JIP1 mediates bidirectional axonal transport and post-translational modification of JIP1 enhances kinesin activity in order to sustain long-distance anterograde transport.

1979

**Recruitment of dynein to endosomes for retrograde survival signal transport requires specific phosphorylation of the dynein intermediate chain by a Trk/ERK pathway.**

*K. R. Blasier<sup>1</sup>, D. J. Mitchell<sup>1</sup>, M. W. Ross<sup>1</sup>, W. R. Smiley<sup>1</sup>, D. Suo<sup>1</sup>, J. Park<sup>1</sup>, A. K. Pullikuth<sup>2</sup>, A. D. Catling<sup>2</sup>, C. D. Deppmann<sup>1</sup>, K. K. Pfister<sup>1</sup>; <sup>1</sup>University of Virginia, Charlottesville, VA, <sup>2</sup>Louisiana State University, New Orleans, LA*

The retrograde transport of Trk containing signaling endosomes from the axon to the cell body by cytoplasmic dynein is necessary for axonal and neuronal survival, but little is known about how dynein binding to these organelles is regulated. We investigated the recruitment of dynein to signaling endosomes formed in response to neurotrophin binding to the Trk receptor kinases in rat embryonic neurons and PC12 cells. We identified a novel phospho-serine on the dynein intermediate chains with mass spectrometry. Using an antibody specific for this phosphorylation site, a time-dependent increase in neurotrophin-stimulated phosphorylation of the intermediate chain (IC) was observed in both cell types. Consensus site prediction algorithms, pharmacological studies, over-expression of constitutively active MEK1, and phosphorylation of recombinant protein in vitro demonstrated that the intermediate chains were phosphorylated by the MAP kinase ERK1/2 (extracellular-signal-regulated kinase), a major downstream effector of Trk. In order to investigate the role of the phospho-IC in living cells, we made mRFP-tagged IC-WT, S/A dephospho- and S/D phospho-mimic mutants. Live cell imaging with the fluorescently-tagged IC mutants demonstrated that the dephospho-mimic mutants had significantly reduced co-localization with Trk and Rab7, but not a mitochondrial marker. Analyses of the motility of the mutants in axons indicated that the kinetic properties of the dynein motor were not regulated by phosphorylation. The phosphorylated dynein intermediate chains were enriched on organelles immuno-affinity purified with antibodies to Trk. Inhibition of ERK decreased IC phosphorylation and reduced the total amount of dynein present on the purified organelles. In addition, inhibition of ERK1/2 decreased the amount of Trk and Rab7 co-localization with dynein and reduced the retrograde movement of Rab7 and TrkB containing endosomes in axons. NGF-dependent survival of sympathetic neurons was significantly reduced by the over-expression of the dephospho-mimic mutant IC-1B-S80A, but not WT IC-1B. This provides further evidence that in the absence of IC phosphorylation there was decreased retrograde transport of signaling endosomes. Phosphorylation on this site did not modulate IC binding to the p150 subunit of dynactin, demonstrating that a component other than dynactin was also involved in dynein binding to the endosomes. Since dynein recruitment to mitochondria is not regulated by phosphorylation on this site, our data support a model in which cells utilize different mechanisms to recruit dynein to different organelles. The results demonstrate that neurotrophin binding to Trk initiates the recruitment of cytoplasmic dynein to signaling endosomes through ERK1/2 phosphorylation of intermediate chains and the subsequent retrograde axonal transport of the endosomes that is essential for cell survival. Thus, the Trk containing signaling endosome regulates its own retrograde transport.

1980

**Ankyrin-B is required for the regulation of synaptic vesicle transport and for the maintenance of long axonal tracts in neurons.**

*D. N. Lorenzo<sup>1,2</sup>, A. Badea<sup>3</sup>, J. Hostettler<sup>1,2</sup>, V. Bennett<sup>1,2</sup>; <sup>1</sup>HHMI, Durham, NC, <sup>2</sup>Biochemistry, Duke University, Durham, NC, <sup>3</sup>Neuroscience, Duke University, Durham, NC*

It has been established that Ankyrin-B, an abundant membrane adaptor protein in the brain, is essential for linking L1 cell adhesion molecules (L1-CAM) to the spectrin-actin cytoskeleton. These interactions ensure mechanical strength and also play a role in establishing proper axon guidance and connectivity. Consequently, mice lacking expression of the large ankyrin-B isoforms (AnkB KO), and of L1-CAM as a result, exhibit early postnatal lethality, brain malformations and neurodevelopmental defects seen in humans and in mice with L1-CAM mutations.

Interestingly, ankyrin-B binds the dynactin-4 subunit of the dynactin complex, which links the motor protein dynein to membrane cargo and helps regulate bidirectional transport along microtubules. Additionally,  $\beta$ 2-spectrin, which is an ankyrin-B partner, also directly interacts with dynactin through its arp-1 subunit, and has been widely implicated in the regulation of transport dynamics in axons. It is possible that both ankyrin-B and  $\beta$ 2-spectrin collaborate in coordinating motor protein interactions with membrane cargoes and contribute to the regulation of intracellular transport. The efficient and regulated bidirectional transport of organelles, synaptic vesicles, and trophic signals along long distances in axons is critical for axon growth and survival, and for maintaining the functional organization of the adult neuronal circuitry. Not surprisingly, deficiencies in axonal transport are often proposed as common mechanism in the pathogenesis of neurodegenerative diseases.

Here we show that the 220 kDa isoform of ankyrin-B regulates the transport dynamics of synaptic vesicles in mouse hippocampal neuron axons. Loss of this ankyrin-B isoform alters the bidirectional transport of multiple synaptic vesicle proteins, as observed by decreased anterograde and retrograde segmental velocities, shorter run length, and increased percentage of stationary and randomly moving vesicles. Interestingly, transport disruption seems to be specific to synaptic vesicles in the axon, since neither axonal transport of other cargoes nor transport in dendrites is affected. Additionally, cultured hippocampal neurons from AnkB KO animals develop shorter axons and numerous organelle-filled swellings. Lastly, the axonal transport phenotypes of AnkB KO neurons can be rescued by expression of wild-type 220 kDa ankyrin-B, but not ankyrin-B mutant proteins unable to associate with either dynactin or spectrin. In vivo functional characterization using diffusion tensor imaging analysis of neonate brains (PND2) reveals the striking consequences of the deficient axonal transport, as evidenced by severe defects in the development of the corpus callosum, the fimbria and the corticospinal tracts, along with degeneration of the optic nerve.

These results suggest a new role for ankyrin-B in the regulation of transport in axons that may be critical for the development and survival of major brain axonal pathways. Future work will explore additional mechanistic details implicated in these new findings and their potential linkage to neurodevelopmental and neurodegenerative diseases.

**Examining the Role for the Survival of Motor Neuron Protein in Axonal mRNA Localization and Transport in Spinal Motor Neurons.**

C. Fallini<sup>1</sup>, P. G. Donlin-Asp<sup>1</sup>, G. Bassell<sup>1</sup>, W. Rossoll<sup>1</sup>; <sup>1</sup>Department of Cell Biology, Center for Neurodegenerative Diseases, Emory University School of Medicine, Atlanta, GA

Spinal muscular atrophy (SMA) is a neuromuscular disease defined by a specific degeneration of motor neurons. SMA results from a reduction in the survival of motor neuron (SMN) protein, which is ubiquitously expressed with a well characterized role in promoting the assembly of spliceosomal small nuclear ribonucleoproteins (snRNPs). While some underlying defects in splicing have been observed in an SMA mouse model, these defects are not unique to motor neurons, making it unclear what extent they play in the selective motor neuron degeneration seen in SMA. We and others have demonstrated that SMN undergoes active transport in the axon of primary motor neurons where it also colocalizes with various mRNA binding proteins (mRBPs) known to play vital roles in mRNA transport. Additionally, a defect in axonal localization of  $\beta$ -actin mRNA at the axon terminus in primary motor neurons derived from the SMA mouse model has been observed. These and other data suggest that SMN may play a non-canonical role in the axon, potentially through mediating the assembly of mRNA and mRBPs into actively transported mRNA granules. To explore this hypothesis, we investigated the effects of SMN deficiency on both the localization and transport of messenger ribonucleoproteins (mRNPs) in axons and growth cones of primary motor neurons. Using quantitative fluorescence in situ hybridization (FISH), we observed a significant defect in the localization of total polyadenylated mRNAs in the axons of SMN-depleted motor neurons. Furthermore, we have identified a significant reduction in the axonal levels of *Gap-43* mRNA, a transcript whose stability and transport is regulated by the mRBPs HuD and IMP1. Interestingly, we can show that HuD and IMP1 specifically associate with SMN in motor neuron axons. Quantitative immunofluorescence (IF) revealed a defect in the axonal localization of IMP1 and HuD in motor neurons with depleted SMN protein. Our results support a model where SMN plays a non-canonical role in the specific assembly, transport or both of mRNPs in the axon of motor neurons.

1982

**Caspase activity promotes Wallerian degeneration in *Drosophila* motoneurons.**

Y. Hao<sup>1</sup>, X. Xiong<sup>1</sup>, X. Chen<sup>1</sup>, C. A. Collins<sup>1</sup>; <sup>1</sup>Molecular Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI

Axonal degeneration occurs after injury and in many neuropathies and neurodegenerative diseases. Axons that have lost connection with the cell body degenerate through via a self-destruction program whose mechanism is poorly understood. While caspases clearly play a role in developmentally programmed pruning, their role in Wallerian degeneration is less clear. Here we use an *in vivo* injury assay of *Drosophila* peripheral nerves to study Wallerian degeneration defined motoneuron axons and synapses. Our findings indicate that the *Drosophila* initiator caspase Dronc and the effector caspase Dcp-1 are required for the degeneration of injured motoneuron axons. Similarly, overexpression of p35 or the *Drosophila* caspase inhibitor DIAP1 also inhibit Wallerian degeneration. We are currently comparing the role of caspases in different *Drosophila* neuronal types, and testing the role of mitochondria in this caspase-mediated Wallerian degeneration. Consistent with a mitochondrial role in caspase activation, mutations which reduce mitochondria in axons inhibit axonal and synaptic degeneration after injury.

### High-Resolution Computational Analysis and Modeling of Tau-Mediated Spatial Organization of Axonal Transport.

M. Qiu<sup>1</sup>, Y. Yu<sup>1</sup>, H-C. Lee<sup>1</sup>, G. Yang<sup>1,2,3</sup>; <sup>1</sup>Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, <sup>2</sup>Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA, <sup>3</sup>Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

Tau is a microtubule-associated protein that is particularly abundant in axons of neuronal cells. It is thought that, under normal physiological conditions, tau binds and stabilizes axonal microtubules, which provide tracks for axonal cargo transport. It has also been hypothesized that tau *in vivo* may modulate axonal transport spatially by serving as roadblocks and thus facilitates detachment of motor-cargo complexes from microtubules. However, this hypothesis has not been fully tested. Understanding the roles of tau in axonal transport may provide important insights into related spatial-temporal transport regulatory mechanisms. In this study, we combined high-resolution computational techniques with *in vivo* fluorescence imaging to examine the relation between the spatial distribution of tau and the spatial behavior of axonal transport in the segmental nerves of *Drosophila* third instar larvae. Specifically, we analyzed spatial properties of the axonal transport of vesicles containing APP-YFP (amyloid precursor protein tagged with YFP) and Synt-GFP (synaptotagmin tagged with GFP) as well as mitochondria under different genetic backgrounds, including knockdown of endogenous *Drosophila* tau and overexpression of wild type and mutant human tau. We found that transport of these vesicles and organelles follows defined and consistent spatial patterns that are cargo specific. We also quantitatively characterized spatial distribution of tau using immunofluorescence in individual neurons within segmental nerves of the *Drosophila* third instar larvae. Based on these data, we developed quantitative models for analyzing and explaining the spatial behavior of the axonal transport. We tested our models by comparing their predictions of cargo behavior based on computer simulations versus actual experimental measurements. We found that the models we proposed can account for some key aspects of spatial-temporal cargo behavior. Overall, high-resolution computational analysis and modeling reveals important roles of tau in mediating the spatial organization of axonal transport.

1984

### Measurements and modeling of axonal transport: Amyloid precursor protein wins over negative charge in the race to the synapse.

J. Pascal<sup>1</sup>, M. Loewenberg<sup>1,2,3</sup>, A. Gonzales<sup>1</sup>, E. Adair<sup>1</sup>, V. Cristini<sup>1,3</sup>, E. L. Bearer<sup>1,4</sup>; <sup>1</sup>Pathology, University of New Mexico, Albuquerque, NM, <sup>2</sup>Chemical and Environmental Engineering, Yale University, New Haven, CT, <sup>3</sup>Chemical and Nuclear Engineering, University of New Mexico, Albuquerque, NM, <sup>4</sup>Marine Biological Laboratory, Woods Hole, MA

Intracellular transport maintains the architecture and function of neurons. Sorting of cellular components into different functional compartments relies on selective microtubule-based transport yet the details of how cargo-motor interactions produce differences in compartments remains elusive. Several cargo-receptors for kinesin-based transport have been proposed. Two of these--phosphatidylinositol, a negatively charged lipid, and the carboxyl terminus of amyloid precursor protein (APP-C)--mediate motility of cargo in living systems. Here we describe an assay in which the transport dynamics of these defined cargo can be directly observed, measured and modeled. We engineered cargo to display a single type of motor receptor by conjugating polystyrene fluorescent nanospheres (100 nm diameter) to either a charged residue (COOH) or APP-C peptides. As controls we conjugated beads to glycine. After injection into the squid giant axon, bead movements were recorded in time-lapse sequences captured by laser-scanning confocal microscopy. In this report we compare the motility of negatively charged

beads with APP-C beads in the presence of glycine-conjugated control beads. Tracking individual beads in digital sequences revealed instantaneous velocities of 0.279 vs 0.371  $\mu\text{m}/\text{sec}$  yielding calculated attachment/detachment rates of 0.04/0.026 vs 0.03/0.032  $\text{sec}^{-1}$  and predicted run lengths ( $v/k_1$ ) of 10.7 vs 11.5  $\mu\text{m}$  for COOH and APP-C beads respectively. By computationally generating thousands of bead trajectories based on real measurements, we obtained cumulative velocities and dispersion coefficients for each bead type. Using these values in the traffic model of Smith and Simmons (2001) we generated cumulative probabilities of distribution and compared these to the data. The Kolmogorov-Smirnov test for goodness of fit demonstrated similarity between model and bead distributions at long time points ( $t=156$ ,  $p=0.96$  and  $0.98$ ). Finally we used the model to predict the relative distribution of each bead type and found that APP-C beads achieve greater progress towards the presynaptic terminal with complete separation of distributions after 3 hr of transport from a single injection site. The significance of this data and accompanying model pertains to the role transport plays in neuronal function, connectivity, and survival, and has implications in the pathogenesis of neurological disorders, such as peripheral neuropathies and neurodegeneration as in Alzheimer's. 1985

### **N-terminal Fragments of Amyloid- $\beta$ Precursor Protein are Trafficked in Association with Short Peripherin-containing Neurofilaments.**

*C. Villegas<sup>1</sup>, V. Muresan<sup>1</sup>, Z. Muresan<sup>1</sup>; <sup>1</sup>UMDNJ - New Jersey Medical School, Newark, NJ*

Intracellular transport of vesicles over long distances – a process that is particularly active in neurons - is powered by molecular motors, kinesins (plus-end movement) and cytoplasmic dynein (minus-end movement), which are recruited to and move individual vesicles along stationary microtubules. It is thought that cytoskeletal polymers, such as short microtubules and neurofilaments, are transported into neurites in a similar way - by recruiting kinesin-1 and cytoplasmic dynein, which move them along stable microtubule tracks. While using the same motile machinery and transport paradigm, vesicles and short cytoskeletal polymers are thought of moving independent of each other and being under distinct regulatory constraints. By investigating transport of the Amyloid- $\beta$  Precursor Protein (APP), we identified a novel form of motility where transport vesicles, containing a fragment of APP, move - not by themselves - but by tightly associating with moving cytoskeletal polymers. APP, a type I transmembrane protein, is cleaved in the neuronal soma into N- and C-terminal fragments (NTFs and CTFs); the NTFs and the CTFs are sorted into distinct vesicles, and are separately transported into neurites, to reach fragment-specific destinations. To characterize the transport of the NTFs and CTFs, we used N- and C-terminal, dual-tagged APP constructs: CFP-APP-YFP for live imaging, and FLAG-APP-Myc for immunolocalization. When expressed at low levels in neuronal CAD cells, both constructs revealed a non-overlapping distribution of NTFs and CTFs in neurites, consistent with their independent transport. The distribution of C- and N-terminal epitopes of endogenous APP, revealed with immunolabeling, showed CTFs associated with randomly distributed vesicle-like structures, and NTFs exclusively localized to short, filamentous structures in processes, which we identified as segments of acetylated microtubules and peripherin-positive neurofilaments. A similar, tight distribution along filamentous tracks was detected for the N-terminal FLAG tag, but not for the C-terminal Myc tag of dual-tagged APP, in CAD cells expressing FLAG-APP-Myc. Treatments that selectively destabilized the acetylated microtubules abrogated this distribution of peripherin and NTFs, but did not affect the random distribution of CTFs. In biochemical subfractionation of neuronal extracts, the NTFs copurified with cytoskeletal filaments, to which they bound via ATP insensitive, stable interactions. These

results suggest that vesicles containing NTFs, rather than recruiting themselves molecular motors, attach to short, moving neurofilaments that likely glide over stationary microtubule tracks. Our work expands the current view on vesicle transport in neurons, by offering an alternative model for microtubule-based transport. We propose that, in addition to the established transport paradigm of individual vesicles moving independently on microtubules, molecular motors could transport en bloc short cytoskeletal filaments loaded with vesicles - such as those carrying the NTFs. These findings are highly relevant to the physiology and pathology of the neuron. Supported by NIH award AG039668 (Z.M.) and by an UMDNJ Foundation grant (ZM, VM).

1986

**Reduction of Mitochondrial Retrograde Molecular Motors Protein Levels and Mitochondria Total Movement in Hippocampal Cell Culture Before and During Neurodegeneration-Related Protein Aggregation.**

*R. S. Chaves<sup>1</sup>, M. F. Ferrari<sup>1</sup>; <sup>1</sup>Genetics and Evolutionary Biology, University of Sao Paulo, Sao Paulo, Brazil*

**Objective:** Decreased mitochondrial transport has been reported after protein aggregation related to several neurodegenerative diseases, however the mitochondrial transport state before and during protein aggregation remains elusive.

The purpose of this study is to analyze protein levels of dynein c1h1 and dynactin, that are mitochondrial retrograde molecular motors and mitochondria total movement in hippocampal cell culture exposed to rotenone a specific inhibitor of mitochondrial NADH dehydrogenase within respiratory chain complex I which can trigger protein aggregation.

**Methods:** All the procedures were performed in accordance with Institutional and International Guidelines for Animal Experimentation. Hippocampal cell culture of neonate Lewis rats were exposed to 0.1, 0.3 and 0.5 nM of rotenone or DMSO diluted in culture medium for 48 hours. Cells were then lysed and total protein was employed to Western blot analysis of dynein c1h1 and dynactin levels; or stained with Mitotracker™ green for live cell analysis of mitochondria total movement through confocal microscopy. Western blot normalization was done using anti-beta actin labeling. Films were quantified using Image J Software and mitochondria transport was evaluate using Image J plugin Difference Filter. Experiments were run in triplicates and results were analyzed by One-way Anova followed by Tukey post-hoc test.

**Results:** The analysis demonstrated a significant down-regulation of dynein c1h1 levels of 30% ( $p < 0.05$ ), 40% ( $p < 0.0001$ ) and 35% ( $p < 0.001$ ) respectively after exposure to 0.1, 0.3 and 0.5nM of rotenone respectively, as compared to DMSO. Exposure to 0.1, 0.3 and 0.5nM of rotenone also decreased dynactin levels in 20% ( $p < 0.05$ ), 35% ( $p < 0.0001$ ) and 50% ( $p < 0.0001$ ), respectively. Mitochondria total movement decreased 15% ( $p < 0.05$ ) after exposure to 0.5nM of rotenone compared to DMSO, however exposure to either 0.1 or 0.3nM did not alter mitochondria movement.

**Conclusion:** Decrease of dynein c1h1 and dynactin protein levels is accompanied by decrease in mitochondria total movement decrease after exposure to 0.3 and 0.5nM of rotenone illustrating the impairment of mitochondrial transport during and before protein aggregation, which possibly triggers neurodegenerative processes.

**Damage to Axonal Mitochondria Arrests their Motility prior to Local Mitophagy.**

G. Ashrafi<sup>1</sup>, X. Wang<sup>2</sup>, T. L. Schwarz<sup>3</sup>; <sup>1</sup>Molecular and Cellular Biology, Harvard University, Boston, MA, <sup>2</sup>Department of Neurosurgery, Stanford University School of Medicine, Stanford University, Stanford, CA, <sup>3</sup>F. M. Kirby Neurobiology Center, Children's Hospital Boston, Boston, MA

To minimize oxidative damage to the cell, malfunctioning mitochondria need to be removed by mitophagy. In neuronal axons, two models have been proposed. In one, mitochondria that have lost their membrane potential are retrogradely transported to the soma where they are destroyed. In the other, mitochondria undergo mitophagy locally in the axon.

We have found that mitochondrial depolarization induces accumulation of Parkin on axonal mitochondria, as has previously been shown in non-neuronal cells. In response to damage, PINK1 and Parkin associate with Miro, a mitochondrial adaptor protein that anchors a kinesin motor complex to the mitochondrial surface. This association leads to proteosomal degradation of Miro and arrest of mitochondrial motility in a Parkin-dependent manner. Following their arrest, axonal mitochondria colocalize with the autophagosomal marker LC3 indicating the local onset of mitophagy.

The arrest of mitochondrial motility prior to their local engulfment by autophagosomes may help prevent the spread of oxidative damage throughout the cell.

1988

**Image-Based Computational Methods for Analyzing Mitochondrial Dynamics in Axonal Transport.**

H-C. Lee<sup>1</sup>, Y. Yu<sup>1</sup>, K-C. Chen<sup>1</sup>, J. Kovacevic<sup>1</sup>, G. Yang<sup>1,2,3</sup>; <sup>1</sup>Department of Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, <sup>2</sup>Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA, <sup>3</sup>Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

Mitochondria are essential organelles of eukaryotic cells, serving a variety of crucial intracellular functions that include energy conversion and distribution as well as signal transduction. In response to changing needs of dynamic cellular processes, mitochondria frequently undergo morphological changes as well as spatial redistribution, a phenomenon referred to as mitochondrial dynamics. Because of their highly polarized configuration, neurons are particularly dependent on proper regulation of mitochondrial dynamics for their survival and function. Quantitative characterization of axonal mitochondrial dynamics is required for studying related functional and regulatory mechanisms. In this study, we developed image-based computational methods for reliable and precise characterization and analysis of mitochondrial dynamics within the axon. To characterize spatial redistribution of axonal mitochondria, we developed automated tracking techniques to recover their complete trajectories. To characterize morphological changes of axonal mitochondria, we developed related image segmentation, shape change detection and quantification techniques. By integrating these techniques, we examined the relation between mitochondrial shape changes and mitochondrial transport in *Drosophila* segmental nerves as well as mouse hippocampal neurons under different perturbations of mitochondrial fusion and fission. We found that sizes of axonal mitochondria follow defined statistical clusters, that mitochondrial morphology affects their motility, and that the maximal velocities of mitochondrial transport are correlated with their sizes. Based on these data, we proposed a quantitative model to account for observed relations between mitochondrial morphology and motility. We present results of testing several prediction of the model using experimental data.

## Establishment and Maintenance of Polarity II

1989

### Developmental timing determines effects of actin on neuronal process formation

*D. D. Brandner<sup>1</sup>, G. S. Withers<sup>1</sup>; <sup>1</sup>Biology, Whitman College, Walla Walla, WA*

In the initial development of neuron polarity, localized instability of actin within a growth cone is associated with the formation of a single axon from that neurite, and global destabilization of actin produces multiple axons (e.g. Bradke & Dotti, 1999). The formation and maturation of the dendritic arbor follows a timecourse that is more protracted than that of axons, and so we varied the timing of actin destabilization in cultured hippocampal neurons to test for contributions of actin dynamics in dendritic development. We applied prolonged, global treatment of pharmacological agents to interfere with the state of actin polymerization at 2 key stages of early dendritic growth: after 24 hours in vitro (1-3 days in vitro, DIV), a time point when most cells have begun to initiate axon formation but dendrites remain undifferentiated; and 3-5 DIV, at the onset of robust dendritic outgrowth. Measures of morphological development and molecular polarity were used to classify process phenotype and determine the effects of treatment. Neurons treated from 1-3DIV with actin depolymerizing agents (Cytochalasin D or Latrunculin A) developed supernumerary axons. These cells also formed significantly more dendrites. Thus, at this stage of development a major outcome of actin depolymerization is net production of more processes generally rather than conservation of process number and fate-switching from dendrite to axon. Treatment at 3-5 DIV also lead to a significant increase in axon number, but did not produce additional dendrites, suggesting a critical period for the formation of primary dendrites. Jasplakinolide, a drug that stabilizes actin, lead to dendrite retraction and loss, suggesting that actin dynamics are essential for the structural integrity and maintenance of the dendritic arbor. To test whether molecular polarity of dendrites was also dependent on actin dynamics, cells were immunostained for MAP2, which becomes polarized to dendrites during development, and tau-1, which is localized to axons. A comparison of fluorescence intensity between F-actin-destabilized and control cells revealed a parallel between actin destabilization at 3-5 DIV and reduced polarized distribution for both markers in axons and dendrites. Since treatment at this stage did not alter the number of primary dendrites, these data suggest separate contributions of actin dynamics in the molecular polarity of the dendritic arbor that are distinct from initial outgrowth.

1990

### NDR2 affects primary dendrite formation by regulating IQGAP1 and CDC42 in hippocampal neurons.

*M. Oh<sup>1</sup>, E-H. Hong<sup>1</sup>, C. Hwang<sup>2</sup>, K-H. Bae<sup>3</sup>, J-H. Kim<sup>3</sup>, K. Lee<sup>2</sup>, D-S. Lim<sup>4</sup>, K-S. Kwon<sup>2</sup>, J-Y. kim<sup>1</sup>; <sup>1</sup>College of Bioscience and Biotechnology, Chungnam National university, Daejeon, Korea, <sup>2</sup>Aging Research Center, Korea Research Institute of Bioscience and Biotechnology, Daejeon, Korea, <sup>3</sup>Biomedical Proteomics Research Center, Korea Research Institute of Bioscience and Biotechnology, Daejeon, Korea, <sup>4</sup>Department of Biological sciences, KAIST, Daejeon, Korea*

NDR kinases (Nuclear Dbf2 Related protein kinase) belong to the AGC group of serine/threonine kinases and include NDR1/2 and Lats1/2 kinases. NDR1/2, conserved from yeast to human, is known to regulate cell morphogenesis. However, the targets and detailed molecular functions of NDR1/2 in hippocampal neurons remain largely unknown. Here we report that NDR2 regulates dendritic morphogenesis through IQGAP1 and CDC42. NDR2 knockdown by shRNA decreased the number of primary dendrite of hippocampal neurons, which was

rescued by NDR2 or CDC42 overexpression. NDR2 overexpression increased the level of activated GTP-bound CDC42, whereas NDR2-knockdown significantly diminished the GTP-CDC42 level. IQGAP1, an effector of CDC42, was identified as an NDR2 interacting molecule, and simultaneous expression of NDR2 and IQGAP1 further increased the GTP-bound CDC42 level. NDR2 prevented the ubiquitin-dependent degradation of IQGAP1. Thus, we propose that NDR2 regulates primary dendrite formation by bringing IQGAP1 and GTP-Cdc42 together and promoting actin cytoskeleton remodeling.

1991

**Mechanisms for axon-specific accumulation of an axonal protein JIP1.**

*T. Maeno<sup>1</sup>, M. Toriyama<sup>1</sup>, N. Inagaki<sup>1</sup>; <sup>1</sup>NAIST, Ikoma, Japan*

The basic function of neurons is to receive, integrate, and transmit signals. To do so, neurons develop polarity by forming a single axon and multiple dendrites. Rat hippocampal neurons polarize in symmetrical *in vitro* environments (Craig and Banker, *Annu Rev Neurosci*, 1994). The process of neuronal polarity formation was divided into five stages and the neurons first form several immature neurites (minor processes) that are similar in length, and at this stage the neurons appear symmetric (stage 2). Thereafter, one of these neurites outgrows its siblings to break this symmetry and the neurite accumulates axon-specific proteins (stage 3). The longest neurite acquires axonal characteristics, whereas the others later become dendrites, to establish neuronal polarity. Thus, this break in symmetry is the initial step of neuronal polarization. Recent studies reported that both excitatory and inhibitory neurons in the cerebral cortex also undergo symmetry breaking steps (Yamauchi et al, *J Neurosci*, 2010; Hatanaka et al, *Cereb Cortex*, 2012). Previous studies identified a number of axon-specific molecules, which play key roles in the establishment of the polarity (Arimura and Kaibuchi, *Nat Rev Neurosci*, 2007). However, the mechanisms by which these molecules accumulate in the nascent axon remain poorly understood. A cargo adaptor JIP1 is transported along microtubules by kinesin1 and strongly accumulates in the nascent axon during neuronal symmetry breaking. In this study, we analyzed the mechanisms underlying the axon-specific accumulation of JIP1, by focusing on the following three possible processes: 1) selective anterograde transport, 2) retrograde diffusion, and 3) selective anchoring at the neurite tip. Previous studies reported that tubulin acetylation promotes kinesin1 transport (Dajas et al, *Curr Biol*, 2008), while tubulin tyrosination inhibits it (Konishi et al. *Nat Neurosci*, 2009). So using polarizing cultured rat hippocampal neurons during stage 2 and early stage 3, we performed immunostaining for JIP1 and posttranslational microtubule modifications (acetylation and tyrosination) in their neurites. Consistent with a previous report (Nakata et al, *J Cell Biol*, 2011), we found that JIP1 accumulation was not correlated with these posttranslational modifications, during the early stage of neuronal symmetry breaking. On the other hand, JIP1 accumulation showed positive correlation with neurite length. Using photoconvertible KAEDE-JIP1, we quantitatively monitored the retrograde diffusion of JIP1 from neurite tips to the cell body. Inverse correlation between the diffusing velocity and the neurite length was observed, suggesting that the retrograde diffusion would contribute to the neurite length-dependent JIP1 accumulation. In addition, time-lapse live cell imaging of EGFP-JIP1 and mCherry-EB3 showed a possible anchoring of JIP1 in growing neurites. Based on these results, we propose that the retrograde diffusion, and selective anchoring of JIP1 at the neurite tip may play key roles in the axon-specific JIP1 accumulation.

1992

**Fluid flows and pattern formation in the one-cell *C. elegans* embryo.**

*N. W. Goehring*<sup>1</sup>, *A. Hyman*<sup>1</sup>, *S. Grill*<sup>1,2</sup>; <sup>1</sup>MPI-CBG, Dresden, Germany, <sup>2</sup>MPI-PKS, Dresden, Germany

The interplay between mechanical stresses and cellular signaling systems plays a central role in cellular organization. Our work focuses on such interplay during the asymmetric division of the *C. elegans* one-cell embryo. In the embryo, mechanical stress is generated within a highly cross-linked, contractile actin cortical network underlying the cell membrane. Due to the influence of local cues, asymmetries develop within this network, resulting in long range flow of actin cortex from posterior to anterior. This flow of cortical actin in turn entrains the surrounding cytoplasm giving rise to a complex pattern of fluid flow within the embryo. Our work suggests that the conserved PAR polarity proteins are transported by these bulk cytoplasmic flows due to particular kinetics behaviors of the PAR proteins. In particular, we suggest that it is their ability to undergo a transition from a free, and rapidly diffusing cytoplasmic state into a slowly diffusing cortex-associated state that allows PAR proteins to tap into this bulk transport mechanism, resulting in an induced PAR asymmetry that can drive cell polarization. By accurately quantifying the patterns of fluid flow in the embryo, the diffusive properties of PAR proteins, and incorporating the results within quantitative models, our data provides insight into how cortex-generated flows shape the distributions of PAR proteins throughout the first cell division.

1993

**Role of Mob1 in regeneration of a single cell.**

*M. M. Slabodnick*<sup>1</sup>, *W. Marshall*<sup>1</sup>; <sup>1</sup>Biochemistry, University of California, San Francisco, San Francisco, CA

Understanding the processes behind the regeneration of cells and tissues is an important cell biological question. Cells need to identify and react to specific damages in and around them, and in order to understand these processes at a basic level we need a model that exhibits a similar regeneration of specialized structures in the context of a single cell. Perhaps the most classical system for studying regeneration in single cells, pioneered by Thomas Hunt Morgan, F.R. Lillie, Vance Tartar and others, is *Stentor coeruleus*, a large ciliate, ~1mm long, with a highly patterned cell cortex and the ability to regenerate and reorganize after surgical or chemical manipulations. Its large size and complex organization rival those of metazoan organisms and the ease of surgical manipulations gives *Stentor* significant advantages over other ciliate models. Using the traditional surgical techniques unique to *Stentor* as well as modern RNA interference (RNAi) methods, visualization techniques, and genomic sequencing I will revive *Stentor* as a model for studying the regeneration of cell polarity and organization. We have partially sequenced *Stentor*'s macronuclear genome and shown that RNAi machinery is functional in *Stentor*. Using an RNAi approach we have begun a systematic investigation of the molecular basis of single-cell regeneration. Mob1 is a highly conserved kinase regulator and is known to interact with NDR/LATS kinases. It plays a role in a variety of functions including apoptosis, mitosis, morphogenesis, and cell proliferation. Recent work in *Tetrahymena thermophila* suggests that Mob1 also performs important roles in ciliates. Results for RNAi of Alpha-Tubulin and Mob1 in *Stentor* result in dramatic changes in cell polarity and organization of the cortex, showing that we can analyze single-celled regeneration in *Stentor* at a molecular level. Knocking down Alpha-Tubulin, a key structural component in the cortex, results in cortical defects and problems with cell regeneration. This is very different from the Mob1 knockdown, which results in the drastic elongation of cells, cortical aberrations, and an apparent loss of proper cell proportions. Using RNAi in conjunction with the unique microsurgical methods available in *Stentor*, it should be possible to restore this classical system to its previous status

as a central model for understanding the basic principles of cell polarity, biological pattern formation, and cellular regeneration.

1994

**Reversing the polarity of migrating Dictyostelium cells.**

*D. K. Jowhar<sup>1</sup>, G. Wright<sup>1</sup>, P. Samson<sup>2</sup>, J. Wikswø<sup>2</sup>, C. Janetopoulos<sup>1,3</sup>; <sup>1</sup>Biological Sciences, Vanderbilt University, Nashville, TN, <sup>2</sup>Physics and Astronomy, Vanderbilt University, Nashville, TN, <sup>3</sup>Cell and Developmental Biology, Vanderbilt University, Nashville, TN*

Cells migrating in a chemical gradient typically have a polarized morphology, where they display a distinct front and back. Cells can also have different localized sensitivities to chemoattractants depending on their degree and type of polarity. To better understand these phenomena, we used the social amoeba *Dictyostelium discoideum* that expressed GFP-tagged proteins known to localize to distinct regions of the cell during cell migration. *Dictyostelium* cells were lured into a specialized microfluidic device developed in our laboratory which confined the cells in narrow 3-dimensional PDMS channels. The chemoattractant gradient in this experimental platform could be reversed so that the rear of the cell was exposed to a higher concentration of chemoattractant than the front of the cell. Cells in the channels would freeze, become unpolarized, and were then capable of forming a new front at the former rear of the cell. We have observed the temporal and spatial loss and gain of localization of various signaling and cytoskeletal molecules at both the rear and front of the cell as polarity is broken down and re-established. We monitored the localization of PHCrac (a biosensor for PI(3,4)P2 and PI(3,4,5)P3), RBD (a biosensor for Ras activity), PTEN-GFP (a phosphatase which elevates levels of PI(4,5)P2), Tubulin-GFP (a biomarker for microtubules) and redistribution during polarity re-establishment. Further experiments were performed in the absence of an actin cytoskeleton by treating cells with Latrunculin A. These experiments have helped elucidate the molecular mechanisms that contribute to the establishment and maintenance of cell polarity.

1995

**How protrusion/retraction switch controls cell polarity, shape, and motion.**

*M. E. Ambühl<sup>1</sup>, F. Raynaud<sup>1</sup>, C. Brepsant<sup>1</sup>, I. F. Sbalzarini<sup>2</sup>, A. B. Verkhovsky<sup>1</sup>; <sup>1</sup>Lab. of Cell Biophysics, EPFL, Lausanne, Switzerland, <sup>2</sup>Dept. of Computer Science, ETH, Zurich, Switzerland*

Persistently migrating fish epidermal keratocytes exhibit nearly perfect separation of protrusion and retraction to, respectively, leading and trailing parts of the cell edge, each occupying approximately half of the cell perimeter. During initial cell polarization these protruding and retracting zones consolidate from several smaller regions, sometimes through intermediate stages with multiple leading edges traveling in circles around the cell center. To understand the evolution of cell shape during polarization and motion we analyzed the distribution of the cell edge velocity and the dynamics of transitions between protrusion and retraction. Protrusion velocity was nearly constant along the central part of the leading edge of migrating cells, but exhibited large fluctuations at the cell lateral extremities. Switches between protrusion and retraction occurred preferentially at the cell extremities in both persistently moving and polarizing cells. To investigate the conditions for switch between protrusion and retraction, we designed the experiment where the cell body was mechanically restricted by a flexible glass needle so that it could not move in the direction of the leading edge. In these conditions, the leading edge continued to extend for a while at a nearly constant velocity causing cell elongation until, abruptly, protrusion switched to retraction and the cell reversed its polarity. Reversal was dependent on the myosin II activity and coincided with the maximum of tension

between the leading edge and the cell body. These observations suggest the following empirical rules for the cell edge behavior: the states of protrusion and retraction are both relatively stable, and the switches between the two states occur preferentially at the threshold stress values which arise at the cell extremities. These rules are consistent with the behavior and shape of polarizing, steadily moving and mechanically confined cells. We are developing a numerical top-down model of cell polarization and motion based on these empirical rules. **Actomyosin Morphodynamics Imprint Spatial Order of the Cytoplasm During Cell Polarization.**

A. J. Lomakin<sup>1</sup>, J. Tytell<sup>1</sup>, A. Mogilner<sup>2</sup>, G. Danuser<sup>1</sup>; <sup>1</sup>Harvard Medical School, Boston, MA, <sup>2</sup>University of California, Davis, Davis, CA

The spatial organization of cells depends on their global geometry and the ability to sense their own shape and size. While the molecular players and interactions involved in the generation and dynamic remodeling of cell shape continue to become identified, a default cell-autonomous mechanism controlling large-scale cell organization remains unknown.

To address this issue, we turn to the use of single epithelial cells, a simplest and evolutionary ancient animal cell type that demonstrates remarkable cell shape plasticity in embryogenesis and postnatal ontogenesis. Investigating this model by multiparametric quantitative live-cell imaging, experimental perturbations, and mathematical modeling, we establish the morphogenetic potential and hierarchy of activities for the universal cytoarchitectural modules, actomyosin and microtubule cytoskeletons.

We show that a balance between myosin-II-dependent cross-linking-contraction and inherent self-organizing activity of polymerizing actin filaments can give rise to structurally and functionally distinct cell morphologies. Decreasing the degree of contractility shifts the balance towards actin-based protrusivity of the plasma membrane. The latter destabilizes cellular shape and can ultimately lead to a spontaneous switch from a planarly symmetric discoid shape of stationary cells to an elongated cell morphology with migratory polarity.

We further establish that a remarkable cooperativity between the actomyosin-driven cell-scale patterns and cytoplasmic microtubule organization mediates the communication process between the global shape of the cell and its interior. The morphologies emerging from the balance between actomyosin contractility and actin protrusivity pose a simple geometric constraint for the self-organization of cytoplasmic microtubules into the patterns that dictate a spatial order of internal cell components. The cooperativity among actin and microtubules in producing the large-scale cell organization is based on the nematic alignment due to collisions of the filaments, and appeared to be independent of previously proposed long-range interactions between the two cytoskeletons.

Thus, we propose that cell-scale morphogenesis is an example of biological self-organization and requires a minimal “tuning” mechanism relying on the pathways directly regulating actomyosin contractility.

**Tipping the balance between adhesion and myosin contraction drives spontaneous motility initiation in keratocytes as revealed by modeling and experiment.**

*K-C. Lee<sup>1</sup>, E. L. Barnhart<sup>2</sup>, G. M. Allen<sup>2</sup>, J. A. Theriot<sup>2,3</sup>, A. Mogilner<sup>1,4</sup>; <sup>1</sup>Neurobiology, Physiology, and Behavior, University of California, Davis, CA, <sup>2</sup>Department of Biochemistry and Howard Hughes Medical Institute, Stanford University School of Medicine, Stanford, CA, <sup>3</sup>Department of Microbiology and Immunology, Stanford University, Stanford, CA, <sup>4</sup>Department of Mathematics, University of California, Davis, CA*

Fish keratocytes spontaneously break symmetry and become motile in the absence of known external cues. It is known that motility initiates at the prospective rear of the cell where centripetal actin flow increases prior to the symmetry break, but what causes this flow increase and whether respective trigger is biochemical or mechanical is not clear. We applied our published model of continuum mechanics of viscous contractile actin network with free boundary to test two simple mechanical pathways of the initial asymmetric flow increase: spatial bias of myosin toward the prospective rear, or weakening of adhesion there. Both scenarios predicted the accelerated actin flow at the rear, but gave opposite predictions about traction force distributions. Experimental measurements showed that the traction forces are attenuated at the rear prior to motility, so the experiment supports the adhesion weakening as the symmetry break trigger. Simulations of the model showed, however, that such transient adhesion change does not support stable motility. We therefore propose a model in which the adhesion strength depends on the actin flow rate or myosin strength such that adhesions slip at high flow or contraction. Simulations of this model with stochastic self-organizing acto-myosin dynamics coupled with mechanosensitive adhesion reproduced the data and made additional predictions on dependence of frequency of the motility initiation on overall adhesiveness of the substrate and localized application of drags that were tested experimentally and confirmed. We propose therefore that the mechanical adhesion-contraction switch underlies the motile polarization in simple keratocyte cells, though additional biochemical mechanisms can complement this switch.

**Cooperative regulation of cellular contractility by Rho-kinase/Scrib/Shroom2 complex.**

*K. Kozawa<sup>1</sup>, K. Kato<sup>1</sup>, T. Hamaguchi<sup>1</sup>, S. M. Hasanuzzaman<sup>1</sup>, X. Zhang<sup>1</sup>, T. Nishioka<sup>1</sup>, M. Amano<sup>1</sup>, K. Kaibuchi<sup>1</sup>; <sup>1</sup>Cell pharmacology, Nagoya University School of Medicine, Nagoya, Japan*

Rho and Rho-kinase/ROCK regulate cellular morphogenesis and motility through cytoskeletal reorganization. We newly identified Scrib, which is a tumor suppressor and regulator of planar cell polarity, as a substrate of Rho-kinase. Rho- and Rho-kinase-dependent phosphorylation of Scrib was detected in COS7 and MDCK II cells with phospho-Scrib antibodies. We also found that Shroom2 bound to the C-terminal portion of Scrib containing phosphorylation sites by Rho-kinase in a phosphorylation state-dependent manner. Shroom2 is an actin- and Rho-kinase-binding protein, and thought to be involved in tissue morphogenesis via control of topological constriction of cellular sheets. Shroom2 formed a ternary complex with Scrib and Rho-kinase, for which phosphorylation of Scrib by Rho-kinase had a critical role. Both Scrib and Rho-kinase reciprocally stabilized the ternary complex formation. Rho-kinase, Scrib, and Shroom2 were localized at the contractile cortical edge of cell colonies and at the contractile wound edge in MDCK II cells. Ectopically expressed Shroom2 was highly accumulated at the contractile cortical edge and recruited endogenous Rho-kinase and Scrib there, leading to the resultant enhancement of MLC phosphorylation. Whereas, Shroom2 mutant lacking Rho-kinase- and Scrib-binding region was still localized at the edge, but failed to recruit Rho-kinase and Scrib.

Depletion of Scrib in MDCK II cells resulted in the decrease of MLC phosphorylation at the cortical edge. Similar result was obtained when Scrib was depleted in human umbilical vein endothelial cells (HUVECs). These results suggest that Rho-kinase/Scrib/Shroom2 ternary complex regulates cell contractility at the cortical edge, and this mechanism may partly account for the role of Scrib in planar cell polarity signaling cascade.

1999

**Analysis of protein interactions involved in rear polarization of rat artery smooth muscle cells in atherosclerosis identify spectrin as a possible interacting partner of RHAMM.**

*R. V. Silverman-Gavrila<sup>1</sup>, L. Silverman-Gavrila<sup>2</sup>, H. Bilal<sup>1</sup>, M. Bendeck<sup>1</sup>; <sup>1</sup>LMP, University of Toronto, Toronto, ON, Canada, <sup>2</sup>Physiology, University of Toronto, Toronto, ON, Canada*

Using a phosphoproteomic screen followed by mass spectrometry we showed in a previous study (Silverman-Gavrila et al., 2011) that 6 proteins have a higher phosphorylation degree in neointimal smooth muscle cells compared to medial smooth muscle cells: ARPC5\_RAT, Actin-related protein 2/3 complex subunit 5; Q9WUF7\_RAT, Hyaluronan receptor RHAMM; LMOD2\_RAT, Leiomodin-2; TRP13\_RAT, Thyroid receptor-interacting protein 13; P2RX3\_RAT, P2X purinoceptor 3; Q5U2P5\_RAT, Transmembrane protein 24. Further analysis showed that RHAMM and ARPC5 play an important role in rear polarization of microtubule organization centres during migration of smooth muscle cells. Using bio-informatics programs such as BLAST, ClustalW, and PPRSpider, the list of proteins obtained from mass spectrometry was analyzed to reveal additional potential interacting partners. One such target protein that was validated is spectrin, an actin binding protein that was shown to play a role in the production of actin nets. Relative distribution of spectrin to actin, RHAMM, and alpha-tubulin in neointimal smooth muscle cells (SMCs) was further assessed using confocal microscopy in order to identify the localization of spectrin during cell cycle as well as its relative distribution and possible colocalization with members of the identified pathway that play a role in rear polarization of the MTOC. In dividing SMCs spectrin is present at spindle poles from prophase to late anaphase and its presence diminishes as the cell cycle progresses. In telophase and cytokinesis spectrin relocates to the midbody. In neointimal SMCs stimulated to migrate in a wound assay spectrin localizes at the membrane of the advancing edge (lamellipodia) and in the cytoplasm where it colocalizes with RHAMM perinuclearly. Spectrin and actin co-localize in the lamellipodia of interphase migratory neointimal SMCs but there is less colocalization of spectrin and  $\alpha$ -tubulin. Our proposed model suggests that spectrin acts as a linker between actin cytoskeleton and RHAMM. The putative interactions will be further validated by biochemistry (co-IP), siRNA, and mutagenesis approaches. We showed previously, that a polygonal actin net localized dorso-lateral of the nuclei in neointimal smooth muscle cells is responsible for rear polarization of microtubule organizing centre during migration from media to neointima. We will further test whether spectrin is involved in organizing actin in the net in neointimal SMCs. Our data show that this multifaceted approach can be a useful tool for identifying interacting partners and decoding pathways involved in polarity regulation during migration of smooth muscle cells in atherosclerosis process that can be used as targets for preventing migration and thus progression of atherosclerosis plaque formation.

**Vangl-mediated non-canonical Wnt/planar cell polarity signalling is not required for the planarly polarized cell morphology of endothelium exposed to laminar flow.**

J. Han<sup>1</sup>, J. Brunetti<sup>1</sup>, A. McGuigan<sup>1</sup>; <sup>1</sup>Chemical Engineering & Applied Chemistry, Biozone, University of Toronto, Toronto, ON, Canada

Background: endothelial cells exposed to laminar flow display planarly polarized cell morphology, becoming elongated and orienting along the flow direction. This planarly polarized phenotype is believed to minimize the physical stress that endothelium is exposed to and consequently dampen the possibly mechanical strain-induced inflammatory response, which could contribute to the development of atherosclerosis. Many signaling pathways have been identified to regulate the response of endothelial cells to shear stress, but few has been shown to specifically co-ordinate the response of a confluent sheet of endothelium. In the current study, we investigated the potential role of non-canonical Wnt/planar cell polarity (PCP) signaling pathway, which was first identified in *Drosophila* for their activity in coordinating the planar polarity of confluent epithelial sheets, in coordinating the response of confluent endothelial sheet to laminar flow.

Methods: among several core PCP proteins (Flamingo/Celsr, Frizzled, Dishevelled, and Strabismus/van Gogh), we chose Vang-like protein as our focus as we found that human umbilical vein endothelial cells (HUVEC) only express one of the two mammalian Vang homologs, Vangl1. We modified the expression level of Vangl1 in HUVEC by lentiviral transduction of vectors that encode GFP-Vangl1 or Vangl1-targeting shRNA. Vangl1-modified or control HUVEC were seeded into microfluidic channels and exposed to shear stress of 12 dyens/cm<sup>2</sup> for 24-48 h. Time-lapse or end-point fluorescent images were taken and the angles of cell nuclei and whole cells were measured using ImageJ.

Results: although there was a slight increase in the endogenous Vangl1 expression level and a change in the sub-cellular distribution of GFP-Vangl1 after cells exposed to shear stress. No difference in the angles of either cell nuclei or whole cell was observed at any time points measured.

Conclusion: Vang-mediated non-canonical Wnt/PCP signaling pathway is not required for the planarly polarized cell phenotype of endothelium under shear stress.

2001

**The Arf3p GTPase acts with its novel effector Bud2p to modulate invasive growth in *Saccharomyces cerevisiae*.**

J-W. Hsu<sup>1</sup>, F-J. S. Lee<sup>1</sup>; <sup>1</sup>Institute of Molecular Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan

The development of filamentous growth in yeast is composed of various stages, including budding pattern switch, elongated cells, and agar invasion. The regulatory network and cooperative signaling of invasive growth is complicated and has been expansively studied. Bud2p, functioning as a GTPase-activating protein (GAP) for Bud1p/Rsr1p, is known to be required for both the axial and bipolar budding patterns and filamentous growth. Arf3p GTPase, the homologue of mammalian Arf6, was reported to be involved in actin polarization and bud site selection. A large-scale of yeast two-hybrid analysis showed that Arf3p interacts with Bud2p; however, the biological significance of this interaction remains unknown. Here, we provide the evidence that Arf3p promotes Bud2p GAP activity to modulate yeast invasive growth. We observed that Arf3p directly interacts with Bud2p in a GTP-dependent manner and that interaction is necessary for yeast invasive growth. Elevation of active GTP-bound Bud1p or lacking Bud2p GAP activity in yeast prevents invasive growth. Furthermore, we show that Arf3p-Bud2p interaction promotes Bud1/Rsr1p GTP hydrolysis and enhances the Bud2p-Bud1p

association in vivo. Thus, our study identifies Arf3p as a Bud2p's activator for promoting Bud1p-GTP hydrolysis and reveals a novel regulatory signaling of Arf3p-Bud2p-Bud1p for yeast invasive growth.

**Role of a cyclin in the establishment of yeast pheromone receptor polarity.**

*M. Sukumar*<sup>1</sup>, *C. Hargreaves*<sup>2</sup>, *B. Surani*<sup>1</sup>, *D. E. Stone*<sup>1</sup>; <sup>1</sup>*Biological Sciences, University of Illinois at Chicago, Chicago, IL*, <sup>2</sup>*Oakton Community college, Des Plaines, IL*

The formation of shmoo by the budding yeast *S. cerevisiae* during mating is a chemotropic response related to chemotaxis. All chemotropic and chemotactic cells exhibit a remarkable ability to interpret gradients and sense direction. The two haploid yeast mating types, *MATa* and *MAT $\alpha$* , sense the pheromone secreted by cells of the opposite type, polarize their growth towards the closest mating partner, and fuse to form diploids. How do these cells sense direction? In *MATa* cells, the Ste2 pheromone receptor is the primary gradient sensor. Ste2 is uniformly distributed on the plasma membrane in vegetative cells, but upon ligand binding, it is rapidly internalized. It then reappears as a polarized crescent that coincides with the incipient shmoo site. In mating mixtures, these receptor crescents orient towards the closest mating partner. Although actin-dependent directed secretion stabilizes and amplifies receptor polarity, we have shown that receptor polarization precedes the polarization of actin cables and occurs in the absence of actin-directed secretion. In contrast, internalization of the receptor is essential for its polarization. Our recent data indicate that a receptor polarization site that can be amplified independently of f-actin is established within 15 minutes of pheromone treatment. How does this occur?

To identify key players in the establishment of receptor polarity, we performed a directed genetic screen of haploid-specific genes. *PCL1* deletion conferred a significant defect in receptor polarization. Pcl1 is one of the ten cyclins for the cyclin-dependent kinase (CDK) Pho85. Studies using alexafluor-phalloidin and yDsRed-Sec4 indicated that this phenotype is not due to a defect in the polarization of actin cables or directed secretion. Unlike wild type cells, *pc1 $\Delta$*  cells were unable to establish a receptor polarization site that could be amplified independently of actin in the first 15 minutes after pheromone treatment. In contrast, over-expression of Pcl1 caused the receptor to polarize to a very narrow region in response to pheromone. Pcl1 over-expression also greatly increased sensitivity to pheromone as visualized by halo assays and microscopy. Furthermore, slight over-expression of G $\beta$  in *pc1 $\Delta$*  cells caused a moderate increase in pheromone sensitivity. Given that G $\beta$  is predicted to have a consensus phosphorylation motif for Pho85/Pcl1, we hypothesize that this G $\beta$ -Pcl1 genetic interaction results from their direct physical interaction. Consistent with its effect on receptor polarization, *pc1 $\Delta$*  conferred a directional sensing defect in mating assays. In summary, our data strongly suggest a novel role for the cyclin Pcl1 and the CDK Pho85 in receptor polarization and directional sensing.

2003

**Gradient tracking in yeast: role of pheromone receptor phosphorylation and endocytosis.**

*A. McClure*<sup>1</sup>, *J. Dyer*<sup>1</sup>, *D. Lew*<sup>1</sup>; <sup>1</sup>*Duke University, Durham, NC*

Cells are extremely proficient at tracking chemical gradients. Chemical signals are detected by G protein-coupled receptors at the cell surface. In many cells, receptors and their associated G proteins are uniformly distributed on the membrane and are thought to accurately transduce the extracellular spatial profile of ligand into an intracellular profile of active G protein. In contrast, yeast pheromone receptors become heterogeneously distributed over the cell surface following exposure to pheromone. Cells exposed to high concentrations of pheromone arrest in G1 and

undergo polarized growth to form a shmoo projection, and pheromone receptors are concentrated near the tip of the shmoo. Receptor distribution results from (i) polarized secretion of new receptors, (ii) slow diffusion of receptors in the plasma membrane, and (iii) ligand-induced receptor endocytosis and degradation. Why would cells reduce their capacity to sense external gradients by restricting receptor localization in this way? Here we address the potential role of receptor distribution in the context of novel findings indicating that at physiological pheromone concentrations, the patch of polarity proteins “wanders” around the cell cortex, allowing for adjustments in growth orientation. Wandering is biased by pheromone, helping yeast cells grow towards mating partners. We have investigated how the receptor modifications (phosphorylation and ubiquitination) that trigger its endocytosis affect polarity site wandering and gradient tracking. We found that the receptor does not need to be ubiquitinated or endocytosed in order to bias patch wandering. However, receptor phosphorylation appears to be important in regulating patch wandering. These findings suggest novel roles for receptor phosphorylation beyond causing ubiquitination and endocytosis.

2004

**Receptor phosphorylation and polarization are regulated by G $\beta$  interaction with Yck1.**

A. Ismael<sup>1</sup>, N. Waszczak<sup>1</sup>, M. Metodiev<sup>2</sup>, W. Tian<sup>3</sup>, Y. Cao<sup>3</sup>, J. Liang<sup>3</sup>, D. Suchkov<sup>1</sup>, R. Arkowitz<sup>4</sup>, D. Stone<sup>1</sup>; <sup>1</sup>Biological Sciences, University of Illinois at Chicago, Chicago, IL, <sup>2</sup>University of Essex, Essex, United Kingdom, <sup>3</sup>Bioengineering, University of Illinois at Chicago, Chicago, IL, <sup>4</sup>University of Nice, Nice, France

The mating response of *S. cerevisiae* is directional. Mating cells must interpret the direction of the pheromone gradient and grow toward the closest potential partner. The pheromone receptors are the most upstream component of the mating response. They are distributed uniformly on the plasma membrane during vegetative growth, but in response to pheromone, are rapidly internalized and subsequently polarized to the region where the mating projection will form. We have previously shown that internalization of the receptor is required for its polarization but that actin-dependent directed secretion is not. Pheromone also induces the polarization of the G protein subunits, G $\alpha$  and G $\beta$ , and this is dependent on receptor internalization. How is receptor polarity established prior to actin-dependent directed secretion? In a genetic screen for proteins that interact with G $\beta$ , we identified Yck1, one of the two yeast casein kinases required for receptor phosphorylation and internalization. Yck1 interacted with G $\beta$  at the incipient shmoo site prior to morphogenesis in a bimolecular fluorescence complementation assay, and was identified by mass spectroscopy as a protein that bound to a G $\beta\gamma$  affinity column. A mutant form of G $\beta$  that cannot be phosphorylated, G $\beta^{\text{P-}}$ , showed a decrease in Yck1 interaction in both genetic and biochemical assays. Mathematical modeling suggests that the interaction between G $\beta$  and Yck1 is important for robust polarization of the receptor in a pheromone gradient. G $\beta^{\text{P-}}$  cells were defective in receptor polarization in both isotropic pheromone and gradient conditions. In mating mixtures, G $\beta^{\text{P-}}$  cells exhibited a defect in asymmetric receptor phosphorylation. Additionally, overexpression of G $\beta$  inhibited receptor phosphorylation. These data are consistent with a model in which G $\beta\gamma$  interacts with Yck1 to inhibit phosphorylation of the receptor, thereby preventing its internalization. On the up-gradient side of the cell, there is more activated receptor and free G $\beta\gamma$ , and therefore, better protection of the receptor. This initiates a positive feedback loop that results in polarization of the receptor and its G protein, thus establishing the growth site.

2005

**The yeast guanine nucleotide dissociation inhibitor (GDI) enforces singularity by enhancing competition between polarity sites.**

C-F. Wu<sup>1</sup>, D. J. Lew<sup>1</sup>; <sup>1</sup>Department of Pharmacology and Cancer Biology, Duke University, Durham, NC

Polarity establishment employs an evolutionarily conserved machinery centered around the Rho-family GTPase Cdc42p. In response to cell cycle cues, *Saccharomyces cerevisiae* concentrates active GTP-bound Cdc42p at a predictable site defined by landmark proteins. In the absence of landmarks (e.g. *rsr1Δ*), however, yeast cells are able to polarize at a single, random site, a process known as symmetry breaking. The local concentration of GTP-Cdc42p during symmetry breaking grows as a result of a self-amplifying positive feedback mechanism. There is also a negative feedback loop in the polarity circuit that buffers the level of GTP-Cdc42p and stops clusters from growing too large. When cells begin to polarize, they can grow several clusters of polarity factors. However, once key factors become depleted from the cytoplasm, the clusters compete with each other, eventually leaving only one winning cluster, which becomes the bud site. We are trying to understand how competition between clusters works. We find that the yeast guanine-nucleotide dissociation inhibitor (GDI), Rdi1p, is needed for rapid competition between clusters. In the absence of Rdi1p the initial clustering of polarity factors is slowed, and competition is also much slower: in some cases cells still have two clusters at the time of bud emergence, and they form two buds. These phenotypes indicate that Rdi1p accelerates competition between clusters, thereby ensuring that a single winner emerges and only a single bud forms. We are testing possible roles for Rdi1p in this process.

2006

**An optogenetic analysis of the minimal requirements for bud-site selection.**

D. Strickland<sup>1</sup>, M. Glotzer<sup>1</sup>; <sup>1</sup>Molecular Genetics and Cell Biology, The University of Chicago, Chicago, IL

An autocatalytic complex of four proteins (Cdc42, Cdc24, Bem1, PAK) is associated with the selection and maintenance of a single site of polarity in budding yeast, and positive feedback in this complex is required to amplify stochastic fluctuations in Cdc42 activity during symmetry-breaking polarization. However, the relevance of this feedback is not clear for situations where cells polarize towards an established spatial cue, and there has been no direct demonstration that artificially localized cues can be recognized and amplified solely through this mechanism. In order to experimentally manipulate signaling processes such as polarity establishment, we have created tunable, light-controlled interacting protein tags (TULIPs) based on genetic fusion with a photosensory LOV2 domain from plants and an engineered PDZ domain binding partner. These domains can be fused to cellular proteins of interest or localization motifs, thereby making their interaction light-regulated. We have shown that the tags function in yeast and mammalian cells and are readily adaptable to diverse signaling pathways. Here, we use TULIPs tags to confer light sensitivity to the activation of Cdc42 in yeast, thereby eliciting light-directed specification of the site of budding. We show that the multifunctional Cdc42 guanine nucleotide exchange factor (GEF), Cdc24, is sufficient to provide a spatial cue upon localized recruitment to the cortex, and that this artificial cue can override the endogenous cue. Furthermore, the polarity-specifying ability of Cdc24 is lost when either its GEF activity or its ability to interact with the scaffold Bem1 is ablated, even when a wild-type copy of Cdc24 is present. These results suggest that several different functionalities are required to trigger positive feedback and successfully specify the site of budding. Future experiments will explore the timing, cell-cycle dependence, and molecular requirements of light-directed polarity specification.

2007

**Electrochemical regulation of budding yeast polarity.**

A. Campetelli<sup>1</sup>, M. Piel<sup>1</sup>, F. Chang<sup>2</sup>, N. Minc<sup>1</sup>; <sup>1</sup>UMR 144, Institut Curie, Paris, France, <sup>2</sup>Dpt of Microbiology, Columbia University, New York, NY

Electrochemical cues, such as ion fluxes, membrane potential and membrane inner leaflet charges have been proposed to influence polarity establishment in different systems. One striking assay highlighting such effects are electrotactic experiments in which cells ranging from bacteria to neutrophils orient their polarized growth or migration to the direction of small exogenous electric fields (EFs). EFs may signal through the membrane by locally altering electrochemical cues around the cell; however molecular mechanisms remain poorly characterized. Here, we use the budding yeast *S. cerevisiae* as a model for eukaryotic polarity to study these effects. These cells polarize by locally selecting sites of bud emergence or by growing shmoo projections towards a mating partner. We grow budding yeast cells in microfluidic chambers in the presence of EFs and assay for polarity orientation. EFs cause budding cells to bud towards the cathode of the EF, when the bud site selection machinery is weak such as in WT diploids or in haploids *bud1* mutants. In the presence of pheromones ( $\alpha$ -factor), the EF directs shmoo growth in the opposite direction, towards the anode. This directional switch depends on downstream activation of Cdc42, as *far1-s* or *cdc24-m* mutants which fail to recruit the Cdc42 GEF, *cdc24* to the mating site, orient shmoo to the cathode, similar to budding cells. A candidate screen for upstream regulators at the plasma membrane, identifies conserved membrane potential regulators such as Nha1 and Trk1, as mediators of the EF response, and put forward the role of negatively charged lipids phosphatidylserine production in these effects. As these charges have been proposed to influence the local binding of Cdc42 for polarity establishment, these experiments begin to define pathways bridging electrochemical signals to the local activation of conserved polarity components. These original studies set the molecular basis of novel layers of polarity regulation that may be relevant to most cell types.

2008

**Cdc42 explores the cell periphery for mate selection in fission yeast.**

F. O. Bendezu<sup>1</sup>, S. G. Martin<sup>1</sup>; <sup>1</sup>Department of Fundamental Microbiology, University of Lausanne, Lausanne, Switzerland

How cells polarize in response to external cues is a fundamental biological problem. During sexual differentiation, yeast cells polarize growth towards the source of a pheromone gradient produced by cells of the opposite mating type. Polarized growth is controlled by the small GTPase Cdc42, a key eukaryotic polarity regulator that coordinates signaling, cytoskeleton polarization and vesicle trafficking. However, how cells establish polarity and choose a mate in complex cellular environments is poorly understood. We find that, in fission yeast, low-level pheromone signaling promotes a novel polarization state, where active Cdc42, its GEF Scd1 and scaffold Scd2, form co-localizing exploratory dynamic zones that sample the periphery of the cell. Two Cdc42 effectors, the actin cable-directed motor Myosin V Myo52 and the vesicle tethering exocyst complex labeled by Sec6 and Sec8, also dynamically co-localize with active Cdc42. However, prior to mate selection cells do not grow due to a block in the exocytosis of cell wall synthases Bgs1 and Bgs4. At the time of mate selection active Cdc42 zones are stabilized and capable of promoting cell wall synthase exocytosis and polarized growth. However, if cells do not experience prior low-level pheromone signaling, Cdc42 exploration fails and cells polarize growth at cell poles by default. Failure to explore results in altered partner choice, with cells mating preferentially with sister rather than non-sister cells. Thus, Cdc42

exploration serves to orient growth for partner selection and may promote genetic diversification.

2009

**Spatial segregation of polarity factors into distinct cortical clusters is required for cell polarity control.**

J. Dodgson<sup>1</sup>, A. Chessel<sup>1</sup>, F. Vagg<sup>2</sup>, S. Cox<sup>3</sup>, M. Sato<sup>4</sup>, A. Csikasz-Nagy<sup>2</sup>, R. Carazo Salas<sup>1</sup>;  
<sup>1</sup>University of Cambridge, Cambridge, UK, <sup>2</sup>The Microsoft Research-University of Trento Centre for Computational and Systems Biology, Trento, Italy, <sup>3</sup>Randall Division of Cell & Molecular Biophysics, Kings College London, London, UK, <sup>4</sup>Dept. of Biophysics and Biochemistry, University of Tokyo, Tokyo, Japan

Cell polarity is key to various cellular processes and much is known about the regulation and general localization of polarity-regulating factors to cortical sub-cellular domains. In contrast how the higher-order organization of polarity factors within sub-cellular domains relates to their function as dynamic positional landmarks is not well understood. We imaged frontally the cortex of live fission yeast (*Schizosaccharomyces pombe*) cells, using advanced imaging techniques including super-resolution microscopy. Interestingly, we found that polarity factors are organized in discrete and dynamic cortical protein clusters, which we can optically resolve to 50nm. Artificial oligomerization of the Kelch-repeat polarity factor Tea1p, in both its wild-type state and with a published deletion of a putative trimerization domain, suggests that the self-oligomerization capacity of polarity factors could be sufficient both to generate clusters and regulate their efficacy as landmarks. We also found from quantitative co-localization analysis that the polarity factors Tea1p and its ERM-family binding partner Tea3p belong to distinct cluster populations, which change in alignment during the cell-cycle becoming maximally co-localized during mitosis. This change in localization can also be associated with changes in the dynamics of both polarity factors. Permanent alignment of the same polarity factors by artificial dimerization created a loss of function, thus spatial segregation of polarity factor clusters provides a means to spatio-temporally control polarity at the cell cortex. We observed similarly clusters in *Saccharomyces cerevisiae* and *Caenorhabditis elegans* cells, indicating this could be a universal regulatory feature.

2010

**Tea5p is a Pseudokinase that Functions in Microtubule-Based Cell Polarization.**

R. A. Lutz<sup>1</sup>, M. A. Ellis<sup>1</sup>, F. Chang<sup>1</sup>; <sup>1</sup>Microbiology and Immunology, Columbia University, New York, NY

Microtubules regulate polarized cell tip growth in the fission yeast *Schizosaccharomyces pombe* by transporting cell polarity factors tea1p and tea4p on their plus ends to the cell tips. These proteins are critical for these rod-shaped cells to initiate growth at the “new” cell end in a process known as new end take off (NETO). How tea proteins regulate cell polarization downstream of microtubules remains unclear. Here we identify a new factor tea5p (also known as ppk2p) required for regulation of cell polarization for NETO. Tea5p is a pseudokinase as it lacks key residues required for kinase activity, and additional mutations in the kinase domain do not affect its function. Overexpression of tea5p leads to a striking loss of polarity, causing cells to become round. Pulldowns show that tea5p associates in a tight complex with tea3p. Genetic studies suggest that tea5p functions with tea3p downstream of tea1p in cdc42p activation via a signaling pathway consisting of the NDR kinase orb6p and a cdc42p GEF gef1p. Thus, tea5p constitutes a novel connection between microtubule +TIP proteins and activation of cdc42p for cell polarization.

2011

**Investigating the influence of mechanics on fission yeast cellular shape and growth pattern.**

*J. Abenza Martinez<sup>1</sup>, A. Chessel<sup>1</sup>, J. Dumais<sup>2</sup>, R. Carazo Salas<sup>1</sup>; <sup>1</sup>Gurdon Institute/Department of Genetics, University of Cambridge, Cambridge, United Kingdom, <sup>2</sup>Facultad de Ingeniería y Ciencias, Universidad Adolfo Ibáñez, Viña del Mar, Chile*

Cell shape and growth pattern are key to cell division, proliferation and differentiation. Although much is known about the role of the cytoskeletal and cell polarity machineries in defining cell shape and growth pattern, much remains to be understood about the influence of physical constraints on those processes, constraints that must ultimately feedback into the biochemical regulation of the cell.

We seek to clarify how physical constraints influence cell growth and how cell shape is transmitted across generations, using the cylindrically-shaped and genetically tractable fission yeast *Schizosaccharomyces pombe* as experimental model.

We have established a new method to track the fine cortical expansion of fission yeast cells as they grow, by decorating the cell wall with fluorescent nanocrystals (quantum dots, Qdots) and filming their displacement over time. With this method, we have been able to infer a geometrical map of the mechanical strains at play involved in the polar growth of *S. pombe* and to compare how that strain map compares with the cortical localization pattern of different cell growth machineries such as the  $\beta$ -glucan synthase GFP-Bgs4. This approach begins to clarify the respective contributions of mechanical and biochemical regulation in controlling cell morphogenesis in *S. pombe*.

In parallel, we have analysed cell shape transmission in  $\approx 30$  *S. pombe* gene knockout strains that display a curved phenotype. They include strains lacking not only genes predicted to be involved in cell polarity or the cytoskeleton (*tea1*, *tea2*, *tea4*, *pom1* or *mto1*), but also other genes that lack an obvious direct relation with those processes (*vps71*, *rpl3702* or *swr1*). As not all cells of a given mutant display the curved phenotype, we have investigated the cell shape fate of individual cells and their progeny after cell division, by carrying out pedigree analysis. We find that cell curvature is not predictably transmitted from one cell to its progeny but rather that cells have distinct cell shape inheritance rules related with the penetrance of their mutant phenotype. Importantly, shape inheritance also changes with the type of machinery affected in each mutant and mutants in similar molecular components give rise to similar shape inheritance patterns, indicating multiple layers of biochemical and mechanical cell shape regulation at play, which we are seeking to unravel.

**Symmetry breaking in fission yeast germination.**

*D. Bonazzi<sup>1</sup>, R. Seddiki<sup>1,2</sup>, M. Romao<sup>1,3</sup>, M. Piel<sup>1</sup>, A. Boudaoud<sup>4</sup>, N. Minc<sup>1</sup>; <sup>1</sup>Institut Curie, Centre de Recherche, Centre National de la Recherche Scientifique, Unité Mixte de Recherche 144, Paris, France, <sup>2</sup>Matière et Systèmes Complexes, UMR 7057 CNRS, Paris, France, <sup>3</sup>Cell and Tissue Imaging Facility (PICT-IBiSA), Paris, France, <sup>4</sup>Laboratoire Joliot-Curie, CNRS, ENS, Université de Lyon, Lyon, France*

The cross-talk between cell polarity and mechanics serves as a central paradigm for cellular morphogenesis. The rod-shape fission yeast *S. pombe* is an excellent model to study mechanisms regulating polarity and morphogenesis. In these cells, spatial landmarks at the cortex direct actin assembly and cell wall synthesis for turgor-driven polarized growth at cell tips. In here, we investigate how these cells become rod in the first place. We monitor germinating spores that exit quiescence to become vegetative cells with quantitative time-lapse microscopy. Rounded spores exhibit an initial near-isotropic growth phase and then break symmetry to

establish a single rod-shape growth axis, in a process termed outgrowth. We observe that the polarisome assembles in a single cap long before outgrowth. Strikingly, the polarisome wanders around the rounded spore yielding localized growth sites that fail to progress, disassemble and reform at a new site around the spore surface. Quantitative volume measurements reveal that polarisome stabilization and outgrowth happen when the spore has doubled its volume. This size sensing is independent of G1/S cell cycle transition, initial spore size, and is maintained in cytoskeleton, polarity or secretion mutants. Electron microscopy reveals that outgrowth is concomitant with the local rupture of the outer spore wall, a thin cell wall structure deposited at sporulation and essential for spore resistance. Strain-stress experiments show that this spore wall is 3 times stiffer than the inner wall, suggesting it may hinder or slow down growth. Photoablation of this outer wall hastens symmetry breaking. We propose models that compute the mechanical stress on the outer wall generated by turgor pressure and local growth. These models predict size-sensing mechanisms and morphogenetic features of outgrowth such as tip curvature establishment and growth rate changes.

**Role of the conserved NDR kinase Orb6 in the control of a cortical gradient of activated Cdc42.**

*M. Das*<sup>1</sup>, *I. Suarez*<sup>1</sup>, *D. Wiley*<sup>1</sup>, *A. Sarkeshik*<sup>2</sup>, *J. R. Yates*<sup>2</sup>, *P. Buchwald*<sup>1</sup>, *F. Verde*<sup>1</sup>; <sup>1</sup>*Molecular and Cellular Pharmacology, University of Miami Miller School of Medicine, Miami, FL,* <sup>2</sup>*The Scripps Research Institute, La Jolla, CA*

Recently our lab has shown that activated Cdc42 GTPase, a key morphology control factor, displays oscillatory dynamics at the two cell tips in fission yeast (Das et al, *Science*, 2012). These oscillations, which are anticorrelated at the two tips, are due to positive and delayed negative feedbacks and competition for Cdc42 activators. In this study, we describe a mechanism by which Cdc42 GEF Gef1 levels are regulated at the cell cortex, thus modulating Cdc42 dynamics at the cell tips.

Conserved NDR kinases regulate cell morphology in eukaryotes. Previous studies in our lab have shown that Orb6 kinase maintains cell polarity by spatially regulating activation of Cdc42 GTPase (Das et al, *Curr Biol*, 2009). *Orb6* mutants exhibit an expansion of the gradient of activated Cdc42 at the cell tips and a loss of polarity. Here we show that Orb6 kinase phosphorylates serine 112 in the N-terminus of Gef1 to facilitate Gef1 binding to the 14-3-3 protein Rad24. Consistent with Rad24 sequestering Gef1 in the cytoplasm, preventing Orb6 kinase phosphorylation of serine 112 leads to increased levels of Gef1 at the cortex. This results in an increased cell diameter, decreased anticorrelation of active Cdc42 oscillations at the cell tips, and precocious bipolar growth activation.

In *S. pombe* cells, activated Cdc42 forms a cortical gradient at the cell tips, which determines cell width (Kelly et al, *Mol Biol Cell*, 2011). We show that NDR kinase phosphorylation of Cdc42 GEF Gef1 modulates cell width, opposing the functional effects of Cdc42 GAP Rga4. Loss of Rga4 in *gef1S112A* mutants leads to complete loss of cell polarity, similar to *orb6* mutants. Thus, our observations indicate that the NDR kinase Orb6 alters Cdc42 dynamics through Gef1 localization to regulate cell diameter and bipolar growth activation.

### Differential Contributions of Nonmuscle Myosin II Isoforms to Stress Fiber Mechanics.

C-W. Chang<sup>1</sup>, S. Kumar<sup>1</sup>; <sup>1</sup>Bioengineering, University of California, Berkeley, Berkeley, CA

Actomyosin stress fibers (SFs) enable cells to generate traction forces against the extracellular matrix through the contractile activity of nonmuscle myosin II (NMMII). While the NMMII isoforms NMMIIA and NMMIIB are known to play distinct roles in cellular tension generation, their respective contributions to stress fiber mechanics remain unclear. To gain insight into this issue, we used femtosecond laser ablation to sever individual mCherry-LifeAct-labeled SFs in U373 MG human glioma cells in which NMMII isoforms were suppressed by lentiviral shRNAs. We recorded the retraction of the two severed SF ends and fit these data to a Kelvin-Voigt model featuring a viscoelastic time constant and a plateau retraction distance. Our results demonstrate that the two isoforms contribute in distinct ways to the viscoelastic properties of SFs located in the cellular center and periphery. Specifically, we find that NMMIIA suppression slightly speeds SF retraction kinetics for central SFs and reduces the plateau retraction distance for both central and peripheral SFs. By contrast, NMMIIB suppression produces significantly greater reductions in the viscoelastic time constant for peripheral SFs while surprisingly increasing the retraction distance of central SFs. The SF retraction dynamics associated with NMMIIA and NMMIIB suppression qualitatively phenocopy our earlier measurements in the setting of Rho kinase (ROCK) and myosin light-chain kinase (MLCK) inhibition, respectively (Tanner et al., Biophys J 2010). This broadly suggests that one functional relationship exists between central SFs, ROCK, and NMMIIA and that another exists between peripheral SFs, MLCK, and NMMIIB. Our study offers new insight into how NMMII isoforms differentially regulate contractile elements in specific cellular compartments and contribute to stress fiber contractility.

2015

### Dynamics of non-muscle myosin II organization into stress fibers and contractile networks.

W. Nie<sup>1</sup>, M-T. Wei<sup>1</sup>, H. Ou-Yang<sup>1</sup>, S. Jedlicka<sup>2</sup>, D. Vavylonis<sup>1</sup>; <sup>1</sup>Department of Physics, Lehigh University, Bethlehem, PA, <sup>2</sup>Department of Materials Science and Engineering, Lehigh University, Bethlehem, PA

The cellular morphology of adhered cells critically depends on the formation of a contractile meshwork of parallel and cross-linked stress fibers along the contacting surface. The motor activity and mini-filament assembly of non-muscle myosin II is an important component of cell-level cytoskeletal remodeling during mechanosensing. To monitor the dynamics of non-muscle myosin II, we used confocal microscopy to image cultured HeLa cells that stably express myosin regulatory light chain tagged with GFP (MRLC-GFP). MRLC-GFP was monitored in time-lapse movies at steady state and during the response of cells to varying concentrations of blebbistatin (which disrupts actomyosin stress fibers). Using image correlation spectroscopy analysis, we quantified the kinetics of disassembly and reassembly of actomyosin networks and compared them to studies by other groups. This analysis suggested that the following processes contribute to the assembly of cortical actomyosin and stress fibers: random myosin mini-filament assembly and disassembly along the cortex; myosin mini-filament aligning and contraction; stabilization of cortical myosin upon increasing contractile tension. We developed simple numerical simulations that include those processes. The results of simulations of cells at steady state and in response to blebbistatin capture some of the main features observed in the

experiments. This study provides a framework to help interpret how different cortical myosin remodeling kinetics may contribute to different cell shape and rigidity depending on substrate stiffness.

**Force Fluctuations within Focal Adhesions Mediate ECM Rigidity Sensing to Guide Directed Cell Migration.**

S. V. Plotnikov<sup>1</sup>, A. Pasapera<sup>1</sup>, B. Sabass<sup>2</sup>, C. M. Waterman<sup>1</sup>; <sup>1</sup>Laboratory of Cell and Tissue Morphodynamics, NHLBI/NIH, Bethesda, MD, <sup>2</sup>II. Institute for Theoretical Physics, University of Stuttgart, Stuttgart, Germany

Cell migration towards areas of higher extracellular matrix (ECM) rigidity via a process called “durotaxis” is thought to contribute to neuronal pathfinding, immune response, and cancer metastasis. To understand how cells dynamically sample ECM rigidity to guide durotaxis, we performed the first characterization of cell-generated forces on the nanoscale within single integrin-based focal adhesions (FAs). We found that individual FAs act autonomously within a cell, exhibiting one of two distinct states of force transmission. Traction within FAs is either constant and positionally static, or dynamically fluctuating in magnitude and position. We found that increasing ECM rigidity reduced the proportion of FAs exhibiting traction fluctuations over ~20kPa. Using pharmacological and genetic perturbations we find that a FAK-phosphopaxillin-vinculin pathway is essential for cells to exert high traction and to enable force fluctuations within FA over this 20kPa range of ECM rigidities. We show that traction fluctuations within FA are dispensable for FA maturation, chemotaxis and haptotaxis, but are critical to direct cell migration towards rigid ECM. Together, our findings show that individual FAs dynamically sample rigidity by applying fluctuating pulling forces to the ECM to guide durotaxis, and that a specific pathway downstream of FAK broadens the range of rigidities over which this dynamic sampling process operates, but is dispensable for directing cell migration in response to biochemical gradients.

**Sarcomere-Like Units Contract Cell Edges.**

G. Meacci<sup>1,2</sup>, M. Stachowiak<sup>3</sup>, S. Liu<sup>4</sup>, T. Iskratsch<sup>1</sup>, A. Mathur<sup>4</sup>, H. Wolfenson<sup>1</sup>, S. Ghassemi<sup>4</sup>, P. Roca-Cusachs<sup>1,5</sup>, E. Tabdanov<sup>6</sup>, N. Gauthier<sup>1</sup>, A. Gondarenko<sup>4</sup>, B. O’Shaughnessy<sup>3</sup>, J. Hone<sup>4</sup>, M. Sheetz<sup>1,7</sup>; <sup>1</sup>Biological Sciences, Columbia University, New York, NY, <sup>2</sup>The Nanomedicine Center for Mechanobiology Directing the Immune Response, New York, NY, <sup>3</sup>Chemical Engineering, Columbia University, New York, NY, <sup>4</sup>Mechanical Engineering, Columbia University, New York, NY, <sup>5</sup>Institute for Bioengineering of Catalonia and University of Barcelona, Barcelona, Spain, <sup>6</sup>Biomedical Engineering, Columbia University, New York, NY, <sup>7</sup>Mechanobiology Institute, National University of Singapore, Singapore, Singapore

Extracellular matrix rigidity directs cell behavior and key processes in development and tumorigenesis. During spreading and migration, cells produce periodic lamellipodial protrusion retractions cycles that require a rigid substrate and the development of adhesions<sup>1</sup>. Moreover, there is evidence that rigidity is detected locally in the region near the cell edge<sup>2</sup>. The motor protein myosin II powers cell retractions, which are simultaneous with rearward flow of the actin filament network<sup>1</sup>. However, the pattern and mechanism of forces exerted by cells to test matrix rigidity have not been characterized. Using high-resolution force sensing pillars, we show here that the primary forces powering periodic edge retraction come from local contraction units, which exert inward forces near the cell edge, correlated with outward forces 2-3 micrometers rearwards from the edge. Pillar displacement correlates with the local concentrations of active

myosin II and the actin crosslinking protein alpha-actinin, but not with local levels of other common actin binding proteins. The contractile units therefore display similarity to striated muscle and stress fiber units, which are ~1-3 micrometers long, rely on myosin II for contractility, and contain alpha-actinin as a major component of the complex that anchors actin filaments. Thus, our results indicate that local contractile units, with sarcomere-like organization, are responsible for periodic cell edge retractions and rigidity sensing. References: [1] G. Giannone, B. ### **Cells Maintain a Constant Lamellar Line Tension Responsible for Traction Stress Generation.**

*P. W. Oakes<sup>1,2</sup>, M. L. Gardel<sup>1,2</sup>; <sup>1</sup>Institute for Biophysical Dynamics, University of Chicago, Chicago, IL, <sup>2</sup>Department of Physics, University of Chicago, Chicago, IL*

Adherent and migratory cells generate tension and exert stress on their substrate via myosin II motors pulling on the actin cytoskeleton. Recent findings have shown that the bundling of actin into radial stress fibers is unnecessary for force generation. Here we show that the transverse arcs in the lamella are responsible for force generation and that the magnitude of the force exerted scales with the size of the cell. Specifically, the total force is directly proportional to the transverse length of the lamella in the cell. Using deep UV micropatterning of polyacrylamide gels, we created a series of circular patterns of constant area but with increasing aspect ratio. Cells on the circular patterns generated the most force, while cells with the most elongated shapes generated the least force. Traction stresses were only seen under the lamellar region of the cells. We confirmed this finding by creating a series of patterns with a constant arc length at the lamella, but with decreasing pattern area. Cells showed no change in the total amount of force exerted despite up to a 50% reduction in area. These results suggest that cells maintain a constant line tension locally in the lamella. The addition of pharmacological myosin inhibitors enabled us to tune the magnitude but not the behavior of the scaling. Furthermore, we find that this scaling is independent of substrate stiffness. Changes in substrate stiffness impacted a cell's ability to spread and form new stable adhesions, but did not affect the inherent line tension. Finally, this scaling law is independent of cell type, with the magnitude of the line tension representing a characteristic measure of contractility. Together these data suggest that a cell can be modeled as maintaining a constant line tension along its lamella, which is responsible for the generation of traction stresses. This work provides important insights into the mechanisms behind transmission of stress from the cytoskeleton to the substrate during migration and overall cellular behavior on soft substrates.

### **Spatiotemporal distribution of tensile forces by single stress fibers at the cell-matrix interface.**

*C-W. Chang<sup>1</sup>, S. Kumar<sup>1</sup>; <sup>1</sup>Bioengineering, University of California, Berkeley, Berkeley, CA*

Stress fibers (SFs) exert tension on the extracellular matrix (ECM) through focal adhesions (FAs). While it is widely appreciated that these tensile forces play key roles in polarity, motility, fate choice, and other defining cell behaviors, it remains poorly understood how single SFs distribute tension across cellular FAs, where adhesion-dependent signals are triggered. We address this open question by using femtosecond laser ablation to sever single SFs in cells while tracking FA tension changes with a vinculin-based optical tension sensor. Surprisingly, disruption of a single SF reduces tension in FAs located throughout the cell, with enriched

tension reduction in FAs oriented parallel to the targeted SF. Remarkably, some FAs exhibit enhanced tension upon SF irradiation, with individual FAs observed to undergo dramatic, unexpected transitions between tension-enhanced and tension-reduced states. These changes evolve with time following SF disruption and depend strongly on the location of the severed SF, consistent with our earlier finding that different SF pools are regulated by distinct myosin activators (Tanner et al., *Biophys J* 2010). To unify these findings, we present a structural model in which central SFs are more interconnected and mutually reinforced than peripheral SFs due in part to the presence of transverse actomyosin structures that link central SFs into a cohesive network. Tension released upon compromise of a central SF is thus broadly redistributed to other stress fibers and focal adhesions, resulting in stabilization of cell shape. This study represents perhaps the most direct and high-resolution measurements of SF tensional homeostatic contributions to date, as well as a new paradigm for studying molecular-scale transmission of tensile force through the actin cytoskeleton to specific molecules at the cell-matrix interface. In addition, this approach could be extended to investigate the role of these forces in modulating cell-cell adhesion, metalloprotease-mediated matrix digestion, and many other problems.

2020

**Myosin II-independent ECM stiffness sensing by nascent adhesions.**

*S. P. Winter*<sup>1,2</sup>, *P. W. Oakes*<sup>2,3</sup>, *M. L. Gardel*<sup>2,3</sup>; <sup>1</sup>*Interdisciplinary Scientist Training Program, University of Chicago, Chicago, IL*, <sup>2</sup>*Institute for Biophysical Dynamics, University of Chicago, Chicago, IL*, <sup>3</sup>*Department of Physics, University of Chicago, Chicago, IL*

Extracellular matrix (ECM) stiffness is known to impact cell spreading, migration, differentiation and proliferation. Such ECM stiffness-dependent changes in cell physiology are thought to be important for tissue organization and maintenance, while misregulation of stiffness sensing is thought to play a vital role during pathogenesis. Current dogma asserts that ECM stiffness sensing occurs by myosin II-generated forces at mature focal adhesions in the lamella. Here, we show that ECM stiffness sensing modulation of cell spread area for NIH 3T3 fibroblasts occurs at a Young's Modulus of 8 kPa, delineating a "soft" and a "stiff" regime. We find that cells on soft ECMs spread about fifty percent less than those on stiff ECMs. Surprisingly, we find that myosin II activity plays almost no role in this response. Cells that have been treated with blebbistatin, a myosin II ATPase inhibitor, or Y-27632, a Rho Kinase inhibitor, spread to slightly larger areas, but otherwise retain differences between soft and stiff regimes. To identify the mechanisms underlying myosin-II independent stiffness sensing, we analyze protrusive activity of the myosin II-independent lamellipodium and assembly of nascent adhesions. We find that protrusion rates are indistinguishable on soft and stiff, but that the protrusions on soft matrices are unstable and rarely lead to productive cell advance. On soft ECMs, immunofluorescent paxillin images reveal a reduced density of nascent adhesions at the base of the lamellipodium. Live imaging of GFP-paxillin expressing cells confirms that cells on soft ECMs form significantly fewer myosin II-independent adhesions than those on stiff ECMs. We were able to partially recover spread area and myosin II-independent adhesion formation on soft substrates through the addition of PDGF, which increases Rac1 signaling, or  $Mn^{2+}$ , which stimulates integrin activation. These data strongly suggest that ECM stiffness regulates myosin II-independent adhesion formation in the lamellipodium and is the origin of the changes in cell spread area on matrices of different stiffnesses.

2021

**Modeling actin, myosin and adhesion dynamics based on measured forces and movements in the lamellipodium and lamellum.**

*E. M. Craig<sup>1</sup>, J. Stricker<sup>2</sup>, M. L. Gardel<sup>2</sup>, A. Mogilner<sup>1</sup>; <sup>1</sup>Department of Neurobiology, Physiology and Behavior, and Department of Mathematics, University of California, Davis, Davis, CA, <sup>2</sup>Institute for Biophysical Dynamics, James Frank Institute, and Department of Physics, University of Chicago, Chicago, IL*

Cell motility relies on the continuous reorganization of a dynamic actin-myosin-adhesion network at the leading edge of the cell, in order to create protrusive force at the leading edge membrane and traction force between the cell and its external environment. We analyze experimentally measured spatial distributions of actin flow, traction force, myosin density, and adhesion density in control and myosin-inhibited epithelial cells and consider a number of mechanical models of this system. A model in which myosin associates and dissociates from the actin network while flowing inward with the network can explain the measured molecular distributions and correctly predict the location of the lamellipodium-lamellum boundary. We use this model to determine the active and passive stresses in the system, and to gain insight into the mechanical properties of the actin network and of the nascent adhesions. The load response characteristics of the nascent adhesions allow the system to maintain a robust inward flow of actin in the presence of greatly varying contractile and traction forces.

2022

**Cell intrinsic mechanochemistry of protruding cells.**

*N. Costigliola<sup>1</sup>, R. Allen<sup>2</sup>, C. Guilluy<sup>3</sup>, M. Vilela<sup>1</sup>, G. Danuser<sup>1</sup>, T. Elston<sup>2</sup>, K. Burrridge<sup>3</sup>, K. Jacobson<sup>3</sup>; <sup>1</sup>Cell Biology, Harvard Medical School, Boston, MA, <sup>2</sup>Pharmacology, University of North Carolina, Chapel Hill, Chapel Hill, NC, <sup>3</sup>Cell Biology, University of North Carolina, Chapel Hill, Chapel Hill, NC*

While the mechanochemical regulation of the cytoskeleton has been studied in depth, it remains a challenge to study these pathways on the relevant time scale *in vivo*. In addition, the regulation of cell movement depends heavily on substrate architecture and composition. In an effort to address the relationship between mechanochemistry and live cell morphology changes, we examined the cell intrinsic mechanochemistry of rounded, rapidly protruding (~1 min) cells. We used a combination of biochemistry, high resolution microscopy, and quantitative image analysis to elucidate signaling pathways occurring at the actomyosin cortex. We found that myosin II contractility and RhoA activity are spatiotemporally regulated at the cortex and co-localize with actin density. In fact, myosin II contractility positively self-regulates via activation of the RhoA activator GEFH1. Upstream of GEFH1, Pak inhibits both GEFH1 activity and distribution and myosin II light chain Ser19 phosphorylation in rounded cells. We show that the dynamic activation of Pak kinase is required for the structural integrity of the actomyosin cortex, suggesting that Pak dynamics may be responsible for the spatiotemporal regulation of contractility we observe. Pak activity also regulates the cortical response to myosin II activity levels, further indicating that Pak dynamics are essential to the regulation of cell intrinsic mechanotransduction.

**Characterizing Tyrosine Phosphorylation in the Vinculin Tail Domain**

*C. E. Tolbert<sup>1</sup>, P. Thompson<sup>2</sup>, R. Superfine<sup>3</sup>, K. Burrridge<sup>1,4</sup>, S. L. Campbell<sup>2,4</sup>; <sup>1</sup>Cell Biology and Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, <sup>2</sup>Biochemistry and Biophysics, University of North Carolina at Chapel Hill, Chapel Hill, NC, <sup>3</sup>Physics and*

*Astronomy, University of North Carolina at Chapel Hill, Chapel Hill, NC, <sup>4</sup>Lineberger Cancer Center, University of North Carolina at Chapel Hill, Chapel Hill, NC*

Vinculin is an essential cell adhesion protein involved in controlling cell shape, motility and force transduction, in part by coupling the actin cytoskeleton to the extracellular matrix. Vinculin is tightly regulated by intramolecular interactions between the N-terminal head domain (Vh) and the C-terminal (CT) tail domain (Vt) which are linked by a flexible proline-rich region. Vt has been shown to bind and bundle F-actin thereby reinforcing maturing focal adhesions. This actin association is believed to induce Vt dimerization, which in turn promotes F-actin bundling. Given the importance of this interaction in focal adhesion maturation and dynamics, it is likely that vinculin/actin interactions are regulated by additional factors such as phosphorylation. Recent studies from our lab have shown that the CT of vinculin containing the only tyrosine phosphorylation site in Vt is necessary for actin-induced bundling, cellular reinforcement and focal adhesion properties. However, the role of tyrosine phosphorylation in Vt (Y1065) and its full impact on vinculin regulation have not been elucidated. Here, we show that Src-mediated phosphorylation of Vt modulates F-actin bundling. Additionally, we show that a common mutation of Y1065 (Y1065F) exhibits an aberrant F-actin bundling capacity. These results are consistent with our findings that the CT hairpin of Vt, containing Y1065, is critical for actin induced Vt-dimerization and F-actin bundling. We have structurally characterized alternate Vt variants that either mimic tyrosine phosphorylation at this site or cannot be phosphorylated to study the cellular role of Y1065 phosphorylation on focal adhesion dynamics and cellular stiffening in response to force. Results from these studies will be presented.

2024

**Membrane tension co-ordinates pseudopod extension during phagocytosis.**

*T. A. Masters<sup>1</sup>, M. P. Sheetz<sup>1,2</sup>, N. C. Gauthier<sup>1</sup>; <sup>1</sup>Mechanobiology Institute, National University of Singapore, Singapore, Singapore, <sup>2</sup>Department of Biological Sciences, Columbia University, New York, NY*

Pseudopod extension in FcγR-mediated phagocytosis occurs in two phases. The first phase is sufficient for the engulfment of small particles (1-3 μm), but a second PI3-Kinase dependent phase is required for ingestion of larger particles. These phases are characterized by differential spatio-temporal regulation of exocytosis and small GTPases. However, the origin of the transition between these two phases is not well understood. We find that this transition is determined by the plasma membrane tension. We show that during frustrated phagocytosis an increase in membrane tension activates exocytosis and dramatically alters the spatial distribution of Rac activation in macrophages. We find the exocytic compartment which responds to membrane tension is linked to an actin-dependent microtubule independent glycosphosphatidylinositol-anchored protein (GPI-AP) recycling pathway. Membrane tension in macrophage plasma membranes increases during phagocytosis of IgG coated beads. By artificially increasing membrane tension with osmotic shock, we dramatically increase phagocytosis efficiency. This effect can partially overcome PI3-Kinase inhibition and microtubule depolymerisation, but fails when secretion is inhibited with NEM. This suggests PI3-Kinase driven protrusion is important for generation of membrane tension during phagocytosis and that tension sensing mechanisms are required to drive exocytosis and the pseudopod transition to complete ingestion of large particles. Given that a GPI-AP rich compartment is recruited to the cell surface during fibroblast spreading and migration, it potentially constitutes a universal membrane area regulation function.

2025

**Regulation of cellular tension: Does the cell have a contractile setpoint?**

*K. D. Webster<sup>1</sup>, W. Ng<sup>2</sup>, D. A. Fletcher<sup>1,2,3</sup>; <sup>1</sup>Biophysics, UC Berkeley, Berkeley, CA, <sup>2</sup>Bioengineering, UC Berkeley, Berkeley, CA, <sup>3</sup>Physical Biosciences, Lawrence Berkeley National Lab, Berkeley, CA*

Adherent cells generate forces through acto-myosin contraction and sense the mechanical properties of their environment. In the context of tissues, these cells have been described as existing in tensional homeostasis with their surroundings, implying an internal regulation of tension at the cellular level. We explicitly test this tension regulation by mechanically perturbing fibroblast cell tension and observing the contractile response. As a cell spreads and contracts sandwiched between two parallel fibronectin-coated surfaces, it exerts a tensile load across the height of the cell. We use a flexible, tipless atomic force microscope (AFM) cantilever as the top surface to measure and to modulate forces, displacements, and stiffness of the contracting cell. Cell spreading is confined on both surfaces to defined regions using micropatterning. We find that within an hour of initial attachment, contraction forces level out to a steady state value as the cell reaches the edges of the fibronectin-coated areas on the cantilever and substrate. To specifically test whether the magnitude of the steady state tension is an internally regulated setpoint, we modulate the tensile load or stiffness once cellular tension has settled at a stable value. Interestingly, fibroblast cells do not maintain the same magnitude of cellular tension after tensile perturbations, while tension remains unchanged for changes in stiffness alone. Our results suggest that the tension cells produce while spreading is not tightly regulated after spreading ceases. These observations have important implications for understanding the timing of cellular control of contraction as a function of environmental loads and stiffness, indicating that the contractile state of cells might be most sensitive to the mechanics of their environment during the initial spreading stage of cellular attachment.

**Actomyosin cytoskeletal organization distinguishes lobopodia from lamellipodia.**

*R. Petrie<sup>1</sup>, N. Gavara<sup>2</sup>, R. S. Chadwick<sup>2</sup>, K. M. Yamada<sup>1</sup>; <sup>1</sup>National Institute of Dental and Craniofacial Research, National Institutes of Health, Bethesda, MD, <sup>2</sup>National Institute on Deafness and Other Communication Disorders, National Institutes of Health, Bethesda, MD*

Three-dimensional (3D) cell migration through chemically and structurally diverse environments is an important component of embryogenesis, immune surveillance, and wound healing. The regulation of cellular force production (mechanotransduction) by cell-matrix adhesions can control how cells move. For example, the rigidity of 2D extracellular matrix regulates cellular contractility to control the speed of cell migration, while the elastic behavior of 3D matrix governs the mechanical mode of membrane protrusion. Cells in non-linear elastic environments use actin polymerization to extend small, fan-shaped lamellipodia, while cells in linear elastic materials are characterized by blunt, cylindrical lobopodia. To determine how linear elastic 3D extracellular matrix regulates mechanotransduction to control the mode of leading-edge protrusion, we investigated the function of the actomyosin machinery during lamellipodia- and lobopodia-based migration. In non-linear elastic 3D collagen, PIP3 and active Rac1 and Cdc42 were targeted to the leading edge, consistent with 2D lamellipodia-based migration. In contrast, cells migrating inside linear elastic dermal explants and cell-derived matrix (CDM) were characterized by non-polarized Rac1, Cdc42, and PIP3 signaling. Despite these differences in polarized signaling, 3D lamellipodia and lobopodia protruded with similar speed and persistence, and RhoA activity remained relatively uniform within cells using either mode of migration. Significantly, myosin IIA localization was different in lobopodia compared to lamellipodia. Myosin IIA was localized along distinct peripheral F-actin fibers in lobopodia, while

in lamellipodial cells, it was organized in a periodic pattern associated with cortical F-actin beneath the plasma membrane. Switching fibroblasts from lobopodia- to lamellipodia-based migration by inhibiting cellular contractility and mechanotransduction corresponded with the loss of GFP-myosin light chain from the peripheral fibrillar structures. Thus, lobopodia are distinguished by distinct myosin IIA-positive structures that may act to generate the intracellular force necessary for this mechanical mode of lamellipodia-independent 3D migration.

2027

**Mechanics of bleb formation and bleb-based migration.**

*M. Bergert<sup>1,2</sup>, S. D. Chandradoss<sup>1,2</sup>, R. A. Desai<sup>1</sup>, E. Paluch<sup>1,2</sup>; <sup>1</sup>Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, <sup>2</sup>International Institute of Molecular and Cell Biology, Warsaw, Poland*

Protrusion formation at a cell's leading edge is an important step during cell migration. Studies in development and cancer cell motility show that contractility-driven blebs are a common alternative to the well characterized actin polymerization-based lamellipodia or filopodia, particularly in three-dimensional environments. Moreover, a cell's ability to switch between different protrusions is thought to facilitate motility in complex environments and to promote cancer dissemination.

Despite the importance of plasticity in migration, the minimal requirements for switching between protrusions and the physical mechanisms of bleb-based motility remain largely unknown. To address these questions, we use Walker 256 carcinosarcoma cells, which can be selected based on the adhesiveness of the substrate to generate two distinct sublines that form either blebs or lamellipodia. By systematically investigating protrusion switching at the single cell level, we demonstrate that shifting the balance between actin polymerization and actomyosin contractility is sufficient to lead to immediate transitions between blebs and lamellipodia. Furthermore, rapid transitions between blebs and lamellipodia could also be triggered upon changes in substrate adhesion during migration on micropatterned surfaces. Our data indicates that instantaneous switching between protrusions occurs without prior changes in global cell shape or polarity, suggesting that protrusion formation is an independent module in the regulatory network that controls the plasticity of cell migration.

We then asked how cell body translocation was achieved during bleb-based migration. We found that blebbing Walker cells require confined environments for efficient migration. Our data suggest that in these cells, in contrast to lamellipodia-based migration, force transmission during locomotion does not require transmembrane coupling via focal adhesions. Using molecular and biophysical approaches combined with microfluidic engineering we are currently investigating the mechanisms of force transmission during bleb-based motility.

**Influence of matrix stiffness on morphology, direction and persistence of motile cells.**

*M. Riaz<sup>1</sup>, M. Versaevel<sup>1</sup>, S. Gabriele<sup>1</sup>; <sup>1</sup>mechanobiology and soft matter, University of Mons, Mons, Belgium*

Cell motility is defined as the capacity of cells to move by a self-generated movement. Motility is fundamental to a wide variety of processes such as embryogenesis (development), wound healing (maintenance), immune responses (lifetime) but also in pathological processes as cancer metastasis. According to the disparities of the physico-chemical properties of the extracellular matrix, stationary cells adapt their internal and external organisations, such as the spreading area, the distribution of focal adhesions, the cytoskeletal organisation, etc... However, only few studies have underlined the impact of the physic-chemical properties of the extracellular environment on motile cells.

In this work, we have used fish keratocytes which have a robust morphology, a persistent shape and movement and a very fast motion (up to 18  $\mu\text{m}/\text{minute}$ ). By using a wide range of ECM stiffnesses covered with a constant cell-ligand density, we have studied the morphology of keratocytes and dynamic parameters (velocity, trajectory, coefficient motility, ...) in response to changes in ECM stiffnesses. We have observed that ECM stiffness controls the cellular shape within the natural phenotypic variability of keratocytes. Then, we have shown that the mechanical rigidity of ECM significantly affects the migratory behavior in terms of directional persistence time, translocation speed and random motility coefficient.

To elucidate the mechanisms by which ECM rigidity affects the internal machinery of motile cells, we have used immunostaining methods and total internal reflection fluorescence (TIRF) microscopy to characterize the organisation of focal adhesions, molecular motors and the cytoskeletal organization in response to ECM stiffnesses.

**Silicone gels for cell rigidity sensing and patterned cell adhesion: robust mechanical properties, TIRF/TFM microscopy, and induced cell polarization on soft substrates.**

*E. Gutierrez*<sup>1</sup>, *E. Tkachenko*<sup>2</sup>, *M. Ginsberg*<sup>2</sup>, *A. Groisman*<sup>1</sup>; <sup>1</sup>Physics, U.C.S.D., La Jolla, CA, <sup>2</sup>Medicine, U.C.S.D., La Jolla, CA

Substrate rigidity impacts cellular migration, gene expression, development, and tumorigenesis, especially in a range of elastic moduli,  $E$ , of 0.1 to 100 kPa. Soft substrates commonly used for cell rigidity sensing studies and cell traction force microscopy (TFM) are hydrogels, such as polyacrylamide gels. Elastic moduli of thin gels are usually measured with atomic force microscopy (AFM), which requires expensive equipment. Elastic moduli of hydrogels can change due to drying, swelling, aging, and hydrolysis of molecular bonds. Here, we formulated and successfully cultured cells in a series of silicone gels with  $E$  covering a range from 0.4 to 300 kPa that were all prepared by mixing different proportions of two components of a commercial silicone, Sylgard 184. Silicone pre-polymers were spin-coated onto microscope cover glasses to  $\sim 35$   $\mu\text{m}$  thickness and a specially built microfluidic device was bound to the silicone gel. Elastic moduli of the gels were measured with 5-10% absolute accuracy by tracking displacements of beads on the surfaces of the gels, when known hydrodynamic shear stresses were applied. Mechanical properties of the silicone gel layers were consistent and robust, with  $\sim 3\%$  variability within a batch and  $\sim 10\%$  change after 6 months of storage.

We also formulated and prepared layers of silicone gels with  $E$  from 0.4 to 130 kPa and with refractive index,  $n$ , of 1.49. The high value of  $n$  made the gels fully compatible with through-the-lens Total Internal Reflection Fluorescence Microscopy (TIRFM) using TIRF objectives with numerical apertures (NA) of up to 1.49. TIRFM enables selective visualization of the dynamics of substrate adhesions, vesicle trafficking, and biochemical signaling at the cell-substrate interface. For TFM, we also chemically functionalized the surface to covalently bind 40nm far-red fluorescent beads and matrix protein to the gel. We plated mouse endothelial cells with fluorescently labeled F-actin on the  $n = 1.49$  silicone gels and successfully performed concurrent TIRFM and TFM. We obtained high-quality TIRF images of the cells showing maps of F-actin localization at the substrate and juxtaposed them with high-resolution traction force maps obtained with TFM.

Using moderately soft gels,  $E$  of 20 kPa, we also patterned matrix protein on the surface creating arrays with different 50x50 micron shapes (e.i. arrows and circles). Variable surface chemistry enabled blocking of the unpatterned area with PEG and covalent binding of 40nm beads and matrix protein to the patterns. The dimension of the shapes fits only one cell per

shape and constrains formation of focal adhesions to the patterned area, either inducing or preventing cell polarization and orientation.

**Lamin-A levels limit 3D-migration but protect against migration-induced apoptosis.**

*T. Harada<sup>1</sup>, J. Swift<sup>1</sup>, J-W. Shin<sup>1</sup>, D. E. Discher<sup>1</sup>; <sup>1</sup>University of Pennsylvania, Philadelphia, PA*

Cell migration through dense tissue and matrix requires a cell and its nucleus to contort and flow. A strong dependence of 3D-migration processes on the variably expressed nucleoskeletal protein lamin-A is revealed here across widely different cell types relevant to disease and regeneration. Crawling through tissue is modeled by motility through micro-pores, with small decreases in lamin-A producing large increases in net migration. Surprisingly, the largest effects occur when wildtype lamin-A is low relative to constitutive lamin-B's. Nuclear shape changes after micro-pore migration as well as nuclear response times in micropipette aspiration scale strongly with the lamin-A:B ratio across cell types, revealing lamin-A's role in nuclear plasticity and lamin-B's role in nuclear elasticity. Lamin-A also protects against apoptosis induced by micro-pore migration, with deeply deficient cells showing defects in stress-resistance. Xenografts provide in vivo insight and show moderately low lamin-A levels promote growth of the graft. The nuclear lamina thus acts as a physical impediment to motility and also promotes survival in withstanding the mechanical stresses of migration.

**Rigidity Sensing in T cells by Actin-Dependent Phosphorylation of Src Family Kinase Substrate Cas-L.**

*L. C. Santos<sup>1</sup>, M. Biggs<sup>2</sup>, S. Wind<sup>3</sup>, M. Dustin<sup>4</sup>, M. Sheetz<sup>1</sup>; <sup>1</sup>Biological Sciences, Columbia University, New York, NY, <sup>2</sup>Network of Excellence for Functional Biomaterials, National University of Ireland-Galway, Galway, Ireland, <sup>3</sup>Department of Applied Physics and Applied Mathematics, Columbia University, New York, NY, <sup>4</sup>School of Medicine, New York University, New York, NY*

The rigidity sensing mechanisms involved in T cell activation are unknown. The Crk-associated tyrosine kinase substrate lymphocyte type (Cas-L) is a scaffold protein mainly expressed in lymphocytes and epithelial cells. Previously we showed that phosphorylation of YxxP repeats on the substrate domain of Cas-L-family member p130Cas is involved in sensing extracellular matrix rigidity in fibroblasts in response to integrin engagement. Here, we show that Cas-L acts in T cells like its homologue p130Cas, undergoing increased tyrosine phosphorylation in cells spreading on substrates of higher Young modulus. T cells spreading on stiff poly dimethylsiloxane (PDMS) substrates coated with agonist antibodies against TCR and integrin ligand ICAM-1 show increased Src-family kinase (SFK)-dependent phosphorylation of Cas-L substrate domain in comparison to softer substrates. Importantly, the ability to discern rigid from soft matrices is lost when actin polymerization is disrupted by cytochalasin D. Moreover, actin-disruption as well as myosin-IIA inhibition affects the total levels of phospho-CasL at early stages of cell spreading. This suggests that Cas-L phosphorylation is driven by forces generated by polymerizing f-actin and myosin-IIA contraction. We propose a two-step model to describe how T cells sense substrate rigidity via actomyosin-dependent Cas-L phosphorylation. This work highlights the importance of mechanosensory systems in T cells responding to different rigidity microenvironments.

**Effect of substrate mechanical properties on T cell spreading and activation.**K. L. Hui<sup>1</sup>, A. Upadhyaya<sup>1</sup>; <sup>1</sup>Physics, University of Maryland, College Park, MD

T cell activation is a key process in cell-mediated immunity, and is important in directing an effective immune response against infections. Engagement of T cell receptors by peptides on antigen presenting cells leads to activation of signaling cascades as well as cytoskeletal reorganization and large scale membrane deformations. While significant advances have been made in understanding the biochemical signaling pathways, the effects imposed by the physical environment and the role of mechanical forces on cell activation are not well understood. In this study, we have used anti-CD3 coated elastic polyacrylamide gels as stimulatory substrates to enable the spreading of Jurkat T cells and the measurement of cellular traction forces. We have investigated the effect of substrate stiffness on the dynamics of T cell spreading and cellular force generation. We found that T cells display more active and sustained edge dynamics on softer gels and that they exert increased traction stresses with increasing gel stiffness. An intact actomyosin cytoskeleton was required to maintain the forces generated during activation, as inferred from small molecule inhibition experiments. Our results indicate an important role for physical properties of the antigen presenting cell as well as cytoskeleton-driven forces in signaling activation.

**Neuronal mechanosensitivity in axonal pathfinding.**H. Svoboda<sup>1</sup>, L. D. Costa<sup>2</sup>, J. Guck<sup>3</sup>, C. E. Holt<sup>1</sup>, K. Franze<sup>1</sup>; <sup>1</sup>Department of Physiology, Development and Neuroscience, University of Cambridge, Cambridge, United Kingdom, <sup>2</sup>Instituto de Fisica de Sao Carlos, University of Sao Paulo, Sao Carlos, Brazil, <sup>3</sup>Department of Physics, University of Cambridge, Cambridge, United Kingdom

During the development of the nervous system, neurons migrate and grow over great distances. During these processes, they are exposed to a multitude of signals influencing their speed and direction. Currently, our understanding of nerve tissue development is, in large part, based on studies of biochemical signalling. Despite the fact that forces are involved in any kind of cell motion, mechanical aspects have so far rarely been considered. Here we used custom-built deformable cell culture substrates, traction force microscopy and calcium imaging to investigate how neurons probe and respond to their mechanical environment. The growth rate of retinal ganglion cell axons was increased on stiffer substrates. However, their tendency to grow in bundles (i.e., to fasciculate), which they commonly show in vivo, was significantly enhanced on more compliant substrates. Moreover, if grown on substrates incorporating linear stiffness gradients, neuronal axons were repelled by stiff substrates. Mechanosensing involved the application of forces driven by the interaction of actin and myosin II, and the activation of stretch-activated ion channels leading to calcium influxes into the cells. Applying a modified atomic force microscopy technique in vivo, we found stiffness gradients in developing brain tissue. Importantly, retinal ganglion cell axons followed a soft pathway. The application of chondroitin sulfate, which is a major extracellular matrix component in the developing brain, resulted in stiffening of the tissue and disrupted axonal pathfinding. Hence, our data suggest that neuronal growth in the central nervous system is not only guided by chemical signals – as it is currently assumed – but also by the nerve tissue's mechanical properties.

2034

**Mechanisms of three-dimensional glioma cell motility in non-fibrillar matrices.**B. Ananthanarayanan<sup>1</sup>, G. Singh<sup>1</sup>, J. MacKay<sup>1</sup>, C-W. Chang<sup>1</sup>, Y. Kim<sup>1</sup>, S. Kumar<sup>1</sup>;<sup>1</sup>Bioengineering, University of California, Berkeley, Berkeley, CA

Diffuse infiltration of single cells into brain parenchyma is a hallmark of malignant glioma. This extreme invasiveness makes complete tumor resection difficult and contributes to the high mortality rate associated with this disease. Brain parenchyma has a distinct physical structure characterized by densely packed neural cell processes and sub-micron extracellular space, and is largely devoid of the fibrillar collagen scaffolding typically found in stromal tissue. Consequently, glioma cells migrating in brain slices exhibit a distinct type of motility, with branched protrusions and hourglass-shaped cell-body deformations that help squeeze cells through tight spaces (Beadle *et al.*, *Mol. Biol. Cell* 2008; 19(8):3357-68). However, the mechanistic details of this unique mode of motility remain incompletely understood. To address this question, we synthesized brain-mimetic nanoporous, non-fibrillar extracellular matrices (ECMs) based on cross-linked hyaluronic acid (HA), the major component of brain ECM, and functionalized them with Arg-Gly-Asp (RGD)-containing peptides to facilitate integrin-mediated cell adhesion. In a three-dimensional (3D) spheroid invasion paradigm, glioma cell motility was highly reminiscent of that seen in brain slices, validating the use of these ECMs a model system (Ananthanarayanan *et al.*, *Biomaterials* 2011; 32(31):7913-23). Eliminating RGD peptides from the ECM abolished invasion, suggesting a requirement for integrin-mediated adhesions for this mode of motility. Increasing matrix density, or inhibiting myosin-based cellular contractility by blebbistatin or shRNA-induced knockdown of Myosin IIA also severely impaired motility. We also report preliminary results from two sets of studies: First, we investigate the balance of protrusive and contractile forces in glioma cell motility by pharmacologically and genetically manipulating the Rho GTPases Rac1 and RhoA. Second, we explore the involvement of hyaluronidase-mediated enzymatic remodeling of the HA matrix in this mode of motility. Our studies collectively help define the intracellular and extracellular signals that underlie the distinct mode of glioma cell motility observed in non-fibrillar matrices.

2035

**Regulation of renal cell migration by septin 2.**L. Dolat<sup>1</sup>, J. R. Bowen<sup>1</sup>, E. Platonova<sup>2</sup>, H. Ewers<sup>2</sup>, E. T. Spiliotis<sup>1</sup>; <sup>1</sup>Biology, Drexel University, Philadelphia, PA, <sup>2</sup>Institute of Biochemistry, ETH, Zurich, Switzerland

Renal cell carcinoma (RCC) is an aggressive metastatic cancer with poor response rates to therapeutic intervention. Recent studies show that the septin 2 GTPase is frequently upregulated in RCCs, which are defective for the von Hippel-Lindau (VHL) tumor suppressor. Septin 2 (SEPT2) is a member of the filamentous septin GTPases, which serve as scaffolds for protein-protein interactions and form diffusion barriers that demarcate distinct membrane compartments. Previous studies have implicated septins in cell motility and migration, but the mechanisms involved remain unknown. Here, we investigate whether and how SEPT2 affects the migration of RCCs. Using the VHL-null RCC cell line 786-O, we show that SEPT2 depletion decreases the rate of wound closure and impairs the ability of 786-O cells to transmigrate along a passive serum gradient. In migrating kidney cells (MDCK) that undergo epithelial-to-mesenchymal transformation after treatment with the hepatocyte growth factor (HGF), SEPT2 filaments appear to localize dorso-distally to paxillin-enriched focal adhesions at the leading edge. Super-resolution microscopy shows that SEPT2 localizes to the tail of focal adhesions and confocal microscopy reveals that SEPT2 colocalizes with the radial actin stress fibers, which are anchored to peripheral focal adhesions. Time-lapse imaging of SEPT2-YFP and

paxillin-mCherry shows that SEPT2 is recruited to the growing focal adhesions of migrating MDCK cells. Interestingly, SEPT2 depletion results in smaller, more numerous and peripheral focal adhesions in both 786-O and MDCK cells. To determine whether SEPT2 affects the maturation of focal adhesions, we stained for phospho-paxillin (pY118), whose levels are known decrease during focal adhesion maturation. We found that focal adhesions in SEPT2-depleted cells contain a two-fold increase in pY118-paxillin relative to control cells. Taken together, these data suggest that SEPT2 regulates the maturation of nascent focal adhesions. On-going studies aim at determining if SEPT2 is essential for the generation and maintenance of mechanical tension at focal adhesions through the assembly and/or contraction of actin stress fibers.

**Filamin is necessary to trigger calcium signaling and cell contraction in vivo.**

*I. Kovacevic<sup>1</sup>, E. J. Cram<sup>1</sup>; <sup>1</sup>Biology, Northeastern University, Boston, MA*

Mechanosensation is critical for normal development and tissue function. We are using the *C. elegans* spermatheca as a model system to study how cells sense and respond to mechanical forces in vivo. The spermatheca is a simple myoepithelial tube that naturally experiences cycles of extreme stretching and constriction as oocytes enter, are fertilized, and exit into the uterus. We have discovered that FLN-1/filamin, a stretch-sensitive actin binding and signaling scaffold, is required for this process. PLC-1/phospholipase C- $\epsilon$  is also required for the exit of embryos from the spermatheca. Using GCaMP, a genetically encoded calcium indicator, we show that entry of an oocyte into the spermatheca initiates a distinctive series of calcium oscillations which propagate across the tissue via gap junctions and eventually lead to coordinated acto-myosin based contraction and expulsion of the fertilized egg. Genetic analysis indicates FLN-1 acts upstream of PLC-1 to initiate phosphatidylinositol (PI) signaling, calcium release, and contraction of the spermathecal cells. We hypothesize that filamin is required in the spermatheca to respond to increased strain, which initiates calcium oscillations via PLC-1. Current work is focused on understanding the dual roles of filamin as a signaling and structural scaffold, as well as uncovering other components of the pathway.

**Mechanical waves orient cell division during monolayer growth.**

*X. Serra-Picamal<sup>1,2</sup>, M. Uroz<sup>1</sup>, X. Trepac<sup>1,2,3</sup>; <sup>1</sup>Integrative Cell and Tissue Dynamics, Institute for Bioengineering of Catalonia, Barcelona, Spain, <sup>2</sup>Departament Ciències Fisiològiques I, Universitat de Barcelona, Barcelona, Spain, <sup>3</sup>Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain*

The growth of epithelial tissues is essential to morphogenesis and is recapitulated in postnatal life to enable wound healing and tissue regeneration. Dysregulation of underlying processes contributes to devastating epithelial-derived diseases such as carcinomas. Epithelial growth is increasingly regarded as a mechanical phenomenon in which physical forces not only drive cell motions but also trigger and feedback signaling pathways. The physical forces that drive epithelial growth and the mechanisms by which they regulate cell division and migration remain poorly understood, however. To study these forces we combine traction microscopy, monolayer stress microscopy, and polydimethylsiloxane (PDMS) cell micropatterning. We design PDMS microstencils with a central rectangular pattern and deposit them on top of a collagen-coated polyacrylamide gel. Cells attach and proliferate on the micropatterned area of the gel until they reach confluence and acquire an epithelial phenotype. Membrane removal triggers collective cell migration, generating a mechanical wave of strain rate that propagates slowly throughout the monolayer, traversing intercellular junctions in a cooperative manner. Moreover, as the

monolayer expands, oscillations in cell-cell stress are generated, whose direction and magnitude define the orientation of cell division. This wave suggests a novel mechanism of long range cell guidance and pattern formation during monolayer expansion.

2038

**Effects of an inflammatory response and changes in substrate stiffness on human mesenchymal stem cell transmigration through the endothelium.**

*J. A. Vaitkus<sup>1</sup>, M. O. Wang<sup>1</sup>, J. P. Fisher<sup>1</sup>, H. Aranda-Espinoza<sup>1</sup>; <sup>1</sup>University of Maryland, College Park, College Park, MD*

Stem cells have been investigated for potential for cell therapy of a wide variety of diseases in the human body. Human mesenchymal stem cells (hMSCs), in specific, have been shown to be present in the bloodstream, and have therefore been believed to hold promise for therapy of diseases such as Parkinson's. However, to date, there have not been many studies aiming to exploit the migration and differentiation of hMSCs for use in novel drug and gene delivery techniques to tackle diseases in all areas of the body. In order to develop such techniques, we must gain a better understanding of the mechanisms of hMSC transmigration through the vascular endothelium, something which has been largely unexplored. Here, we investigate the effects of an inflammatory response and varying substrate stiffnesses on the percentage and speed of hMSC transmigration through the endothelium. The inflammatory cytokine tumor necrosis factor-alpha (TNF- $\alpha$ ) was added to human vascular endothelial cell (HUVEC) monolayers to simulate inflammatory conditions. Results show that while TNF- $\alpha$  does not cause a significant change in the percentage of hMSC transmigration, it does cause a decrease in the speed of transmigration. Additionally, experiments were repeated on hydrogels of various biologically-relevant stiffnesses, and results show that substrate stiffness does not cause a change in percentage or speed of hMSC transmigration. Together, our results show that while substrate stiffness may not be an important variable in understanding hMSC transmigration, inflammation of the vascular endothelium affects hMSC transmigration mechanics and therefore needs to be taken into consideration as research continues in the area of stem cell transmigration, so that the application of stem cell therapy may be fully and successfully utilized.

**Fluid shear stress and sphingosine 1-phosphate promote Filamin A membrane translocation and complex formation with VE-cadherin during endothelial cell invasion.**

*H. ang<sup>1</sup>, R. R. Kaunas<sup>2</sup>, K. J. Bayless<sup>1</sup>;*

<sup>1</sup>Molecular and Cellular Medicine, Texas A&M Health Science Center, College Station, TX,

<sup>2</sup>Biomedical Engineering, Texas A&M University, College Station, TX

Cell junctions play a key role in regulating angiogenic responses and the receptors. Vascular endothelial (VE)-cadherin and PECAM-1 have been previously defined as mechanosensors. Filamin A and Filamin B are highly expressed in endothelial cells and have been reported to be regulated by shear stress. We previously demonstrated sphingosine 1-phosphate (S1P) and fluid wall shear stress (WSS) stimulate endothelial cell (EC) invasion in three-dimensional (3D) collagen matrices. In this study we explored the role of junction proteins and filamins in the regulation of EC invasion in response to S1P and WSS. EGTA, a chelator of calcium ions, fully disrupted localization of junction proteins to the plasma membrane and significantly decreased S1P- and WSS-induced invasion. Short hairpin RNA-mediated gene silencing of VE-cadherin, PECAM-1, filamin A, and filamin B reduced S1P- and WSS-induced invasion. Also we observed that S1P and WSS synergistically promoted filamin membrane localization as determined by immunofluorescence. Further, these observations were confirmed by co-immunoprecipitation

studies where S1P and WSS enhanced VE-cadherin interactions with filamin and PECAM-1. Our data show for the first time that filamin A complex with VE-cadherin in response to S1P and WSS to regulate endothelial sprouting in 3D collagen matrices.

2040

#### **Endothelial Cell Response to Complex Flow Profiles.**

*M. A. Ostrowski<sup>1</sup>, N. F. Huang<sup>2</sup>, T. W. Walker<sup>1</sup>, C. Poplowski<sup>1</sup>, A. S. Khoo<sup>2</sup>, M. Devicha<sup>1</sup>, J. P. Cooke<sup>2</sup>, G. G. Fuller<sup>1</sup>, A. R. Dunn<sup>1</sup>; <sup>1</sup>Chemical Engineering, Stanford University, Stanford, CA, <sup>2</sup>Division of Cardiovascular Medicine, Stanford University, Stanford, CA*

The ability of the endothelial cells that line the interior of blood vessels to sense and respond to fluid flow is an essential component of cardiovascular development, homeostasis, and disease. In particular, the endothelium at arterial bends, branches, and at surface irregularities is prone to chronic inflammation that contributes to the development of atherosclerotic lesions. However, while extensive work has characterized the response of these cells to uniform, laminar flow, the response of endothelial cells to the complex, spatially varying wall shear stresses present in vivo remains poorly understood. We investigated the effects of complex flows on endothelial cells in vitro using a novel impinging flow device that exposes endothelial cells to shear stress gradients and stagnation point flows similar to those found at arterial bifurcations. We investigated multiple shear stress levels over a range found in the aorta (9-200 dynes cm<sup>-2</sup>) and found that in all cases human microvascular endothelial cells migrated toward the vicinity of the stagnation point, and against the direction of fluid flow. We also found that these cells aligned parallel to the flow direction at low levels of shear stress, but perpendicular to the flow direction near the center, stagnation point. These observations suggest that endothelial cell migration and polarization may thus play presently unrecognized roles in the early stages of atherosclerotic lesion formation, particularly in regions of complex flow.

2041

#### **Defining the Mechanism of Enhanced Cellular Invasion Induced by Mechanical Stimulation.**

*S. Ozarkar<sup>1</sup>, K. A. Beningo<sup>1</sup>; <sup>1</sup>Department of Biological Sciences, Wayne State University, Detroit, MI*

Formation of secondary tumors by metastasis is a leading cause of death in cancer patients. During metastasis cells separate from the primary tumor, invade the stroma, travel through blood and lymph and colonize tissues distant from the primary mass. Several biochemical factors have been identified which are able to drive the metastatic cascade. However information of the role of mechanical factors in cancer metastasis has primarily been focused on the effect of compliance, overshadowing other mechanical factors that might facilitate metastatic progression. For instance, contractile cells within the stroma can produce tugging and pulling forces in the extracellular matrix as they migrate and remodel the stroma. These activities provide a transient and variable force that would propagate between cells. To simulate this mechanical force, we previously developed an in vitro mechano-invasion assay where cancer cells are subjected to tugging or pulling forces. These forces simulate those produced by contractile cells in the tumor microenvironment, without interference of any cell secreted factors. Surprisingly, we discovered a significant difference in the extent of invasion in mechanically stimulated versus non-stimulated cell culture environments. This mechanically enhanced invasion by cancer cells requires the presence of fibronectin in the extracellular matrix. The objective of our study is to understand the mechanotransduction pathway leading to enhanced invasion. We hypothesized that in response to mechanical forces in the stroma, tumor cells will show an altered expression of genes involved in mechanosensing. We performed expression

profiling of several genes related to cell migration, adhesion and tumor metastasis by real-time PCR analysis. Six genes were confirmed to be differentially expressed between mechanically stimulated and non-stimulated conditions. Surprisingly, one of the genes found to be significantly down-regulated in the mechanically stimulated invasion culture is a fibronectin specific integrin subunit. Over-expression of this gene resulted in a significant decrease in enhanced invasion, supporting its role in sensing the mechanical stimulus. We further propose that mechanical stimulation during invasion, results in integrin crosstalk, leading to the down-regulation of this fibronectin specific integrin while enriching others within the invadopodia.

### **Cell Type Specific Durotactic Response on Polyelectrolyte Multilayer Compliance Gradients.**

*J. S. Martinez<sup>1</sup>, A. M. Leha<sup>2</sup>, J. B. Schlenoff<sup>2</sup>, T. C. Keller<sup>1</sup>; <sup>1</sup>Biology, Florida State University, Tallahassee, FL, <sup>2</sup>Chemistry, Florida State University, Tallahassee, FL*

To explore the usefulness of polyelectrolyte multilayers (PEMUs) as biocompatible coatings, adhesion and motility of rat aortic smooth muscle A7r5 and human osteosarcoma U2OS cells cultured on PEMUs were investigated. These cells are representative of the vascular smooth muscle and osteoblast cell types that could interact with surfaces of PEMU coated biomedical implants. The PEMUs investigated were built layer-by-layer with a photosensitive negatively-charged polyelectrolyte PAA (poly(acrylic acid)) modified with 4-(2-Hydroxyethoxy) benzophenone (PAABp) and the positively-charged polyelectrolyte PAH (poly(allylamine hydrochloride)). These polyelectrolytes form stable PEMUs through electrostatic interactions and can be covalently crosslinked creating C-C bonds between the layers with ultraviolet irradiation. PEMU surface and bulk properties such as compliance were tuned by varying the degree of ultraviolet light exposure to generate uniform surfaces or gradients of crosslinking using optical filters or edge masking for a steeper gradient. Cell type-specific responses to surface compliance resulted in different adhesion, cytoskeleton organization, and motility behaviors. Although both cell types adhere and spread better on stiffer surfaces, the A7r5 cells were more tolerant than the U2OS cells to a wider range of Young's elastic modulus on which they redistributed vinculin-containing focal adhesions and rearranged stress fibers in response to different surface compliances. In contrast, U2OS were less tolerant of the more compliant surfaces and underwent apoptosis on the softest surfaces. In addition, the A7r5 cells exhibited durotactic responses on both shallow and steep compliance gradients. Along shallow compliance gradients, the A7r5 cells established a polar orientation toward increasing Young's modulus. Windrose plot analysis of cell motility on steeper edge gradients show A7r5 cell durotaxis toward the stiffer portion of the PEMU surface. Analysis of collective cell sheet durotactic response to compliance gradients is ongoing.

2043

### **Influence of extracellular matrix proteins and substratum topography on corneal epithelial cell alignment and migration.**

*B. Rose<sup>1</sup>, V. Raghunathan<sup>1</sup>, C. McKee<sup>1</sup>, P. Russell<sup>1</sup>, C. J. Murphy<sup>1,2</sup>; <sup>1</sup>Dept of Surgical and Radiological Sciences, School of Veterinary Medicine, University of California Davis, Davis, CA, <sup>2</sup>Dept of Ophthalmology, School of Medicine, University of California Davis, Davis, CA*

The basement membrane (BM) of the corneal epithelium presents biophysical cues in the form of topography and compliance that can impact the phenotype and behaviors of cells and their nuclei through modulation of cytoskeletal dynamics. It is also well known that the intrinsic biochemical attributes of BMs can modulate cell behaviors. In this study, the influence of an exogenous coating of extracellular matrix proteins (FNC) in addition to substratum topography on cytoskeletal changes, alignment and migration of immortalized corneal epithelial cells (hTCEpi) was investigated. In the absence of FNC coating, a significantly greater percentage of cells aligned parallel with the underlying anisotropically ordered topographic features however their ability to migrate was impaired. Also, changes in surface area, elongation and orientation of cytoskeletal elements were differentially influenced by the presence or absence of FNC. These results suggest that the presence of surface associated ECM proteins modulate the effect of topographic cues. These findings have relevance to the conduction of experiments using culture with biomimetic biophysical attributes as well as the integration of biophysical cues in tissue engineering strategies and the development of improved prosthetics.

2044

### **A GEF/GAP modulator defines locomotory and invasive protrusion polarity in migrating tumor cells.**

*J. J. Bravo-Cordero<sup>1,2</sup>, V. P. Sharma<sup>1,2</sup>, M. Roh-Johnson<sup>1,2</sup>, X. Chen<sup>1</sup>, R. Eddy<sup>1</sup>, J. Condeelis<sup>1,2</sup>, L. Hodgson<sup>1,2</sup>; <sup>1</sup>Anatomy and Structural Biology, Albert Einstein College of Medicine of Yeshiva University, Bronx, NY, <sup>2</sup>Gruss Lipper Biophotonics Center, Bronx, NY*

Locomotory and invasive protrusions are essential first steps that precede tumor cell invasion and migration. Spatial control of actin polymerization is necessary to achieve directional protrusion during cell migration. By using a RhoC biosensor we show that the localization of RhoC activity is crucial to maintain actin polymerization asymmetry in order to sculpt the amplitude and the shape of locomotory and invasive protrusions. This spatial localization of RhoC activity is necessary to place active cofilin right at the leading edge of locomotory protrusions by phosphorylating cofilin behind it. Here we show that RhoC activation at leading edge protrusions is regulated by a p190RhoGEF/p190RhoGAP module that spatially restricts actin barbed end distribution to shape lamellipodia during protrusion. The same mechanism is used to shape invadopodia into needle shaped protrusions. This mechanism reveals a dynamic plasticity in the distribution and amplitude of barbed ends, which can be modulated by fine-tuning RhoC activity by upstream GEFs and GAPs for directed cell motility. p190RhoGEF/p190RhoGAP are able to dynamically tune the location and amplitude of actin barbed ends in protrusions through direct effects on RhoC/Cofilin pathway. In addition, our data show that RhoC is an important component of the cellular steering-mechanism during chemotaxis by defining where actin polymerization takes place in response to external signals.

**Cellular contact guidance through dynamic sensing of nanotopography.**

*W. Losert<sup>1</sup>, M. Driscoll<sup>1</sup>, C. Guven<sup>1</sup>, X. Sun<sup>1</sup>, J. Fourkas<sup>1</sup>; <sup>1</sup>University of Maryland, College Park, MD*

We investigate the shape dynamics of the amoeba *Dictyostelium discoideum* on surfaces with nano-topography. Contact guidance (cellular alignment and migration parallel to one-dimensional surface features) has been observed for many cell types migrating on various surfaces. While patterning of focal adhesion complexes (FACs) has been implicated in contact guidance, we observe significant contact guidance of *Dictyostelium* along ridge and groove shaped nano- and microtopographic surfaces, even though *Dictyostelium* lacks FACs. We find that cells that move parallel to the ridges are faster and more elongated than cells that move perpendicular to ridges. Cells that move parallel to ridges are also more protrusive at their fronts than cells that move perpendicular to ridges. Quantification of contact guidance efficiency shows that ridges with a spacing of about 1.5  $\mu\text{m}$  have the greatest contact guidance efficiency. To further analyze contact guidance we measured cell shape dynamics in depth. In a baseline study on flat surfaces, we had demonstrated that cell shapes change in a wave-like manner, with regions of high boundary curvature that propagate from the leading edge toward the back, usually along alternating sides of the cell. Such protrusion waves are easily seen in cells that do not adhere to a surface, such as cells that are electrostatically repelled from surfaces or cells that extend over the edge of micro-fabricated cliffs, but wave-like dynamics of protrusions are also present during migration on surfaces. Therefore we model contact guidance on nanogratings in terms of stochastic cellular harmonic oscillators that couple to the periodicity of the ridges. The wavelength and speed of the oscillations that best couple to the surface are consistent with actin waves, indicating that the dynamics of the actomyosin machinery may be crucial for the contact guidance process. Finally, we explore the possibility to direct cells unidirectionally, utilizing the dynamic nature of the contact guidance process.

**Walking the line: a fibronectin fiber-directed lymphangiogenesis assay.**

*M. Mitsi<sup>1</sup>, M. Schulz<sup>2</sup>, M. Detma<sup>2</sup>, V. Vogel<sup>1</sup>; <sup>1</sup>Department of Health Sciences and Technology, ETH, Zurich, Switzerland, <sup>2</sup>Institute of Pharmaceutical Sciences, ETH, Zurich, Switzerland*

The terms angiogenesis and lymphangiogenesis refer to complex morphogenetic processes, whereby new blood or lymphatic vessels respectively, grow from the pre-existing vasculature to meet the needs of the tissue, for example during embryonic development, wound healing or cancer. Although several growth factors and signaling pathways have been identified as regulators of angiogenesis, the role of the extracellular microenvironment, including the biomechanical properties of the extracellular matrix, remains poorly understood. In the present work, we aimed to develop a suitable assay, where questions of that nature can be addressed. Our experimental approach involves manually pulled fibronectin fibers interacting with microcarrier beads, on the surface of which a confluent layer of lymphatic endothelial cells is grown. The whole system can be monitored microscopically. Under various experimental conditions, we have observed cell outgrowth from the microcarrier surface to the fibers. Even when the substrate underneath the fibers consisted of fibronectin or collagen, cells preferred to migrate along the fibers, providing evidence for the importance of fibrillar fibronectin as guiding cue for the first steps of sprouting angiogenesis. Consistent with the known ability of VEGF to enhance endothelial cell motility and promote angiogenesis, the number of outgrowth events was increased upon VEGF stimulation. Importantly, we were able in this novel assay to observe and study qualitative differences in the cell movement induced by VEGF. In the absence of

VEGF, the majority of outgrowth events consisted of single cells migrating away from the microcarrier along the fibers. In contrast, when VEGF was added to the medium, the cell activity was dominated by collective cell movement. Although the central role of VEGF in angiogenesis is well established, our assay allows asking new questions regarding the mechanisms concerning the differentiation of tip from stalk cells, as well as factors that coordinate the movement of the cells during sprouting angiogenesis.

#### **Fluxes of water across AQP9 modulate cell migration and cellular junctions.**

*T. Karlsson<sup>1</sup>, B. C. Lagerholm<sup>2</sup>, E. Vikström<sup>1</sup>, V. M. Loitto<sup>1</sup>, K-E. Magnusson<sup>1</sup>; <sup>1</sup>Department of Clinical and Experimental Medicine, Linköping University, Linköping, Sweden, <sup>2</sup>University of Southern Denmark, Odense, Denmark*

During epithelial wound healing, the cells migrate as an epithelial sheet of interconnected cells often described as collective cell migration. In this process, cell-cell communication is of major importance for guidance of multi-cellular units. In contrast, single cell migration is based on extracellular cues that act at the single cell level, rather than through direct cell-cell communication between front and rear of an entire cell sheet. Fluxes of water across the cell membrane through aquaporins (AQP), have been shown to impact on cell migration. During cell motility, increased expression of AQPs appears to facilitate locomotion. However, the role of AQPs has not been assessed in the context of single cell versus collective cell migration. In this study, we have over-expressed the mammalian AQP9 in epithelial MDCK-1 cells and compared the migration both at single and collective cell levels. We found that in the epithelial wound healing assay, cells over-expressing AQP9 migrated faster than cells expressing an empty vector. In contrast, the latter migrated over larger distances as single cells. Moreover, we found an enhanced transepithelial resistance in cells over-expressing AQP9, indicating a tighter epithelial monolayer. We assume that AQP9 contributes to the strengthening of intercellular attachments in the monolayer, possibly by enabling rapid volume regulation. It is likely that this also enhances the collective migration mode and provides the monolayer with a forward push to migrate into the wound.

2048

#### **EB1-recruited microtubule +TIP complexes coordinate protrusion dynamics during 3D epithelial remodeling**

*S. Gierke<sup>1</sup>, T. Wittmann<sup>1</sup>; <sup>1</sup>University of California San Francisco, San Francisco, CA*

Epithelial remodeling, in which apical-basal polarized cells switch to a migratory phenotype, plays essential roles in development and disease of multicellular organisms. How microtubule dynamics are controlled or contribute to epithelial remodeling in a more physiological three-dimensional (3D) environment is not understood. We used confocal live-cell imaging to analyze microtubule function and dynamics during 3D epithelial morphogenesis and remodeling of polarized Madin-Darby kidney epithelial cells that undergo a partial epithelial-to-mesenchymal transition (EMT) in response to hepatocyte growth factor (HGF). We found that extensions at the basal surface of HGF-treated cysts are densely packed with microtubules. Computational tracking of EB1-2xEGFP showed large numbers of microtubules growing persistently from the apical domain into these extensions, often deforming the extension tip, and an increase in microtubule growth rate in response to HGF before morphological changes were evident. Next, we tested the role of microtubule plus-end tracking protein (+TIP) complexes in 3D epithelial remodeling by depleting cells of EB1, an adaptor protein that mediates recruitment of other +TIP proteins to growing microtubule plus-ends. In EB1-depleted cells, microtubules displayed rapid

lateral and retrograde movements demonstrating that EB1 is required to anchor and stabilize growing microtubules in HGF-induced extensions. EB1-depleted cysts formed shorter, more branched, extensions further suggesting that EB1 is required for productive HGF-induced extension outgrowth. Analysis of cell-matrix interactions and F-actin dynamics revealed that control extensions progressively pulled on and deformed the extracellular matrix (ECM) typically with one F-actin-rich protrusion near the cell tip. In contrast, EB1-depleted cells produced multiple highly dynamic F-actin rich protrusions that did not productively engage the matrix, resulting in extensions that rapidly protruded, retracted and changed direction. The inability to engage the matrix and stabilize a dominant protrusion was also associated with defects in cell-matrix adhesions. EB1-depleted extensions formed nascent adhesions that did not mature, were mislocalized, and were uncoordinated, in contrast to the highly coordinated adhesions of control cells. Finally we show that trafficking of VAMP3-positive vesicles to the protrusion tip is disrupted in EB1-depleted cells. Together these data suggest that EB1-mediated organization of the MT cytoskeleton and associated vesicle delivery to the tip of HGF-induced extensions are likely required to coordinate cell-matrix adhesion and protrusion dynamics during 3D epithelial remodeling.

**Spontaneous oscillatory rotational behavior during collective cell migration.**

*S. Manivannan<sup>1</sup>, J. P. Gleghorn<sup>1</sup>, J. M. Nestor<sup>2</sup>, Y. G. Kevrekidis<sup>1</sup>, C. M. Nelson<sup>1,2</sup>; <sup>1</sup>Department of Chemical and Biological Engineering, Princeton University, Princeton, NJ, <sup>2</sup>Department of Molecular Biology, Princeton University, Princeton, NJ*

Collective migration is a remarkable behavior observed in nature, from populations as diverse as flocks of birds and schools of fish to the motion of cells during embryonic development and wound healing. Here we show that epithelial cells confined within monolayers spontaneously organize and undergo rotational collective motion. We used microlithography-based techniques to create adhesive islands of fibronectin and time-lapse imaging combined with pseudo-automated cell tracking algorithms to visualize the movements of cells within monolayers cultured on these islands. We found that the coherence of group rotation is affected by the size and shape of the tissue geometry. In addition, while the initial direction of rotation is selected stochastically, disturbances within the monolayers such as those from cytokinesis are able to switch the direction of rotation. Using computational simulations, we found that cells within monolayers behave not as pure random walk particles, but instead as Vicsek-Czirok type self propelled, interacting particles, similar to birds within a flock or fish within a school. These results indicate that basic principles of collective motion that govern animal behavior may be conserved in cellular motion. An improved understanding of these underlying principles will benefit future studies of collective cell migration.

2050

**Rab11 regulates cell-cell communication during collective cell movements.**

*D. Ramel<sup>1</sup>, X. Wang<sup>2</sup>, C. Laflamme<sup>1</sup>, D. Montell<sup>3</sup>, G. Emery<sup>1</sup>; <sup>1</sup>IRIC - Université de Montréal, Montréal, QC, Canada, <sup>2</sup>Cnrs, Toulouse, France, <sup>3</sup>The Department of Biological Chemistry, Johns Hopkins University School of Medicine, Baltimore, MD*

Collective cell movements contribute to development and metastasis. The small GTPase Rac is a key regulator of actin dynamics and cell migration. However, the mechanisms regulating Rac in time and space during collective cell migration are poorly understood. Here, we demonstrate that Rab5 and Rab11 regulate Rac activity and polarization during collective cell migration. We

use photoactivatable forms of Rac to demonstrate that Rab11 acts on the entire group to ensure that Rac activity is properly restricted to the leading cell through regulation of cell-cell communication. In addition, we show that Rab11 binds to the actin cytoskeleton regulator Moesin and regulates its activation *in vivo* during migration. Accordingly, reducing Moesin activity also affects cell-cell communication, whereas expressing active Moesin rescues loss of Rab11 function during migration. Our model suggests that Rab11 controls the sensing of the relative levels of Rac activity in a group of cells leading to the organization of individual cells in a coherent multicellular motile structure.

2051

### **Paxillin Controls Tumor Angiogenesis by Changing Neuropilin-2 Expression.**

A. E. German<sup>1,2</sup>, A. Mammoto<sup>2</sup>, T. Mammoto<sup>2</sup>, E. Jiang<sup>2</sup>, D. E. Ingber<sup>2,3,4</sup>, <sup>1</sup>Harvard-MIT Division of Health Sciences and Technology, MIT, Cambridge, MA, <sup>2</sup>Vascular Biology Program, Harvard Medical School, Boston, MA, <sup>3</sup>Wyss Institute, Boston, MA, <sup>4</sup>Harvard School of Engineering and Applied Sciences, Cambridge, MA

Angiogenesis - the growth of new capillary blood vessels - is required for tumor growth; however, tumor vessels commonly exhibit abnormal structure and function, which impairs the targeted delivery of anti-cancer agents. Although a number of growth factors and receptors that control tumor angiogenesis are characterized, relatively little is known about the mechanism by which these factors influence directional endothelial cell migration so as to produce malformed tumor vessels. Recently we reported that the focal adhesion protein, paxillin, is required for directional migration of fibroblasts *in vitro*. Here we show that paxillin knockdown decreases expression of neuropilin 2 (NRP2), which enhances capillary cell migration and invasion, and thereby, interferes with microvessel network formation *in vitro* and *in vivo* in a Matrigel plug implantation model in mice. Soluble factors secreted by tumors also decrease expression of both paxillin and NRP2 in endothelial cells, and over expression of NRP2 restores both oriented cell migration and normal microvessel formation. These results suggest that the paxillin-NRP2 pathway could represent a new therapeutic target for cancer and other angiogenesis-related diseases.

### **A Transparent, Implantable Device for the Generation of Chemoattractant Gradients in the Tumor Microenvironment.**

J. K. Williams<sup>1</sup>, M. R. Padgen<sup>1</sup>, A. N. Clark<sup>1</sup>, Y. Wang<sup>2</sup>, D. Entenberg<sup>2</sup>, J. S. Condeelis<sup>2</sup>, J. Castracane<sup>1</sup>; <sup>1</sup>College of Nanoscale Science and Engineering, University at Albany, Albany, NY, <sup>2</sup>Gruss Lipper Biophotonics Center, Albert Einstein College of Medicine, Yeshiva University, Bronx, NY

New technologies are needed to provide a better understanding of the role of the tumor microenvironment in promoting metastasis. The Nano Intravital Device (NANIVID) is being developed as a tool to collect cells *in vivo* and study the motility characteristics of invasive cell populations from metastatic mammary tumors. Transparent, biocompatible materials are used to fabricate the device to enable intravital imaging while implanted in the tumor. A reservoir is etched into a glass substrate and loaded with a hydrogel matrix containing epidermal growth factor (EGF) as a chemoattractant for the invasive tumor cell population. The reservoir is sealed using a polymer membrane and a second glass substrate to produce the final device featuring a single outlet for chemoattractant release. When the hydrogel becomes hydrated, EGF diffuses from the outlet and forms a sustained concentration gradient suitable for attracting invasive

cells. The device has overall dimensions of 3 mm x 1.3 mm, and the reservoir outlet is located approximately 100 microns from the back edge of the device. When fully inserted into the tumor *in vivo*, the outlet will be located at the proper depth for intravital imaging of cell migration. Validation of the device has been previously performed *in vitro* in 2D using MTLn3-Mena<sup>INV</sup> cells, a rat mammary adenocarcinoma cell line. Current work is focused on transitioning the NANIVID to an *in vivo* platform. Experiments are being performed *in vivo* utilizing MDA-MB-231 cell-derived mammary tumors in SCID mice. Cell motility parameters such as velocity, directionality, and displacement will be compared between cell populations in an extended range from the device outlet. Various EGF concentrations will be compared to determine the optimal concentration for attracting tumor cells. Complementary work is also underway focused on *in vivo* cell collection.

### **Follower Cells Become Leader Cells during the Closure of Spontaneously Formed Holes in Zebrafish Keratocyte Sheets.**

S. M. Knight<sup>1</sup>, J. F. Reyes<sup>2</sup>, K. E. Cooper<sup>1</sup>, K. J. Leyva<sup>3</sup>, E. E. Hull<sup>1</sup>; <sup>1</sup>Biomedical Sciences Program, Midwestern University, Glendale, AZ, <sup>2</sup>Arizona College of Osteopathic Medicine, Glendale, AZ, <sup>3</sup>Microbiology & Immunology, Arizona College of Osteopathic Medicine, Glendale, AZ

Collective cell migration plays an important role in epithelial wound healing. *In vitro* studies have used scratch assays and closure of experimentally created holes as models to study the mechanisms of wound healing within epithelial sheets. We have observed a novel form of spontaneously forming holes within zebrafish keratocyte sheets. In 24-hour primary explant culture, keratocytes collectively migrate away from the scale and holes often form within the follower cells of the sheet. The observation that the closure of one hole frequently leads to the opening of one or more holes in adjacent areas suggests that tension may play a role in the formation of these holes. Indeed, the entire sheet is under tension, as illustrated by sheet retraction after inhibition of adhesion formation at the leading edge. In addition, brief serum starvation, likely contributing to disassembly of adhesions, accelerates the rate of hole formation. The time for hole closure varies considerably and appears to depend on hole size and the tension within the sheet. During the initial, spontaneous formation and growth of holes, cells retain the characteristics of follower cells. As holes begin to close, the cells surrounding the hole appear to adopt characteristics of leader cells as evidenced by four observations: 1) An actin cable surrounding the hole forms. 2) Calcium transients, with a frequency and intensity comparable to those seen in leader cells, are observed in the cells surrounding the hole. 3) Keratocytes may break away from the edge of the hole and proceed to migrate individually across the hole in a manner resembling the break-away of cells at the leading edge. 4) The pattern of phosphorylated myosin light chain is similar to the leading edge of keratocyte sheets and individually migrating cells. These results suggest that follower cells may become leader cells during the process of hole closure. Within the keratocyte sheet, a partial second layer of cells that adopt leader cell morphology and apparently migrate independently, may accelerate the rate of hole closure. Ongoing experiments seek to further characterize the mechanism of hole closure and the transition of keratocytes from follower to leader cells within a sheet.

2054

**ADAM control of cranial neural crest cell migration.**

*D. Alfandari<sup>1</sup>, G. Abbruzzese<sup>1</sup>, H. Cousin<sup>1</sup>; <sup>1</sup>Vet and Animal Sciences, University of Massachusetts Amherst, Amherst, MA*

Cranial neural crest cells are embryonic stem cells that can differentiate in many different cell types to contribute to the muscle, bone, cartilage and ganglia of the face. These cells are induced at the border of the neural and non-neural ectoderm and subsequently migrate great distances inside of the embryo both as a collective sheet of cells and then as individual cells.

We have shown that multiple members of the ADAM family of cell surface metalloproteases control key steps of CNC migration. In particular, ADAM9 and ADAM13 cleave the cell adhesion molecule Cadherin-11 producing an extracellular fragment that promotes cell migration. Replacement of Cadherin-11 by a mutant protein that can't be cleaved by ADAM13 does not allow for CNC migration unless a recombinant form of the extracellular fragment is provided. This combination allows us to investigate the relative importance of the homophilic binding site of Cadherin-11 on the integral versus cleaved form of the protein.

In addition to the proteolytic role of ADAM13, the cytoplasmic domain of ADAM13 is cleaved during CNC migration translocates into the nucleus and regulates multiple gene expression. This processes requires an autoproteolytic cleavage of ADAM13 followed by a subsequent cleavage by gamma secretase. In the absence of ADAM13, the cytoplasmic domain of ADAM19 can also perform this function. We further show that the activity of ADAM13 depends on successive activating phosphorylation by GSK3 and Polo Kinase, and that the phosphomimetic mutants of ADAM13 can rescue CNC migration in embryos expressing dominant negative forms of both kinases. Interestingly neither of these phosphorylations is required for the proteolytic activity of ADAM13 *in vitro* and *in vivo* suggesting that they may regulate either the subcellular localization and/or transcriptional activity of the cytoplasmic domain.

While the detail molecular mechanism and regulation of ADAM13 is in itself complex, the protein function is only required *in vivo* in the context of the three dimensional environment of the cell. Using grafts, partial dissections and *in vitro* assays we test when ADAM13 activity is required and when it is dispensable. Our results suggest that ADAM13 controls CNC interaction with the underlying mesoderm and/or extracellular matrix to promote cell migration *in vivo*.

2055

**Long-range Ca<sup>2+</sup> waves transmit brain-damage signals to microglia.**

*C. Moritz<sup>1</sup>, D. Sieger<sup>1</sup>, F. Peri<sup>1</sup>; <sup>1</sup>EMBL, Heidelberg, Germany*

One central topic in biology is how the behaviour of motile cells is controlled by positional cues present in the extracellular environment. Unfortunately, in most contexts the spatial and temporal dynamics of these guidance cues is not known due to an inability to visualize these signals in intact tissues. Here, we present a zebrafish larval model system that allows the directional migration of brain phagocytes, microglia, towards neuronal injuries to be studied for the first time *in vivo*. By performing targeted laser neuronal ablations in the brains of transgenic calcium reporter fish, we reveal rapid Ca<sup>2+</sup> waves whose range defines which microglia will move to the damage site. Preventing their formation by extracellular calcium chelation is sufficient to suppress microglial targeted migration, whereas ectopic induction of Ca<sup>2+</sup> signals by photo-uncaging mimics the attraction of microglia to neuronal injury. While, we confirm that calcium-transmitted microglial attraction to damage requires ATP, we show that calcium waves formation and propagation are ATP independent and we identify glutamate as a potent inducer of calcium-transmitted microglial attraction. These findings provide a new handle for understanding and controlling microglia. The involvement of glutamate and Ca<sup>2+</sup> in this process provides great potential for future pharmacological modulation of microglial behaviour.

2056

### **Characterization of Leader and Follower Cells in Collectively Migrating Sheets in Zebrafish Keratocyte Explant Cultures.**

*J. L. Rapanan<sup>1</sup>, J. F. Reyes<sup>2</sup>, K. E. Cooper<sup>1</sup>, K. J. Leyva<sup>3</sup>, E. E. Hull<sup>1</sup>; <sup>1</sup>Biomedical Sciences Program, Midwestern University, Glendale, AZ, <sup>2</sup>Arizona College of Osteopathic Medicine, Glendale, AZ, <sup>3</sup>Microbiology & Immunology, Arizona College of Osteopathic Medicine, Glendale, AZ*

Collective cell migration is an important mechanism during tissue repair, embryonic metastasis, and tumor metastasis. Although single cell migration has been well studied, little is known about the mechanisms of collective cell movement. Primary explant cultures of zebrafish keratocytes are an excellent in vitro system to study collective cell migration as keratocytes rapidly migrate out from harvested scales so that real-time video microscopy experiments are possible. Key to the ability to migrate collectively is the complex relationship between leader and follower cells within a migrating cell sheet. To investigate distinctions between leader and follower cells within a zebrafish keratocyte sheet, we have localized adhesion molecules (integrin, vinculin, E-cadherin), cytoskeletal elements (actin, tubulin, actin binding proteins) and signaling pathways (Grb2, Rho GTPases) by immunofluorescence. Our results showed that there are distinct differences between leader cells and follower cells in both cytoskeletal arrangement and adhesion. Initial measurements of migration speed indicate that the rate of advance of the leading edge of the cell sheet is an order of magnitude faster than in other collective cell systems, a difference that is consistent with the relative migration speeds of individual cells. Addition of RGD peptide, to inhibit adhesion formation at the leading edge, produces a rapid retraction of the entire keratocyte sheet. This suggests that the leader cells pull the sheet forward rapidly enough to create tension within the sheet. Possibly as a product of this tension, holes naturally occur within the follower cells of the sheet. Observation of these holes over time suggests that follower cells may rapidly become leader cells to effectuate hole closure. Ongoing experiments are focused on communication between and the interconversion of leader and follower cells within this system.

2057

### **Connective Tissue Growth Factor Modulates Macrophage Recruitment During Pancreatic Alcohol Injury in Mice.**

*A. Charrier<sup>1</sup>, D. Brigstock<sup>2</sup>; <sup>1</sup>The Ohio State University, Columbus, OH, <sup>2</sup>Nationwide Children's Hospital Research Institute, The Ohio State University, Columbus, OH*

Acute or chronic pancreatitis (AP, CP) are associated with long-term heavy alcohol consumption resulting in pancreatic acinar cell injury and death. Previous data strongly support a pro-fibrotic role for CTGF in CP. Here we report that CTGF is unexpectedly produced by acinar cells at a much earlier time point after injury, corresponding to the time of extensive macrophage infiltration.

6 week old male wild type (WT) C57/BI 6 mice received ethanol once daily six times a week and cerulein injections once a week for 16 days. Control mice received water alone. In a second approach, Swiss Webster mice that were WT or transgenic (TG) for human CTGF and eGreen Fluorescent Protein received ethanol or water for 5 weeks. At the end of the treatment periods, pancreata were analyzed for acinar CTGF, interleukin-1 $\beta$  (IL-1 $\beta$ ) or macrophage inflammatory protein 1 $\alpha$  (MIP1 $\alpha$ /CCL3), as well F4/80, an activated macrophage marker. To study mechanistic relationships in vitro, a rat acinar cell line (AR42J) was used. Gene expression was evaluated in CTGF-transfected AR42J cells using a PCR Array. CTGF, IL-1 $\beta$  or MIP1 $\alpha$ /CCL3

mRNA were evaluated by qRT-PCR in ethanol or CTGF stimulated rat AR42J cells. A fluorometric chemotaxis assay was used to test the response of NR8383 rat alveolar macrophages to conditioned medium from CTGF treated AR42J cells with or without BX471, a CCR1 antagonist.

In WT C57/BL6 mice, CTGF was strongly localized in acinar cells by Day 16 of treatment with ethanol + cerulein when no fibrosis was present but CTGF was not detected in the acini of mice receiving water. Ethanol-induced CTGF was spatially and temporally correlated with that of IL-1 $\beta$  or MIP1 $\alpha$ /CCL3 as well as F4/80-positive macrophage infiltration. In TG Swiss Webster mice receiving ethanol, a marked increase occurred in acinar GFP, CTGF, IL-1 $\beta$  or CCL3 expression as compared to TG mice receiving water. Macrophage infiltration increased significantly in the pancreata of TG mice receiving ethanol as compared to all other groups. Transfection of AR42J cells with CTGF cDNA resulted in enhanced expression of CCL3. Comparable patterns of CTGF or IL-1 $\beta$  mRNA expression were stimulated in AR42J cells exposed to ethanol for up to 48 hours. CCL3 and IL-1 $\beta$  expression also increased in CTGF treated cells. CTGF treated AR42J cell conditioned medium resulted in an increase in NR8383 macrophage chemotaxis which was abrogated in a dose-dependent manner by BX471.

Following alcoholic injury, CTGF is produced by acinar cells and appears to play a novel role in the inflammatory process by increasing infiltration by macrophages and increasing acinar production of inflammatory mediators such as IL-1 $\beta$  or MIP1 $\alpha$ /CCL3. Inhibition of CCR1, a CCL3,-5 or -7 receptor reduces macrophage chemotaxis to basal levels suggesting a potential role of CTGF in modulating macrophage infiltration via a CCL3-dependent pathway. We conclude that CTGF dynamically regulates inflammatory cell recruitment following pancreatic injury in a way that is novel and distinct from its role in driving fibrogenic pathways in PSC at later stages of injury.

2058

**Mechanisms of the effects of Erythropoietin in wound healing: A morphologic study.**

R. G. Aktas<sup>1</sup>, A. Guven<sup>2</sup>, H. S. Ozacmak<sup>3</sup>, V. H. Ozacmak<sup>3</sup>, M. Ickin<sup>2</sup>, O. E. Tok<sup>4</sup>, A. G. Oktayer<sup>1</sup>;  
<sup>1</sup>Histology and Embryology, Koc University, Istanbul, Turkey, <sup>2</sup>Onsekiz Mart University, Canakkale, Turkey, <sup>3</sup>Karaelmas University, Zonguldak, Turkey, <sup>4</sup>Marmara University, Istanbul, Turkey

Recent studies have demonstrated that Erythropoietin (EPO) promotes wound healing. It has been reported that EPO increases angiogenesis and stimulates re-epithelization. EPO administration also shortens the time to final wound closure. Another recent study states that EPO induces bone repair and fracture healing. Further studies are required to clarify the mechanisms of the effects of EPO on wound healing. These studies will determine if preclinical studies can be translated to the clinical settings.

The main aim of the study was to investigate the localization of the following proteins which are shown as important factors during wound healing process:

- (i) Erythropoietin (EPO),
- (ii) Receptor which is specific for Erythropoietin (EPO-R),
- (iii) Basic fibroblastic growth factor (bFGF),
- (iv) Receptor which is specific for basic fibroblastic growth factor (bFGF-R),
- (v) Transforming growth factor-alpha (TGF-alpha)
- (vi) Caspase -3

Study included the comparison of the location of these proteins before and after EPO administration.

Paraffin blocks from our previous experimental study, which is related with EPO administration, were used for the experiments in this study. Sections from these blocks were labeled with primary antibodies which are specific to the proteins listed above. After application of suitable secondary antibodies, staining on the sections were analyzed under light and fluorescence microscopes. The study has revealed the changes on the expression of six proteins which plays important role during wound healing process and angiogenesis. It also provides information about the effect of EPO administration on the expression of these proteins at microscope level.

## Dynamics of Focal Adhesions and Invadosomes

### 3D Traction force microscopy in fibrin gels.

A. S. Adhikari<sup>1</sup>, N. Leijnse<sup>1,2</sup>, L. B. Oddershede<sup>2</sup>, A. R. Dunn<sup>1</sup>; <sup>1</sup>Chemical Engineering, Stanford University, Stanford, CA, <sup>2</sup>Niels Bohr Institute, University of Copenhagen, Copenhagen, Denmark

The mechanical forces exerted and detected by living cells play integral roles in diverse biological phenomena, including growth and development, wound healing, and cancer metastasis. In the past decade, techniques such as traction force microscopy and micropost arrays have proven to be powerful tools for measuring the forces generated by cells. In particular, traction force microscopy has recently been extended to three-dimensional cell culture environments by embedding tracer beads in either a synthetic polyethylene glycol (PEG) hydrogel (Legant et al., Nat. Meth. 2010) or in collagen gels (Koch et al., PLoS ONE 2012). The embedded beads move in response to cell-generated distortions of the matrix, allowing cell-generated forces to be calculated. We sought to develop an experimental system that would exhibit the excellent mechanical properties of the PEG hydrogel while using a naturally occurring biological matrix. Fibrin gels fulfill both of these requirements: fibrin is elastic up to ~50% strain (Brown et al., Science 2009) and is also widely used for 3D cell culture. Here we describe the use of fluorescently labeled fibrin gels to measure the forces generated by cells in 3D culture. We observe dramatic but elastic deformations of the fibrin matrix surrounding cells as they grow, divide, and migrate. Further, we find that the dynamic forces generated by the cell can be measured using the deformations of the matrix itself, providing a direct observation of how the cell modifies its surroundings. We discuss the use of this new technique in studying matrix remodeling and cell migration.

### VASP highlights endothelial tip cell dynamics *in vivo*.

R. S. Fischer<sup>1</sup>, C. Waterman<sup>1</sup>; <sup>1</sup>Cell Biology, NHLBI/NIH, Bethesda, MD

Angiogenesis is the process of sprouting and extending new vessels from the sides of pre-existing vessels, and is critical to development and human diseases. Key to angiogenesis is the migration of “tip cells”, which lead the new vessel in its path, using dynamic protrusions to explore the surrounding tissue. While much is known about signals that specify tip cells and induce their migration, little is known about the cytoskeleton and adhesion organization and components that form in tip cell protrusions to guide vessel outgrowth. To analyze the organization and dynamics of the actin cytoskeleton and adhesions during tip cell guidance, we transiently expressed GFP-tagged VASP specifically in zebrafish endothelial cells and analyzed dynamics by time-lapse 3D imaging of the developing vasculature in embryos. In cultured cells, VASP associates with polymerizing actin barbed ends, and localizes to the tips of filopodia and

lamellipodia and focal adhesions. In tip cells of forming intersegmental vessels, we found that GFP-VASP is enriched in the tips of advancing and stable filopodia-like protrusions, but this local enrichment decreases upon filopodia retraction. Filopodia with GFP-VASP show longer excursion times and are more stable in the direction of cell migration than in peripheral directions. GFP-VASP also localizes to focal-adhesion-like structures within the cell body behind the cell leading edge, and to cell-cell junctions both in the dorsal aorta as well as the newly formed adhesions between intersegmental vessels. Transient expression demonstrates that high levels of GFP-VASP expression inhibits normal tip cell migration, while moderate levels of GFP-VASP expression allow for normal vasculature formation through embryo development to adulthood. Since VASP tracks with free polymerizing barbed ends of actin filaments, these data demonstrate that tip cell filopodia cytoskeletal organization is similar to those observed in neuronal growth cones and cells cultured *in vitro*, and that GFP-VASP is a potentially powerful tool for further analyses of actin cytoskeleton organization in normal and pathogenic angiogenesis *in vivo*.

**Adhesions in 3D are guided by myosin activation state and matrix fiber architecture.**

K. E. Kubow<sup>1</sup>, S. K. Voncannon<sup>1</sup>, A. R. Horwitz<sup>1</sup>; <sup>1</sup>University of Virginia, Charlottesville, VA

Despite the growing number of studies describing the effects of “dimensionality” on cellular behavior, the mechanisms that cause a cell to have distinct phenotypes in 2D and 3D are not understood. In particular, little is known about the origins of 3D cell morphologies and adhesion phenotype and their relationship to those observed in 2D. For example, substrate stiffness, acting through a myosin contractility feedback loop, is a major determinant of adhesion and cell morphology in 2D; however, while these same basic principles are likely at work in 3D, it is not clear that they fully explain the phenotypes seen in 3D. For example, the architecture of the 3D matrix may alter how stiffness and forces are both experienced and transmitted by cells. We studied how stiffness and myosin II activity contribute to adhesion and morphology in 3D matrices. To delineate the role of myosin in 3D, we manipulated U2OS osteosarcoma cells in collagen matrices with a panel of myosin inhibitors and mutants. We demonstrate that myosin contractility guides adhesion phenotype in 3D matrices similar to that in 2D culture: myosin light chain (MLC) phosphorylation at Ser19 is critical for adhesion maturation, while phosphorylation at both Thr18 and Ser19 promotes larger, more-stable adhesions. Also similar to 2D, MLC di-phosphorylation is responsible for constraining areas of cell protrusion; however in 3D, myosin accumulates along the sides of protrusions resulting in distinctive elongated morphologies. We next tested the effect of changing bulk stiffness in 3D. Unexpectedly, cells in matrices 100-fold softer than our standard matrices still formed similarly sized, although fewer, adhesions, suggesting the cells were not differentiating between the bulk matrix stiffnesses. Time-lapse imaging showed that adhesions forming on fibers that were aligned to the direction of protrusion matured and stabilized while those forming on perpendicular fibers resulted in fiber bending, but no adhesion maturation. Further investigation revealed that local fiber alignment by cells provides both greater resistance to tensile forces and a longer continuous adhesive area, allowing the cells to generate large adhesions, even in soft matrices. Notably, this mechanism is the same in fibrillar substrates regardless of dimensionality or bulk stiffness. Our results indicate that, while myosin-mediated contractility plays similar roles in 2D and 3D, the effect of microenvironment stiffness on adhesion is distinctly local and is modulated by fiber architecture.

### Functional linkages between single-molecule integrin dynamics and edge protrusion in motile cells.

*K. Jaqaman<sup>1</sup>, J. Galbraith<sup>2</sup>, M. Davidson<sup>3</sup>, G. Danuser<sup>1</sup>, C. Galbraith<sup>2</sup>; <sup>1</sup>Harvard Medical School, Boston, MA, <sup>2</sup>National Institutes of Health, Bethesda, MD, <sup>3</sup>Florida State University, Tallahassee, FL*

Integrins are the key receptors in cell-matrix adhesions and play a critical role in cell migration. Although recent advances in high-resolution microscopy have made it possible to localize single molecules such as integrins, following the dynamics of large numbers of molecules in living cells and establishing the relationship between molecular behaviors and cell-level outputs like edge movement has remained a major challenge. To address the difficulties of both the disparity in the spatial and temporal scales of single-molecule and cell-level event dynamics and the inherent complexity and heterogeneity of molecular behaviors, we measured single molecule  $\alpha_v\beta_3$ -integrin, talin or actin dynamics at 40 Hz sampling and associated them to the local protrusion and retraction state sampled at 0.1 Hz in analysis windows of 220 x 220 nm. We developed a diffusion mode decomposition algorithm that revealed 4 integrin diffusion states: (1) practically immobile at the 25 ms scale, in which integrins are likely associated with talin and the actomyosin meshwork; (2) slow, in which they are associated with talin only; (3) medium, in which they are most likely associated with a faster-diffusing sub-population of talin and dynamic, metastable actin filaments; and (4) fast, in which they are associated with neither talin nor actin. Using this approach, we discovered local transient changes in molecular dynamics near the leading edge that were strongly linked to the protrusion of the cell. 20-30 s prior to protrusion onset,  $\alpha_v\beta_3$ -integrin molecules often slowed down, suggesting formation of nascent adhesions ahead of protrusion. During protrusion, the mobility of integrins increased, reaching a plateau 40-50 s after onset. The increase in integrin mobility was due to a preferential recruitment of the medium and fast integrin sub-populations to the newly-established cell-matrix contact area. These transient changes were limited to  $\approx 1 \mu\text{m}$  from the cell edge. Truncation mutants demonstrated that the variations in integrin mobility associated with cell edge protrusion were dependent upon interactions of the tail with cytoplasmic components. In agreement with this notion, talin and actin exhibited parallel changes in mobility and density with cell edge protrusion. Our approach provides a generalizable methodology for extracting localized patterns in molecular dynamics and interactions that underlie higher-order cellular-level behavior.

### A molecular mechanism for pH-dependent autophosphorylation of focal adhesion kinase.

*C-H. Choi<sup>1</sup>, D. L. Barber<sup>1</sup>; <sup>1</sup>Department of Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA*

Activation of focal adhesion kinase (FAK) is one of the early signaling events after integrin-matrix engagement and is necessary for cell spreading and migration. FAK activation is initiated by release of an autoinhibited interaction between N-terminal FERM and C-terminal kinase domains. Release of this autoinhibited conformation unmasks the autophosphorylation site Tyr397 within the linker region between FERM and kinase domains. Phosphorylated Tyr397 is the docking site for Src kinase, which phosphorylates Tyr576/577 in the kinase domain to activate FAK. Our previous data suggested increased intracellular pH > 7.2 is necessary for FAK activation and focal adhesion turnover. Here we show a molecular mechanism of direct pH-dependent FAK activation that involves release of the autoinhibited conformation by deprotonation of His residues at the interface of the FERM and kinase domains. In vitro kinase assays with recombinant FAK show pH-dependent autophosphorylation of full-length FAK

requires the FERM domain and a truncated FAK lacking FERM domain is constitutively active and pH-independent. Also phosphorylation of Tyr397 in trans using separate FERM and kinase domains is pH-dependent and requires pH > 7.2. Three histidines (His41, His58 and His75) are at the FERM-kinase domain interface but our data indicate His58 is the critical residue conferring FAK autophosphorylation at higher pH. A His58Ala mutant has pH-independent Tyr397 autophosphorylation using full-length FAK and phosphorylation in trans using separate FERM and kinase domains. Molecular dynamics simulations with each of the interface histidines charged or neutral also predict deprotonation of only His58 is associated with conformational changes consistent with release of FERM and kinase domains. These data indicate for the first time a mechanism for how the autoinhibited conformation of FAK is released by an increase in pH to allow FAK activation.

#### **Focal adhesion size uniquely predicts cell migration.**

*D-H. Kim<sup>1,2</sup>, D. Wirtz<sup>1,2</sup>; <sup>1</sup>Johns Hopkins University, Baltimore, MD, <sup>2</sup>Johns Hopkins Physical Sciences - Oncology Center, Baltimore, MD*

Focal adhesions are large protein complexes organized at the basal surface of cells, which physically connect the extracellular matrix to the cytoskeleton and have long been speculated to mediate cell migration. However, whether clustering of these molecular components into focal adhesions per se is actually required for these proteins to regulate cell motility is unclear. Here, we use quantitative microscopy to characterize large families of focal adhesion and cell motility descriptors across a wide range of matrix compliance, following genetic manipulations of focal adhesion proteins. This analysis revealed a tight, biphasic relationship between mean size of focal adhesions - not their number, surface density, or shape - and cell speed. The predictive power of this relationship was comprehensively validated by disrupting non-focal adhesion proteins and subcellular organelles (mitochondria, etc.) not known to affect either focal adhesions or cell migration. This study suggests that mean size of focal adhesions robustly and precisely predicts cell speed independently of focal adhesion surface density and molecular composition.

#### **Proteomic profiling of adhesion complex dynamics.**

*D. Ng<sup>1</sup>, J. D. Humphries<sup>1</sup>, A. Byron<sup>1</sup>, A. Carisey<sup>1</sup>, M. J. Humphries<sup>1</sup>; <sup>1</sup>Wellcome-Trust centre for Cell-Matrix Research, University of Manchester, Manchester, England*

Adhesion complexes (ACs) are large macromolecular complexes of integrins and associated proteins that connect the actin cytoskeleton to the extracellular matrix (ECM). In migrating cells ACs are highly dynamic, forming and maturing at the cell front and disassembling at the cell rear. The turnover of ACs enables and localises the necessary traction forces required for cell migration. Evidence exists for spatiotemporal recruitment of specific proteins during AC maturation or disassembly; however, a holistic understanding of the compositional changes to ACs during these states is lacking. We sought to characterise the dynamic changes that occur during AC turnover using a mass spectrometry (MS)-based proteomics approach. A major challenge in studying AC turnover is the desynchronised nature of AC formation, maturation and disassembly within a population of cells. Therefore, a nocodazole-washout assay was used to synchronise mechanical stress-induced AC maturation and microtubule-induced AC disassembly. Immunofluorescence staining for vinculin showed that AC area was increased 3-fold upon nocodazole treatment, and ACs disassembled by 60 minutes of washout. Plasma membrane protein complexes from control and nocodazole treated cells were isolated and both Western blotting and MS analysis demonstrated that AC components were increased upon

nocodazole treatment. Surprisingly, the levels of the fibronectin binding  $\alpha_5\beta_1$ -integrin did not change whilst ECM proteins decreased. Immunofluorescence experiments confirmed these findings and suggest the conversion of ACs from fibrillar adhesions to focal adhesions upon nocodazole treatment.

**CLASP-mediated localized exocytosis controls extracellular matrix degradation and focal adhesion turnover.**

*S. Stehbens<sup>1</sup>, M. Paszek<sup>1</sup>, H. Pemble<sup>1</sup>, T. Wittmann<sup>1</sup>; <sup>1</sup>University of California San Francisco, San Francisco, CA*

Turnover of integrin-based focal adhesions (FAs) with the extracellular matrix is essential for coordinated cell movement during tissue remodeling and wound healing. In collectively migrating human keratinocytes, FAs assemble near the leading edge, grow and mature as a result of actomyosin-mediated contractile forces, and subsequently disassemble underneath the advancing cell body. FA turnover is essential for productive cell migration, and although microtubules have been implicated in FA turnover, the molecular mechanisms by which FA turnover is coordinated are incompletely understood. Here we identify CLASPs that belong to the growing family of microtubule plus-end-tracking proteins, as critical molecules linking microtubules to FA turnover. CLASPs stabilize lamella microtubules in migrating cells, and CLASP-microtubule association is spatiotemporally regulated by GSK3 $\beta$  phosphorylation. Using high-resolution dual-wavelength confocal microscopy, we found that FA turnover and CLASP dynamics are tightly spatially and temporally correlated: CLASP-decorated microtubules surround FAs at the base of the lamella shortly before FA disassembly. To test the hypothesis that CLASPs function during the disassembly phase of FA turnover, we depleted both mammalian CLASP homologues by lentivirus-mediated shRNA in HaCaT cells stably expressing paxillin-mCherry as a FA marker. FAs in CLASP-depleted cells were larger, turned over more slowly, and were associated with extensive actin stress fibers. In CLASP-depleted cells FAs often disassembled only after extensive sliding across the ventral cell surface suggesting that these FAs were ripped apart by actomyosin-mediated pulling forces. In contrast, FA assembly was not affected in CLASP-depleted cells. Depletion of LL5 $\beta$  that is required to recruit CLASPs to FAs resulted in similar FA turnover defects. Using Scanning Angle Interference Microscopy, a novel axial super-resolution technique, we further found that close interactions of microtubules with FAs are disrupted in CLASP-depleted cells, indicating that CLASPs anchor microtubules at FAs. In addition, Rab6a-positive vesicle transport to FAs as well as MMP-dependent, FA-associated degradation of the extracellular matrix was disrupted in CLASP-depleted cells. Thus, CLASP-mediated microtubule-tethering at FAs establishes a Rab6a-positive vesicle transport pathway for delivery, docking and fusion of exocytic vesicles near FAs, thereby promoting FA-associated, localized degradation of the extracellular matrix. We propose that CLASPs function as key molecules coupling microtubule organization, vesicle transport and cell interactions with the extracellular matrix, and that local protease secretion may initiate FA turnover by severing cell-matrix connections.

**Regulation of FAK stabilization and cell migration by tyrosine phosphorylated caveolin-1 requires an intact scaffolding domain**

*F. Meng<sup>1</sup>, B. Joshi<sup>1</sup>, P. Bernatchez<sup>2,3</sup>, I. R. Nabi<sup>1</sup>; <sup>1</sup>Department of Cellular & Physiological Sciences, Life Sciences Institute, University of British Columbia, Vancouver, BC, Canada, <sup>2</sup>Department of Anesthesiology, Pharmacology and Therapeutics, University of British*

*Columbia, Vancouver, BC, Canada, <sup>3</sup>UBC James Hogg Research Centre, Institute for Heart & Lung Health, Vancouver, BC, Canada*

Caveolin-1 (Cav1) is a key component of cell surface caveolae and is also associated with the regulation of multiple cancer-associated processes including tumor growth and cell migration and metastasis. Cav1 is also a major substrate of Src kinase phosphorylated on tyrosine 14 (Y14). Our previous studies revealed that Y14-phosphorylated Cav1 (pCav1) stabilizes focal adhesion kinase (FAK) within focal adhesions, stimulates Rho activation and promotes cancer cell motility. The Cav1 scaffolding domain (CSD), amino acids D82 to R101 in Cav1, was defined by its structural and functional interaction with Src kinase. Using a CSD-disrupting F92A, V94A mutant of Cav1, we have shown that the CSD is required for Cav1 negative regulation of EGFR diffusion and signaling. However, whether the CSD is involved in Cav1 Y14 phosphorylation-dependent activities, such as FAK stabilization in focal adhesions and cell motility has yet to be determined. We have made Cav1 constructs combining mutations on tyrosine 14 (phosphomimetic Y14D, dominant negative Y14F or positively charged Y14R) with the F92A, V94A mutation in the CSD. Stable expression of these constructs in DU145 prostate cancer cells, which express Cav1 but not pCav1, showed that F92A, V94A mutation of the CSD prevented the increased cell migration and focal adhesion stabilization of FAK-GFP due to wild-type Cav1 and Cav1Y14D and Cav1Y14R mutants. CSD mutation of the Cav1Y14F mutant construct did not affect either cell migration or FAK stabilization in focal adhesions. Expression of a membrane-permeable CSD competing peptide (Cav1 amino acids 82-101 fused to an internalization sequence from Antennapedia [AP-CAV]) also prevented the focal adhesion stabilization of FAK-GFP due to Cav1 wild-type, Cav1Y14D and Cav1Y14R. AP-CAV did not affect FAK stabilization in control DU145 cells or Cav1Y14F transfected DU145 cells. This suggests that an intact CSD is specifically required for pY14Cav1-dependent stabilization of FAK within focal adhesions and consequently enhanced cell migration of these prostate cancer cells. pCav1 stabilizes FAK in focal adhesions and stimulates cancer cell motility in a CSD-dependent manner.

**Activation of Rac by Asef2 Promotes Myosin II-Dependent Contractility to Inhibit Cell Migration on Type I Collagen.**

*L. Jean<sup>1</sup>, D. Majumdar<sup>1</sup>, M. Shi<sup>1</sup>, N. Diggins<sup>1</sup>, M. Ao<sup>1</sup>, J. A. Broussard<sup>1</sup>, C. Evans<sup>1</sup>, D. Choma<sup>1</sup>, D. J. Webb<sup>1,2</sup>; <sup>1</sup>Department of Biological Sciences and the Kennedy Center for Research on Human Development, Vanderbilt University, Nashville, TN, <sup>2</sup>Cancer Biology, Vanderbilt University, Nashville, TN*

The Rho family of small GTPases, which includes Rho, Rac, and Cdc42, are key regulators of cell migration through their modulation of the actin cytoskeleton. Activation of the small GTPases is regulated by guanine nucleotide exchange factors (GEFs), which catalyze the release of GDP allowing GTP to spontaneously bind and thereby activate the proteins. While the role of the small GTPases in migration has been studied, much less is known about the GEFs that activate them. Here, we show that the Rho family GEF Asef2 inhibits cell migration on type I collagen. The migration speed of HT1080 cells stably expressing GFP-Asef2 was decreased 2-fold compared with control GFP stable cells plated on type I collagen. In a GTPase pulldown assay, the amount of active Rac was increased 1.9-fold in GFP-Asef2 stable cells compared with GFP controls, while no effect was observed on Rho or Cdc42. Moreover, using acceptor photo-bleaching fluorescence resonance energy transfer, a significant enhancement in the level of active Rac was seen in mCherry-Asef2 expressing cells compared

to mCherry controls. Since Rho family GTPases have been linked to actomyosin contractility, we hypothesized that Asef2 regulates cell migration through myosin II (MyoII). Indeed, treatment with the MyoII-specific inhibitor blebbistatin abolished the effects of Asef2 on migration. In addition, a 1.5-fold increase in the amount of active MyoII, as determined by immunostaining for MyoII phosphorylated on serine 19, was observed in GFP-Asef2 cells compared to controls. The Asef2-mediated increase in active MyoII was dependent on Rac, because treatment with the Rac-specific inhibitor NSC23766 abolished this effect. Since integrins have been shown to play an essential role in cell migration, we assessed cell-surface levels of active  $\beta$ 1 integrin using HUTS-4 antibody and flow cytometry. A 2.5-fold increase in the amount of active  $\beta$ 1 integrin was observed in GFP-Asef2 stable cells compared to GFP controls. The higher levels of  $\beta$ 1 integrin affected adhesion dynamics, because adhesions assembled and disassembled 2-fold and 1.5-fold slower, respectively, in GFP-Asef2 stable cells compared with controls. Collectively, these results indicate that Asef2 regulates cell migration on type I collagen by a mechanism that is dependent on Rac, MyoII, and  $\beta$ 1 integrin.

### **Essential roles of Crk and CrkL in cell structure and motility in fibroblast cells.**

*T-J. Park<sup>1</sup>, T. Curran<sup>1</sup>; <sup>1</sup>Pathology and Lab Medicine, The Children's Hospital of Philadelphia Research Institute, Philadelphia, PA*

Cytosolic adaptor proteins containing SH2 and SH3 domains such as Crk and Crk-like (CrkL) are broadly expressed, interact with a variety of proteins, and play key roles in signal transduction pathways triggered by stimulation of receptor tyrosine kinases and non-receptor tyrosine kinases. Crk and CrkL are similar to each other in structure and function, and their distinct and overlapping functions have been studied during development. However, more detailed and systematic analyses of their functions at the cellular level are needed to understand their diverse biological functions. We induced a knockout of Crk, CrkL, or both by infecting fibroblast cells derived from Crk and CrkL floxed mice with a lentivirus expressing GFP and Cre. When both Crk and CrkL were removed from fibroblast cells, the cells became small, round and refractive. This morphological alteration was accompanied by a decrease in spontaneous motility and wound healing. Fibroblast cells lacking Crk and CrkL lost focal adhesions and actin stress fibers, and their microtubule structure collapsed. The results suggest that loss of cellular connections to the extracellular matrix causes altered cell shape, reduced cell motility, and cytoskeletal collapse. A decrease in actin protein followed the loss of Crk and CrkL, and stabilization of polymerized actins with jasplakinolide suppressed the morphological alteration, suggesting that a decrease in cytoskeletal elements including actin might contribute to the cytoskeletal collapse. Partial rescue of the morphological alteration by a reintroduction of CrkI, CrkII, and CrkL to the cells together with small but significant morphological alterations with selective knockout of Crk or CrkL indicates that both Crk and CrkL are important for the maintenance of cell structure. Our results suggest that Crk and CrkL play critical roles in cell structure and motility by maintaining the cytoskeletal connection to the extracellular environments.

### **Network analysis of the focal adhesion-invadopodia transition identifies a PI 3-kinase-PKC $\alpha$ invasive signaling axis.**

*D. Hoshino<sup>1</sup>, J. Jourquin<sup>2</sup>, W. Emmons<sup>2</sup>, T. Miller<sup>2</sup>, M. Goldgo<sup>2</sup>, K. Costello<sup>2</sup>, D. Tyson<sup>2</sup>, B. Brown<sup>2</sup>, Y. Lu<sup>3</sup>, N. Prasad<sup>4</sup>, B. Zhang<sup>2</sup>, G. Mills<sup>3</sup>, W. Yarbrough<sup>2</sup>, V. Quaranta<sup>2</sup>, M. Seiki<sup>1</sup>, A. M. Weaver<sup>2</sup>; <sup>1</sup>Institute of Medical Science University of Tokyo, Tokyo, Japan, <sup>2</sup>Vanderbilt University*

Medical Center, Nashville, TN, <sup>3</sup>MD Anderson Cancer Center, Houston, TX, <sup>4</sup>Indiana University School of Medicine, Indianapolis, IN

A central question in cancer is how deregulated signaling leads to acquisition of an invasive cellular phenotype. Here, we modeled the invasive transition as a theoretical switch between focal adhesions and extracellular matrix (ECM)-degrading invadopodia and built molecular interaction network models of each structure. To identify upstream regulatory hubs, we added first degree binding partners and applied graph theoretic centrality analyses. By comparing the results to clustered signaling state data from human head and neck squamous cell carcinomas (HNSCC), phosphatidylinositol 3-kinase (PI3K) and Protein Kinase C alpha (PKCa) were chosen for further combinatorial analysis. Consistent with a previous report, PI3K activity promoted both the formation and activity of invadopodia along with focal adhesion reorganization. Surprisingly, knockdown of PKCa led to divergent effects on invadopodia formation, depending on the activation state of PI3K. Thus, loss of PKCa inhibited invadopodia formation in cells with wild-type PI3K pathway status. Conversely, in cells with either activating mutant PI3K molecules or endogenous loss of the opposing enzyme phosphatase and tensin homolog (PTEN), PKCa knockdown greatly augmented invadopodia formation. This signaling relationship held true for invasive cells from multiple cancer types, including HNSCC, breast and melanoma. Investigation of the molecular mechanism revealed that a negative feedback loop from PKCa dampens PI3K activity and invasive behavior in cells with genetic overactivation of the PI3K pathway. Thus, knockdown of PKCa in PI3K mutant-expressing cells led to a large increase in the ratio of PI(3,4,5)P3 to PI(4,5)P2 in individual cells. Furthermore, similar to the effects of PKCa knockdown, expression of a non-phosphorylatable mutant of the p85 regulatory subunit of PI3K led to greatly increased invadopodia activity. These studies demonstrate the potential of network modeling as a discovery tool and identify a PI3K-high/PKCa-low signaling state as highly invasive.

Bièche<sup>5</sup>, P. Parker<sup>6</sup>; <sup>1</sup>Institut Curie, Paris, France, <sup>2</sup>Nikon Imaging Centre@Institut Curie-CNRS, Paris, France, <sup>3</sup>Cellular & Molecular Medicine, Katholieke Universiteit Leuven, Leuven, Belgium, <sup>4</sup>Pathology Department, Institut Curie, Paris, France, <sup>5</sup>Oncogenetic Laboratory, Institut Curie, Paris, France, <sup>6</sup>Cancer Research UK London Research Institute, London, United Kingdom

The trademark of a metastatic tumor cell is its ability to disseminate from the primary tumor by degrading the extracellular matrix and basement membrane that form a barrier around the tissue. Remodeling of the extracellular matrix by tumor cells requires formation of actin-based protrusions of the plasma membrane called invadopodia, where the trans-membrane matrix metalloproteinase MT1-MMP accumulates. We previously found that in MDA-MB-231 human breast adenocarcinoma cells, MT1-MMP localizes to late endosomes and we identified an exocytic machinery based on the vesicle-docking exocyst complex required for MT1-MMP delivery to invadopodia. Atypical protein kinase C (aPKCs) iota and zeta are upregulated in several cancers including breast carcinomas and exocyst and aPKCs coordinately regulate cell motility. How MT1-MMP transport intermediates are generated from late endosomes to reach invadopodia and whether this mechanism involves aPKCs remain to be established.

We observed a partial association of ectopically expressed aPKC iota with F-actin/cortactin/dynamin-2-enriched domains on MT1-MMP-positive endosomes and found that aPKC phosphorylated cortactin directly. Silencing of aPKC led to cortactin accumulation on MT1-MMP-endosomes and interfered with dynamin-2 recruitment, resulting in endosome tubulation, impaired MT1-MMP trafficking and inhibition of matrix degradation and invasive migration. Analysis of breast tumors revealed a positive correlation of MT1-MMP and aPKC iota mRNA expression, which was associated with poor prognosis. Immunohistochemistry analysis documented an overexpression of aPKC iota in breast tumors and its relocalization from a polarized apical distribution in normal breast epithelial cells to a cytoplasmic vesicular pattern in poorly differentiated carcinomas. A new function for aPKC in controlling MT1-MMP trafficking to the plasma membrane is identified during breast tumor cell invasion.

**Tks5 regulates invadopodium precursor stability through PI(3,4)P<sub>2</sub> in breast cancer cells.**

V. P. Sharma<sup>1,2</sup>, R. Eddy<sup>1</sup>, M. Kai<sup>3,4</sup>, F. Gertler<sup>3</sup>, J. Condeelis<sup>1,2</sup>; <sup>1</sup>Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, <sup>2</sup>Gruss Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, <sup>3</sup>Department of Biology and Koch Center for Cancer Research, Massachusetts Institute of Technology, Cambridge, MA, <sup>4</sup>Biologics Research Laboratories, Tokyo, Japan

Cancer cells make invasive protrusions, called invadopodia, whose primary function is to degrade extracellular matrix (ECM) and protrude into degraded space, creating a tunnel-like passage through the extracellular space. Cancer cells are thought to utilize these tunnels to migrate through the primary tumor to enter the bloodstream and eventually metastasize at distant sites to make secondary tumors. A growing body of research implicates invadopodia in cancer cell invasion and metastasis, a leading cause of death among cancer patients. Recently, many invadopodium core molecules (e.g. cortactin, N-WASp, cofilin and Tks5) have been identified and studied. The adapter protein, Tks5 has been shown to regulate invadopodium formation, but the dynamic interaction of Tks5 with other invadopodium molecules is poorly understood. In this study we investigated the role of Tks5 during invadopodium precursor assembly using high spatial and temporal resolution live-cell fluorescence imaging and report here several novel findings: (1) Cortactin, N-WASp and cofilin arrive together to form the invadopodium precursor, followed by Tks5 recruitment. (2) Tks5 is not required for invadopodium precursor formation but is needed for precursor anchoring/stabilization. (3) Invadopodium precursor stabilization is mediated by the interaction of PX domain of Tks5 with PI(3,4)P<sub>2</sub>. (4) PI(3,4)P<sub>2</sub> localizes to the invadopodium core, but PI(3)P and PI(4,5)P<sub>2</sub> do not. We also show for the first time that SHIP2, a 5' inositol phosphatase, localizes at invadopodium, modulates PI(3,4)P<sub>2</sub> levels locally at the invadopodium and is required for the maturation of invadopodia. Together, these findings provide novel insights into how invadopodial core proteins and phospholipids cooperate to stabilize the invadopodium precursor, a key step for invadopodium maturation and matrix degradation.

2074

**Ubiquitination of PIPKly by HECTD1 regulates focal adhesion dynamics and cell migration.**

X. Li<sup>1</sup>, Q. Zhou<sup>1</sup>, M. Sunkara<sup>1</sup>, Z. Wu<sup>1</sup>, P. Rychahou<sup>1</sup>, A. Morris<sup>1</sup>, H. Zhu<sup>1</sup>, B. Evers<sup>1</sup>, C. Huang<sup>1</sup>; <sup>1</sup>University of Kentucky, Lexington, KY

PIPKly binds talin and localizes at focal adhesions (FAs). PIP2 generated by PIPKly is essential for FA formation and cell migration. On the other hand, PIPKly and the  $\beta$  integrin tail

compete for overlapping binding sites on talin. It is unknown how PIPKly binds talin to provide on-site PIP2 without inhibiting the talin- $\beta$  integrin tail interaction, a key step for integrin activation and FA formation. Here we show that PIPKly is a substrate for HECTD1, an E3 ubiquitin ligase regulating cell migration. HECTD1 ubiquitinated PIPKly at Lys97 and resulted in PIPKly degradation. Expression of PIPKlyK97R enhanced PIP2 and PIP3 production and inhibited FA disassembly and disassembly, cancer cell migration, invasion and metastasis. Interestingly, mutation at Trp647 abolished the inhibition of PIPKlyK97R on FA dynamics and partially rescued cancer cell migration and invasion. Thus, cycling PIPKly ubiquitination by HECTD1 and consequent degradation release the inhibition of PIPKly on the talin- $\beta$  integrin tail interaction after on-site PIP2 production, providing an essential regulatory mechanism for FA dynamics and cell migration.

2075

### **Large Scale Matrix Degradation by Stromal Cells Independent of Invadopodia.**

*H. Cao<sup>1</sup>, R. Eppinga<sup>1</sup>, E. Krueger<sup>1</sup>, J. Chen<sup>1</sup>, M. McNiven<sup>1</sup>; <sup>1</sup>Mayo Clinic, Rochester, MN*

Metastatic invasion of tumors into peripheral tissues is known to rely upon protease-mediated degradation of the surrounding stroma. This remodeling process is dependent upon complex, actin-based, specializations of the plasma membrane termed "invadopodia" that act to both sequester and release matrix metalloproteases. Two well established components of invadopodia are the large membrane remodeling GTPase Dynamin 2 (Dyn2), and oncogenic Src kinase. Here we report that cells of mesenchymal origin degrade substantial amounts of surrounding matrix by a mechanism independent of conventional invadopodia. Two distinct human, or rat, cultured fibroblast cell lines (HFs/RFs) or a pancreatic tumor stellate cell line (PSC) exhibit little to no matrix degradation when plated on fluorescent gelatin over a 24 hour period. Surprisingly, siRNA mediated knock down of Dyn2 in these cells induces a massive increase (3-4 fold) of substrate degradation. These degradative sites lack the punctate shape of conventional invadopodia but are instead spread along the cell base and are reticular and/or fibrous in character. In strong support of these findings, a tamoxifen-activated knock out of Dyn2 in mouse embryonic fibroblasts also induces a marked increase (7-8 fold) in the degradation of matrix exhibited by these cells. Re-expression of wt Dyn2 or Dyn1, but not a Dyn2-K44A GTPase defective mutant, actually reduces/eliminates matrix degradation to near normal levels. In stark contrast, siRNA knock down of Dyn2, or expression of Dyn2-K44A, in pancreatic adenocarcinoma cell lines (DANG, BXPC3) resulted in a near complete inhibition of canonical invadopodial-based degradation consistent with the past findings of others. As matrix degradation in the mesenchymal cell lines appears to be induced by a reduction in Dyn2 levels and exhibits a pattern distinct from conventional invadopodia, we tested a role for Src kinase in this novel process. While treatment of the pancreatic tumor cells with PP2 or SU6656 inhibitors markedly reduced invadopodia-based matrix degradation these had almost no effect on this process in the fibroblast cell lines. These findings provide evidence for a novel matrix remodeling process conducted by mesenchymal cells that is substantially more effective than conventional invadopodia, distinct in structural organization, and Dyn2 and Src kinase independent. **N-WASP coordinates the delivery and F-actin mediated reversible capture of MT1-MMP at invasive pseudopods to drive breast cancer cell invasion.**

*T. Zech<sup>1</sup>, X. Yu<sup>1</sup>, L. MacDonald<sup>1</sup>, E. G. Gonzalez<sup>2</sup>, A. Li<sup>1</sup>, I. MacPherson<sup>1</sup>, R. Insall<sup>1</sup>, I. Anton<sup>2</sup>, K. Oien<sup>3</sup>, K. Blyth<sup>1</sup>, J. C. Norman<sup>1</sup>, L. M. Machesky<sup>1</sup>; <sup>1</sup>The Beatson Institute for Cancer Research, Glasgow, United Kingdom, <sup>2</sup>Centro Nacional de Biotecnología, Madrid, Spain, <sup>3</sup>College of Medical Veterinary and Life Sciences, Glasgow University, Glasgow, UK*

Metastasizing tumor cells use matrix metalloproteases, such as the transmembrane collagenase MT1-MMP, together with actin based protrusion, to break through extracellular matrix barriers and migrate in dense matrix. Here we show that the actin nucleation factor N-WASP is upregulated in breast cancer and that N-WASP has a pivotal role in mediating the assembly of elongated pseudopodia instrumental in matrix degradation. In actively invading cells N-WASP promotes trafficking of MT1-MMP from late endosomes to “actin-hotspots” in invasive pseudopodia. These actin rich domains on pseudopods in matrix are shown to mature from adhesion sites to degradative foci by actively sequestering MT1-MMP via direct actin binding of the metalloprotease. This clustering of MT1-MMP is shown to be required to achieve matrix degradation and N-WASP mediated actin polymerization is a prerequisite for this process. We demonstrate regulation of the MT1-MMP interactions with actin networks by phosphorylation.

Our results thus suggest a new integrated model of regulated actin mediated receptor targeting in 3D cancer cell invasion.

**Co-ordinated functions of WASH and exocyst complex underlie the biogenesis of invadopodia in metastatic breast tumor cells.**

*P. Monteiro<sup>1</sup>, M. Hertzog<sup>1</sup>, C. Rossé<sup>1</sup>, C. Desnos<sup>2</sup>, T. Zech<sup>3</sup>, E. Formstecher<sup>4</sup>, F. Darchen<sup>2</sup>, L. Machesky<sup>3</sup>, A. Gautreau<sup>5</sup>, P. Chavrier<sup>1</sup>; <sup>1</sup>Institut Curie, Paris, France, <sup>2</sup>Université Paris Descartes, Paris, France, <sup>3</sup>Beatson Institute, Glasgow, United Kingdom, <sup>4</sup>Hybrigenics SA, Paris, France, <sup>5</sup>LEBS, Gif-sur-Yvette, France*

The trade-mark of a metastatic tumor cell is its ability to disseminate from the primary tumor by degrading the extracellular matrix and basement membranes that form a barrier around the tissue. Remodelling of the extracellular matrix by metastatic cells requires formation of actin-based protrusions of the plasma membrane called invadopodia, where the trans-membrane matrix metalloproteinase MT1-MMP accumulates. How the cell coordinates targeting of MT1-MMP with actin assembly to form a functional invadopodium remains unclear. Here, we describe an interaction between the exocyst complex and the endosomal Arp2/3 activator WASH on MT1-MMP-containing late endosomes in MDA-MB-231 human breast adenocarcinoma cells. Exocyst and WASH regulate actin assembly on MT1-MMP-containing endosomes to control their dynamics. Both protein complexes are required for invadopodia formation and matrix degradation by a mechanism that involves transient tubular connections between the endosomes and the plasma membrane, which ensure focal delivery of MT1-MMP. These connections are accompanied by recruitment of another Arp2/3 activator, N-WASP, to mature invadopodia and loss of WASH. These findings imply a new definition of invadopodia as structures where late endosomes fuse transiently with the plasma membrane to promote actin assembly and deliver the matrix metalloproteinase to focal sites of matrix degradation.

**A specific subset of RabGTPases controls cell surface exposure of MT1-MMP, extracellular matrix degradation and 3D invasion of macrophages.**

S. Linder<sup>1</sup>, C. Wiesner<sup>1</sup>; <sup>1</sup>University Medical Center Eppendorf, Hamburg, Germany

The matrix metalloproteinase MT1-MMP has a decisive impact on invasive cell migration in both physiological and pathological settings such as immune cell extravasation or metastasis of cancer cells. Surface-associated MT1-MMP is able to cleave components of the extracellular matrix, which is a prerequisite for proteolytic invasive migration. However, current knowledge on the molecular mechanisms that regulate MT1-MMP trafficking to and from the cell surface is limited. Here, we identify three members of the RabGTPase family, Rab5a, Rab8a, and Rab14, as critical regulators of MT1-MMP trafficking and function in primary human macrophages. Both overexpressed and endogenous forms show prominent colocalization with MT1-MMP-positive vesicles, while expression of mutant constructs as well as siRNA-induced knockdown revealed that these RabGTPases critically regulate MT1-MMP surface exposure, contact of MT1-MMP-positive vesicles with podosomes, extracellular matrix degradation in 2D and 3D, as well as 3D proteolytic invasion of macrophages. Collectively, our results identify Rab5a, Rab8a, and Rab14 as major regulators of MT1-MMP trafficking and invasive migration of primary human macrophages

2079

**The proto-oncogene Vav1 promotes Cdc42-dependent invadopodia formation and tumor cell invasion.**

G. L. Razidlo<sup>1</sup>, B. Schroeder<sup>1</sup>, M. A. McNiven<sup>1</sup>; <sup>1</sup>Mayo Clinic, Rochester, MN

Tumor cell metastasis requires an active degradation and remodeling of the extracellular matrix to facilitate migratory invasion into peripheral tissues and vessels. This process is dependent in part on specialized, actin-rich, protrusive structures at the plasma membrane termed "invadopodia" that sequester and dispense active metalloproteases. The oncogenic guanine nucleotide exchange factor Vav1, an activator of Rho family GTPases, is ectopically expressed in pancreatic cancers, where it promotes tumor cell survival and invasive migration. The GOAL of this study was to test if Vav1 contributes to tumor cell invasion by regulating invadopodia function during matrix degradation. Reduction of Vav1 levels in DanG cells by siRNA-mediated knockdown inhibited invadopodia formation and subsequently reduced the degradation of a fluorescent substrate by 80%. Re-expression of WT Vav1 restored degradation in these cells, while expression of a GEF-inactive form of Vav1 did not, demonstrating that Vav1 GEF activity is required for matrix degradation. Because Vav1 can function as a GEF for multiple members of the Rho super-family, we tested which GTPase might mediate the effects of Vav1 on matrix degradation. Vav1-depleted cells were transfected with constitutively active forms of Rac1, RhoA, or Cdc42 in an attempt to bypass a GEF requirement and restore matrix degradation. Importantly, only the expression of active Cdc42, known to be required for invadopodia assembly, but not active Rac1 or active RhoA, restored invadopodia formation and matrix degradation, suggesting that Cdc42 functions downstream of Vav1 to regulate matrix remodeling and invasion by pancreatic tumor cells. These data reveal a novel mechanism by which invadopodia formation is regulated and identify an additional process by which Vav1 contributes to tumor cell invasion. Supported by NCI R01 CA104125 to MAM.

**The role of StarD13 in breast cancer proliferation and motility.***S. Hanna<sup>1</sup>, B. Khalil<sup>1</sup>, M. El-Sibai<sup>1</sup>; <sup>1</sup>Lebanese American University, Beirut, Lebanon*

Breast cancer is one of the most commonly diagnosed cancers in women around the world. In general, the more aggressive the tumor, the more rapidly it grows and the more likely it metastasizes. Cell migration, is a complex process, which requires the dynamic regulation of actin cytoskeleton. Members of the Rho subfamily of small GTP-binding proteins (GTPases) play a central role in breast cancer cell motility. The switch between active GTP-bound and inactive GDP-bound state is regulated by Guanine nucleotide exchange factors (GEFs), GTPase-activating proteins (GAPs) and Guanine-nucleotide dissociation inhibitors (GDIs). Here we study the role of StarD13, a newly identified Rho-GAP that specifically inhibits the function of RhoA and Cdc42. We aim to investigate its role in breast cancer proliferation and metastasis. The level of expression of this Rho-GAP in tumor tissues of different grades is assayed using immunohistochemistry. Moreover, the role of StarD13 in breast cancer cell lines is studied using two approaches. StarD13 is overexpressed using a StarD13-GFP construct, in the second approach StarD13 is knocked down using a specific siRNA. The effect on the activity of Rho-GTPases is observed using pull down activation assay, which confirmed StarD13 as a negative regulator for Rho and Cdc42 and not Rac. Our results also showed that StarD13 plays a negative role in cellular proliferation. Moreover to investigate the role of StarD13 in cell motility, StarD13 knock down resulted in an inhibition of cell motility and cells were not able to detach their tail and move forward. Being a Rho-GAP and localizing to focal adhesions, we hypothesize that StarD13 is inhibiting Rho to allow the formation of Rac-dependent focal complexes and the detachment of focal adhesions for the cells to move forward.

**Identification of novel Par1b substrates that regulate cell-extracellular matrix signaling.***D. M. Fernandez<sup>1</sup>, A. Muesch<sup>1</sup>; <sup>1</sup>Albert Einstein College of Medicine, Bronx, NY*

The serine/threonine kinase Par1b is well known for its role in regulating epithelial cell polarity and morphology. Recent evidence suggests that Par1b mediates its function as polarity determinant in part by regulating cell-extracellular matrix (ECM) signaling, which includes the process of cell spreading. How Par1b regulates ECM signaling mechanisms remains to be explored in full detail. We conducted an unbiased screen for novel Par1b substrates in polarized kidney-derived MDCK cells. The identification strategy was based on a chemical genetics approach in which the ATP-binding pocket of a kinase was altered to accommodate bulky ATP-analogues that when offered as phosphate donor in complex mixtures can only be utilized by the engineered kinase to selectively phosphorylate its substrates. The ATP-analogues contain a chemical affinity tag that is transferred onto the substrates and allows their isolation along with the identification of the phosphorylation sites by LC-MS/MS analysis. Using this approach, we have identified a total of 74 novel candidate substrates, as well as 5 known substrates. According to their gene ontology association, more than half belonged to categories, which are known to regulate Cell-ECM interactions. From those novel candidates, we have validated 14 as Par1b substrates. We are currently exploring how regulation of these substrates by Par1b effects cell spreading.

**Role of GNE in cell adhesion.**S. Grover<sup>1</sup>, R. Arya<sup>1</sup>; <sup>1</sup>*School of Biotechnology, Jawaharlal Nehru University, New Delhi, India*

Sialylation of cell surface glycoproteins and glycolipids regulates variety of cellular functions such as adhesion, migration, signaling and immune response. The enzyme UDP-N-acetylglucosamine 2-epimerase/N-acetyl-mannosamine kinase (GNE) is a key regulatory enzyme in the sialic acid biosynthesis. Homozygous missense mutations in this gene lead to Hereditary Inclusion Body Myopathy or Distal Myopathy with Rimmed Vacuoles. The present study depicts the effect of GNE on cell adhesion and migration. We generated stable GNE knockdown HEK cell line using shRNA. Approx. 70% inhibition in the GNE protein expression was observed in the knockdown cell lines compared to wild type HEK using immunoblots with anti-GNE antibody. The colorimetric assays specific for UDP-N-acetylglucosamine-2-epimerase and N-acetylmannosamine kinase activity showed 70-80% reduction in the enzymatic activity of knockdown vs wild type cell lines. Also, the sialic acid content of membrane and cytosolic fractions was reduced to 80-85% in knockdown cell lines. To study the effect of GNE on cell adhesion, knockdown and wild type cell lines were plated on different substrates such as laminin, collagen and fibronectin. GNE knockdown cell lines showed remarkable increase in adhesion property. In addition, GNE knockdown cells showed less migration compared to vector control by live cell imaging. To further elucidate the role of GNE, sialylation levels of key adhesion molecule,  $\beta$ 1 integrin, was studied. Shift in the electrophoretic mobility of  $\beta$ 1 integrin from knockdown cell lines confirmed that  $\beta$ 1 integrin was hyposialylated in the absence of GNE. Our results show for the first time that inhibition of GNE leads to hyposialylation of  $\beta$ 1 integrin which causes increased cell adhesion and reduced migration of GNE deficient cell lines.

2084

**Regulation of VLA-4 mediated hematopoietic stem/progenitor cell adhesion by CD82.**C. M. Termini<sup>1</sup>, M. L. Cotter<sup>1</sup>, K. D. Marjon<sup>1</sup>, T. Buranda<sup>1</sup>, K. Lidke<sup>2</sup>, J. M. Gillette<sup>1</sup>; <sup>1</sup>*Department of Pathology, University of New Mexico, Albuquerque, NM*, <sup>2</sup>*Department of Physics & Astronomy, University of New Mexico, Albuquerque, NM*

The adhesive events between hematopoietic stem and progenitor cells (HSPC) and the bone marrow niche are important for maintenance of HSPC cell number and function. Critical to the HSPC/niche interaction is the spatial arrangement of membrane proteins, such as adhesion and signaling molecules, on the surface of HSPCs. At this time, the regulation of specific adhesion and signaling components remains poorly defined. CD82 or Kai1 is a member of the tetraspanin family of proteins, which function as regulatory scaffold proteins by assisting in the formation of membrane domains. In primary human CD34+ cells and the KG1a human progenitor-like cell line, the site of cell contact with osteoblasts is enriched with CD82. Furthermore, the use of CD82 blocking antibodies inhibited the homing and engraftment of CD34+ cells in vivo. As such, we hypothesize that CD82 is a critical molecule involved in regulating HSPC adhesion within the bone marrow niche. Using the KG1a progenitor-like cell line, we examined the effects of overexpression and knock down of CD82 on HSPC adhesion. We found that the overexpression of CD82 in HSPCs leads to increased adhesion to fibronectin and osteoblasts, while CD82 knockdown led to decreased adhesion. The change in adhesion to fibronectin and osteoblasts suggests the involvement of the  $\alpha$ 4 $\beta$ 1 integrin. Therefore, we treated cells with the  $\alpha$ 4 $\beta$ 1 blocking peptide, LDV, which blocked the CD82-mediated adhesion, and further implicated the  $\alpha$ 4 $\beta$ 1 integrin in HSPC adhesion. With the overexpression of CD82, we detected only a modest increase in  $\alpha$ 4 and  $\beta$ 1 surface expression, but no difference in total  $\alpha$ 4 $\beta$ 1 protein levels or  $\alpha$ 4 $\beta$ 1 affinity. Next, we evaluated whether the CD82 overexpression results in greater adhesion due to changes in  $\alpha$ 4 $\beta$ 1 avidity or surface clustering. Using the super resolution imaging technique

dSTORM, we examined the role of CD82 in regulating the clustering of  $\alpha 4$  and  $\beta 1$  on the surface of HSPCs. We also generated palmitoylation mutants of CD82 to assess the importance of this modification in CD82 function. The CD82 palmitoylation mutants display a reduced adhesion when compared to WT CD82 overexpressing cells suggesting a role for CD82 palmitoylation in mediating HSPC adhesion. Taken together these data suggest that CD82 mediates HSPC adhesion to components of the bone marrow niche by regulating the surface expression of  $\alpha 4\beta 1$ . Future work will analyze the role of additional CD82 motifs and post-translational modification in mediating  $\alpha 4\beta 1$  surface distribution.

### **Role of Lutheran blood group glycoprotein/Basal Cell Adhesion Molecule (Lu/B-CAM) in cellular interaction with laminin $\alpha 5$**

*Y. Kikkawa<sup>1</sup>, T. Hamakubo<sup>1</sup>, M. Nomizu<sup>1</sup>; <sup>1</sup>Laboratory of Clinical Biochemistry, Tokyo University of Pharmacy and Life Sciences, Tokyo, Japan*

Lu is a member of the immunoglobulin superfamily and has been studied primarily in the contexts of blood group antigens and sickle cell disease. B-CAM, a splice variant of Lu, has the same N-terminal extracellular domain as Lu, but it lacks the C-terminal 40 amino acids of the cytoplasmic tail which carries an SH3 binding motif and potential phosphorylation sites that could be involved in intracellular signaling pathways. B-CAM was also identified as an up-regulated antigen in carcinoma, suggesting its involvement in tumor progression. Our previous study showed that Lu/B-CAM is a specific receptor for laminin  $\alpha 5$ , a major component of basement membranes in various tissues. Despite of recent advances, the biological functions of Lu/B-CAM are still unclear. In this study, using transfectants overexpressing Lu/B-CAM, we examined the role of Lu/B-CAM in cellular interaction with laminin  $\alpha 5$ . The recombinant protein containing laminin  $\alpha 5$  was prepared from the conditioned media of HEK293 cells that were transfected with laminin  $\alpha 5$ ,  $\beta 1$ , and  $\gamma 1$  chains. For avoiding clonal variation of transfectants, we used the Flp-In System. Lu or B-CAM gene was cloned into pcDNA5/FRT expression vector and then transfected into HT1080F, human fibrosarcoma, that was Flp-In host cell line. Flow cytometry analysis showed that the transfectants well expressed Lu or B-CAM and did not change the expression of integrin  $\alpha 3\beta 1$  and  $\alpha 6\beta 1$ . Cell attachment assay showed that both transfectants attached to laminin  $\alpha 5$  slightly weaker than parent cells. Inhibition assay using anti-integrin and Lu monoclonal antibodies showed that Lu/B-CAM had little, if any, contribution in the cell adhesion to laminin  $\alpha 5$ . The result showed that the parent cells and transfectants attached to laminin  $\alpha 5$  in a similar manner. We also examined the cell migration of transfectants on laminin  $\alpha 5$ . Cell migration was monitored using time-lapse video microscopy, and the video images were collected at 5 min. The positions of nuclei were tracked to quantify cell motility for 8 hours. Velocities were calculated in micrometers per 1 hour using Image-J. Lu and B-CAM similarly promoted cell migration on laminin  $\alpha 5$ , suggesting that the cytoplasmic tail of Lu did not involve in cell migration. Furthermore, the cell migration of transfectants on laminin  $\alpha 5$  was also suppressed in the present of a function-blocking antibody against Lu/B-CAM. Our results showed that Lu/B-CAM contributed to cell migration rather than cell attachment.

2086

**Selective effects of fungal  $\beta$ -glucans and  $\alpha$ -D-mannans on leukocyte integrins Mac-1 and P150,95.***W. Cao<sup>1</sup>, E. Pluskota<sup>1</sup>, E. F. Plow<sup>1</sup>, D. A. Soloviev<sup>1</sup>; <sup>1</sup>Molecular Cardiology, Cleveland Clinic Lerner Research Institute, Cleveland, OH*

Poly- and oligosaccharides are important modulators of immune system, particularly as in their role as activators of the leukocyte  $\beta$ 2-integrin subfamily. These integrins are present on the surface of nonstimulated leukocytes in inactive "closed" conformation and activation enhances their recognition of ligands with high affinity. (1,3) $\beta$ -glucans from *S. cerevisiae* (zymosan) is an activator of integrin Mac-1 (CD11b/CD18,  $\alpha$ M $\beta$ 2, CR3). Upon ligation with the integrin lectin domain, zymosan activates the integrin, stabilize it in an intermediate active conformation, and enhance lectin domain-independent recognition of many Mac-1 ligands such as fibrinogen D-fragment. However, recognition of the ligands interacting with the lectin domain such as *Candida albicans* Pra1 mannoprotein is ablated by  $\beta$ -glucans. Recently, we found that another member of  $\beta$ 2-integrins subfamily, integrin p150,95 ( $\alpha$ X $\beta$ 2, CD11c/CD18, CR4), also contains a lectin-like binding function within its  $\alpha$ X subunit. The goal of this study was to compare the effect of fungal (1,3)  $\beta$ -glucans and  $\alpha$ -D-mannans on integrins Mac-1 and p150,95. Employing a variety of cell systems including human and mouse neutrophils, monocytes and macrophages, Mac-1 or p150,95-deficient leukocytes, as well as HEK 293 cells overexpressing these integrins, we found that: a) The effect of zymosan on p150,95 was similar to that observed with Mac-1:  $\beta$ -glucans enhanced p150,95-dependent leukocyte adhesion to fibrinogen D-fragment and blocked p150,95 interaction with *C. albicans* Pra1. b) Fungal  $\alpha$ -D-mannans promotes both Mac-1- and p150,95-mediated cell adhesion to fibrinogen D-fragment. In contrast, when leukocyte interaction with the lectin domain-dependent ligand *C. albicans* Pra1 was analyzed,  $\alpha$ -D-mannans inhibited Mac-1 dependent leukocyte adhesion to this ligand, but had minimal effect ( $p=0.068$ ) on  $\alpha$ X $\beta$ 2-dependent fungal recognition. The observed differences in sugar selectivity of the integrins may play an important role in the regulation of leukocyte activation and host defense against fungal infections.

2087

**The moieties of complement iC3b recognized by I-domain of Integrin  $\alpha$ X $\beta$ 2 and  $\alpha$ M $\beta$ 2***S-U. Nham<sup>1</sup>, D. Buyannemekh<sup>2</sup>; <sup>1</sup>Science Education, Kangwon National University, Chuncheon, Korea, <sup>2</sup>Biology, Kangwon National University, Chuncheon, Korea*

The  $\beta$ 2 integrins play a vital role in leukocyte activation including cell adhesion, migration, and phagocytosis. This integrin binds many different types of ligands, including fibrinogen, iC3b, and ICAM-1. Complement fragment iC3b binding to  $\beta$ 2 integrin initiates inflammation and complement-mediated cytolysis. It has been shown that I domains in the  $\alpha$  subunits of  $\beta$ 2 integrin ( $\alpha$ X and  $\alpha$ M I-domains) are the ligand binding moieties. In order to define structural aspect of the binding, we investigated the iC3b binding sites for  $\alpha$ M and  $\alpha$ X I domains by site directed mutagenesis and solid phase binding analysis. It was found the basic amino acids on the loop of  $\alpha$ X I domain are the important residues for iC3b recognition. And the  $\alpha$ X and  $\alpha$ M I-domains were found to bind two amino acid termini of iC3b:  $\alpha$ NTN (D730-E737) and  $\alpha$ CUN (S1280-K1319). In  $\alpha$ NTN, acidic residues near the N-terminus play an important role on the interaction with the I domains: D730, E731, E746 and E747. The whole chain of  $\alpha$ CUN serves as a binding site of the I domains, but some acidic residues are critical for the I domains binding: E1285, E1287 and E1294. In addition, the C3dg domain of iC3b, was identified as an important moiety for the I domains of  $\alpha$ X and  $\alpha$ M. It was found that three amino acid residues (E1131,

D1134 and K1261) which located at the edge of concave pocket of C3dg were critical for the I domains binding.

**Subtype specific integrin suppression on the integrin binding peptide conjugated polysaccharide matrices.**

*K. Hozumi<sup>1</sup>, C. Fujimori<sup>1</sup>, F. Katagiri<sup>1</sup>, Y. Kikkawa<sup>1</sup>, M. Nomizu<sup>1</sup>; <sup>1</sup>Tokyo University of Pharmacy and Life Sciences, Hachioji, Japan*

Peptide-polysaccharide matrices promote biological activity and are useful as a biomaterial for use in tissue engineering. Previously, we conjugated extracellular matrix derived cell adhesive peptides on polysaccharide, chitosan or alginate, matrices and found that peptide-polysaccharide matrices exhibited biological activities with peptide- and/or polysaccharide-dependent manner. Here, we focus on three integrin binding peptides derived from extracellular matrix proteins, FIB1 (12 aa peptide, from human fibronectin), EF1zz, (20 aa peptide, from mouse laminin  $\alpha$ 1 chain), and 531 (14 aa peptide, from human type IV collagen  $\alpha$ 1 chain) that bind to  $\alpha$ v $\beta$ 3,  $\alpha$ 2 $\beta$ 1, and  $\alpha$ 3 $\beta$ 1 integrin, respectively. We mixed these peptides and examined their cell attachment and cell spreading activities using human dermal fibroblasts to analyze the cross-talk between integrin subtypes. The FIB1-, EF1zz-, and 531-chitosan matrices promoted cell attachment and spreading with peptide specific cell morphology. When FIB1:EF1zz and FIB1:531 were mixed, mixed-peptide-chitosan matrices showed cell attachment with intermediate cell morphology of two different peptides. In contrast EF1zz:531-peptide-chitosan matrix showed the suppression of cell attachment and spreading. Same results were observed on the mixed-peptide-alginate matrices. These results suggest that  $\beta$ 1 integrin subtypes may compete or compensate each other whereas no effect on different  $\beta$  subunit integrin subtypes. TS2/16 integrin activation anti- $\beta$ 1 integrin antibody partially recovered the suppression. Further, protein kinase A inhibitor of 14-22 amide promoted cell attachment suppression, whereas protein kinase C inhibitor of Go 6976 did not showed any effect on the suppression. These results suggested that protein kinase A involving integrin activation was down-regulated by the cross-talk of  $\alpha$ 2 $\beta$ 1 and  $\alpha$ 3 $\beta$ 1 integrin. We conclude that the mixed peptide-polysaccharide matrices have a potential to analyze the specific receptor-receptor cross-talk among different receptors.

**Clonal derivation and clonal survival of human embryonic stem cells on human laminin-521-based matrix in xeno-free and chemically defined environment.**

*S. Rodin<sup>1</sup>, C. Niaude<sup>2</sup>, A. Domogatskaya<sup>1</sup>, Z. Xiao<sup>1</sup>, C. Betsholtz<sup>2</sup>, L. Antonsson<sup>3</sup>, O. Hovatta<sup>3</sup>, K. Tryggvason<sup>1</sup>; <sup>1</sup>Division of Matrix Biology, Karolinska Institute, Stockholm, Sweden, <sup>2</sup>Division of Vascular Biology, Karolinska Institute, Stockholm, Sweden, <sup>3</sup>Division of Obstetrics and Gynecology, Karolinska Institute, Stockholm, Sweden*

Clinical use of human embryonic stem (hES) cells has been hampered by poorly defined derivation and culturing procedures as well as ethical concerns caused by the destruction of human embryos in the process. Feeder cell layers, currently used as surfaces for derivation of new ES cell lines, are undefined and variable and can be sources of viral and bacterial contaminations. We have cloned, produced and purified human recombinant laminin isoforms that are expressed in hES cells. Laminins, as well as other proteins of extracellular matrix, have been always regarded as a minor, insignificant part of stem cell niches with no specific functions other than cell adhesion. We have shown that laminins have diverse effects on cultured hES and human induced pluripotent stem (iPS) cells. Thus, laminin-521 (LN-521) and LN-511 permit

long-term self-renewal of hES and iPS cells by interaction with  $\alpha 6\beta 1$  integrin activating PI-3K signaling pathway. Karyotypically normal stem cells can be cultured for 9 months with stable expression of pluripotency markers and can subsequently be differentiated into cell lineages of all three germ layers. Importantly, a combination of LN-521 with other proteins of the natural hES cell niche allows clonal survival of hES cells. The LN-521-based matrix fully substitutes undefined and potentially hazardous feeder cells for hES cell derivation both from whole inner cell masses of blastocysts or from single blastomere cells without need to destroy the embryo, potentially addressing central ethical issues of hES cell derivation. The derivation from single blastomeres does not imply co-cultures with either the parental blastocyst or established hES cells. The methods provide a fully chemically defined animal component-free culture system for new hES cell line derivation and propagation, which can bridge the gap between academic stem cell research and clinical science.

2090

### **Laminin-derived integrin binding peptide-polysaccharide matrices as basement membrane mimetics.**

*K. Sato<sup>1</sup>, Y. Yuji<sup>1</sup>, H. Kentaro<sup>1</sup>, K. Fumihiko<sup>1</sup>, K. Yamato<sup>1</sup>, N. Motoyoshi<sup>1</sup>; <sup>1</sup>Tokyo University of Pharmacy and Life Sciences, Hachioji, Japan*

Basement membrane (BM) is a thin extracellular matrix existing among tissues and plays a critical role on tissue repair. The major components of BM are type IV collagen, laminin, perlecan, and nidogen, and laminin is mainly involved in biological function of BM. Laminins are heterotrimeric BM proteins consisting of  $\alpha$ ,  $\beta$ , and  $\gamma$  chains and exert multiple biological functions through interactions with other matrix molecules and with cell surface receptors. Matrigel, an extract of BM derived from mouse sarcoma, has been widely used as a three-dimensional cell culture matrix, but it is not possible to apply for human. Previously, we have identified a number of cell adhesive peptides from laminins. Our goal is to develop a synthetic Matrigel and use for tissue engineering. We conjugated the laminin active peptides to polysaccharide, alginate or chitosan, matrices and demonstrated their usefulness for cell transplantation and cell culture [1,2]. Here, we focused on integrin-binding peptides derived from laminins because integrins are known as major cell surface receptors for BM. We synthesized 22 integrin-binding peptides by Fmoc-based solid-phase peptide synthesis and examined their biological functions on both alginate and chitosan matrices. First, we evaluated the cell attachment activity on the peptide-alginate and -chitosan matrices using human dermal fibroblast (HDFs). As a result, ten peptide-alginate and eleven peptide-chitosan matrices showed HDF attachment activity in a dose-dependent manner. Six peptide-alginate and seven peptide-chitosan matrices promoted cell spreading, and the HDF attachment to these matrices was significantly inhibited by EDTA. These results indicate that the six peptide-alginate and seven peptide-chitosan matrices promote integrin-mediated cell adhesion. Next, we evaluated the inhibitory effect of anti-integrin antibodies on the 10 peptide-alginate matrices and 11 peptide-chitosan matrices to identify integrin subtypes. Integrins  $\alpha 2$ ,  $\alpha 3$ ,  $\alpha 6$ , and/or  $\beta 1$  were involved in the HDF adhesion to the peptide-alginate and -chitosan matrices with peptide-dependent manner. We also investigated neurite outgrowth activity of the peptide-alginate and -chitosan matrices using PC12 cells. Six peptides promoted neurite outgrowth on both alginate and chitosan matrices. These results demonstrated that these laminin-derived integrin-binding peptide-polysaccharide matrices are useful to develop a synthetic Matrigel and can be applied for tissue engineering.

### **Cell matrix interactions and spheroid formation in 3D alginate cell culture system**

*T. Andersen<sup>1</sup>, C. Markussen<sup>1</sup>, M. Dornish<sup>1</sup>; <sup>1</sup>FMC BioPolymer/NovaMatrix, Sandvika, Norway*

The use of 3-dimensional (3D) matrices for cell culture is gaining popularity as a substitute for traditional 2D cell culture as it can enable formation of multi-cellular structures and a more biologically relevant cell-cell contact such as found in tissues, organs and tumors. NovaMatrix<sup>®</sup>-3D is an alginate-based hydrogel cell culture system comprising an alginate foam matrix and an alginate immobilizing solution. Cells are entrapped uniformly throughout the alginate foam by first suspending them in a solution of sodium alginate that is applied to the foam. As the foam absorbs the suspension, in situ gelation occurs as calcium ions are donated from the foam cross-linking the added alginate. A hydrogel forms in the pores of the foam. Cells then grow in 3D and can form multicellular structures such as spheroids, myotubes, etc.

Some cells, however, require signaling molecules and matrix interaction in order to proliferate. This was evaluated by culturing cells in the presence of alginate to which the peptide sequence RGD (Arg-Gly-Asp) was covalently attached (RGD-alginate) thereby facilitating a signaling cascade via integrin-RGD interaction. Single cells of NHIK 3025 (human cervix carcinoma), OVCAR-3 (human ovarian adenocarcinoma), SKOV-3 (human ovarian carcinoma), NIH:3T3 (murine fibroblasts), C2C12 (murine myoblasts), V79-379A (hamster lung fibroblast) and MDCK (Madin Darby canine kidney) suspended in 0.5 - 1% alginate or RGD-alginate were added to the alginate foams. Cell localization and cell structure within the foam was visualized by confocal microscopy of fluorescently labeled cells. Cell proliferation was measured by counting cells after de-gelling the foam using sodium citrate that chelates calcium. Similar cell proliferation and spheroid formation occurred during three weeks of culture in foams with or without RGD-alginate for NHIK 3025, SKOV-3, 3T3 and V79-379A indicating that these cell lines do not require the presence of RGD within the alginate matrix for cell growth. However, during the same period, cell proliferation of OVCAR-3, MDCK or C2C12 was only seen in the foams containing RGD-alginate. The proliferation rate was affected by the RGD density. Cells that did not proliferate in alginate without RGD were still metabolically viable. Cell-matrix interaction can be controlled by type and concentration of signaling molecules covalently attached to the alginate. Portions of this work were funded by METOXIA project no.222741, EU 7th Framework Programme.

### **ECM interaction with signaling events and cellular functions.**

*M. Noda<sup>1</sup>; <sup>1</sup>TMDU, Tokyo, Japan*

Extracellular matrix is deposited by the cells that are under the control of multiple signaling molecules such as hormones and local factors. Extracellular signals in turn regulates cell behavior. This is called "inside-out" and "outside-in" signaling. Among these extracellular proteins, SPP1 is a unique molecule that possess RGD domain being recognized by integrins as well as stretches of aspartic acid that make the protein to be highly adhesive to calcified tissues. Since this protein is secreted by the cells that produce calcified matrix, the function of this molecule has been considered to be important for the responses of the cells to microenvironment. One of the major stimuli to the individual body is the extra cellular force

stimuli. This is especially important for skeletal tissue as well as cardiovascular tissues where external forces are either due to locomotions or heart beat and blood flow. The force stimuli is in part mediated by neural regulation but also calciotropic hormones. In the case of skeletal tissues, SPP1 is produced by both types of cells including bone forming cells as well as bone resorbing cells. Hormones are regulating such activities. The deletion of this molecule resulted in the loss of tissue response to unloading that is normally enhances bone resorption and suppresses bone formation leading to rapid bone loss in the individual bodies. Quite importantly, this molecule is not only secreted or not only deposited in the extracellular matrix but also being functional inside the cells. Such examples include not only skeletal cells but also immune cells. Such mechanical stimuli against skeletal tissues are also under the control of nervous tissues. In fact, inhibitors for the sympathetic nervous system have been shown to regulate skeletal mass. The receptors for the transmitter molecules expressed on bone cells are considered to convey the regulation by nervous system. Importantly, we have found that this nervous system signaling links to the function of SPP1 inside the cells as well as outside cells. The conversion of the signals from both inside and outside the cells determined the final direction of the cell response to the external force stimuli.

### **Tumor Endothelial Marker 8 and its role in vasculogenesis and connective tissue homeostasis.**

*T. Y. Besschetnova<sup>1</sup>, B. R. Olsen<sup>1</sup>; <sup>1</sup>HSDM, Boston, MA*

The process of angiogenesis is an essential part of vascular development and various human pathologic disease states such as cancer, hemangioma, chronic inflammation, diabetic retinopathy and fibrosis. The Tumor Endothelial Marker 8 (TEM8) gene, which encodes a cell surface integrin-like receptor, also known as Anthrax toxin receptor 1 (ANTXR1), was originally identified as a component of endothelial cells in highly vascularized tumors. The physiological function of TEM8, however, remains elusive. Detailed understanding of TEM8 function will offer valuable mechanistic insights into the etiology of angiogenesis-related diseases.

It has been reported that TEM8 plays a role in adhesion, spreading and migration of endothelial cells through its interaction with extracellular matrix (ECM) components, such as collagen type I and type IV and actin cytoskeleton. In addition, *in vitro* assays show a correlation between increased TEM8 expression and initiation of endothelial tubular structure formation. Altogether, these data suggest that TEM8 can impact the process of vessel formation at any steps of vasculogenesis/angiogenesis. To explore TEM8 function in vascular morphogenesis we have studied a *Tem8* -/- mice, in which eight exons of the gene are removed.

Inspection of mutant animals revealed hemorrhage in digestive, respiratory and reproductive systems that pointed to a defective, leaky vascular system in both *Tem8* -/- and *Tem8* +/- mice. This was confirmed by extravasation of FITC-coupled dextran in skin tissue samples of FITC-dextran-perfused animals. Notably, the overall phenotype was less severe in heterozygous than homozygous animals, suggesting that the level of expression and/or activity of TEM8 is important for vascular morphogenesis. Our data show that proliferation and apoptosis of cells in deep and subcutaneous skin layers are markedly increased in mutants compared to wild type littermates at 7 weeks of age. Moreover, we observed strong correlation between increased CD31 staining and increased vessel density in skin. Furthermore, phenotypic characteristics of dermal and subcutaneous vessels in *Tem8* +/- and *Tem8* -/- animals included (i) thin-walled blood-congested vessels, (ii) defective basement membranes associated with reduced levels of collagen IV and collagen XVIII/endostatin, (iii) abnormal activation of Ang-2/Tie-2 signaling and (iv) mural cell detachment. Intriguingly, in addition to vascular abnormalities *Tem8* null animals exhibited increased deposition of ECM molecules, including collagen I, fibronectin and vitronectin accompanied by fibrosis in various organs.

Matrix deposition and accumulation of fibrous tissue were also found in two recently reported conditional Tem8 mouse models; reminiscent of systemic hyalinosis, a disease caused by mutations in capillary morphogenesis protein-2 (CMG2) sharing 60% identity with TEM8 in the vWF extracellular domain.

Together our data suggest that TEM8 can regulate vascular and connective tissue homeostasis in part through ECM-TEM8 signaling.

**Mammary epithelial cells require Integrin Linked Kinase signalling for lactational differentiation and the formation of polarised acini.**

*N. Rooney<sup>1</sup>, C. H. Streuli<sup>1</sup>; <sup>1</sup>The Wellcome Trust Centre for Cell Matrix Research, Faculty of Life Sciences, University of Manchester, Manchester, United Kingdom*

Epithelial cell adhesion to the surrounding extracellular matrix is necessary for their proper behaviour and function. During pregnancy and lactation mammary epithelial cells (MECs) require signals imparted by specific  $\beta 1$  integrin-laminin interactions for their functional differentiation in response to prolactin and for the correct formation of polarised secretory acini. Downstream of  $\beta 1$  integrin, our lab has identified the scaffold protein Integrin Linked Kinase (ILK) as the key signal transducer that is required for both prolactin driven lactational differentiation and the establishment of apico-basal polarity in MECs. ILK is a multifunctional adaptor protein that links integrins to the actin cytoskeleton and Rho GTPases such as Rac1. ILK forms a ternary IPP complex with PINCH and Parvins, which are central to its adaptor functions. However, it is not known which of ILKs interacting partners are important in controlling tissue-specific gene expression and polarity. We have now established that inducible ILK deletion in MECs from ILK<sup>fl/fl</sup>CreER mice causes inverted apico-basal polarity and a failure to phosphorylate STAT5 leading to the failure of prolactin-induced milk protein expression. We have also developed a 3-dimensional culture model using the EpH4 mammary epithelial cell line, which respond to prolactin treatment and form polarized acini similar to primary cells. In these cells knocking down beta1-integrin by lentiviral shRNA delivery has a profound effect on beta-casein production. By utilising lentiviral shRNA knockdown of ILK associated proteins, coupled with an ILK mutant rescue approach, we are currently piecing together the role of ILK and its specific binding partners in MEC differentiation and polarity.

**Sarcospan-Dependent Akt Activation is Required for Utrophin Expression, Binding to the Extracellular Matrix, and Muscle Regeneration.**

*J. Marshall<sup>1</sup>, J. Holmberg<sup>1</sup>, E. Chou<sup>1</sup>, J. Oh<sup>1</sup>, J. Lee<sup>1</sup>, P. T. Martin<sup>2</sup>, R. Crosbie-Watson<sup>1</sup>;  
<sup>1</sup>Integrative Biology and Physiology, University of California, Los Angeles, Los Angeles, CA,  
<sup>2</sup>Pediatrics, Ohio State University College of Medicine and Public Health, Columbus, OH*

Utrophin is normally confined to the neuromuscular junction (NMJ) in adult muscle and partially compensates for the loss of dystrophin in mdx mice. We show that Akt signaling and utrophin levels were diminished in sarcospan-deficient muscle. By creating several transgenic and knockout mice, we demonstrate that sarcospan regulates Akt signaling to control utrophin expression. Sarcospan determined  $\alpha$ -dystroglycan glycosylation by affecting levels of the NMJ-specific glycosyltransferase, Galgt2. After cardiotoxin injury, regenerating myofibers express utrophin and Galgt2 modified  $\alpha$ -dystroglycan around the sarcolemma. Sarcospan-null mice displayed delayed differentiation after cardiotoxin injury due to loss of utrophin and Akt signaling. Treatment of sarcospan-null mice with viral Akt increased utrophin and restored muscle repair after injury, revealing an important role for the sarcospan-Akt-utrophin signaling axis in regeneration. Sarcospan improved cell surface expression of utrophin by increasing

transportation of utrophin and dystroglycan from ER/Golgi membranes. Our studies reveal functions of utrophin in regeneration and new pathways that regulate utrophin expression at the cell surface.

2096

**Amelioration of dystrophin-deficient muscular dystrophy is dependent on  $\alpha 7 \beta 1$  integrin.**

J. L. Marshall<sup>1</sup>, J. Oh<sup>1</sup>, E. Chou<sup>1</sup>, J. Lee<sup>1</sup>, J. Holmberg<sup>1</sup>, D. J. Burkin<sup>2</sup>, R. Crosbie-Watson<sup>1</sup>;  
<sup>1</sup>*Integrative Biology and Physiology, University of California, Los Angeles, Los Angeles, CA,*  
<sup>2</sup>*Pharmacology, University of Nevada, Reno, Reno, NV*

Duchenne muscular dystrophy (DMD) is a progressive muscle wasting disorder caused by loss of the predominant adhesion complex at the muscle membrane, the dystrophin-glycoprotein complex (DGC), which connects the muscle cell membrane with the extracellular matrix. Over-expression of laminin-binding adhesion complexes,  $\alpha 7 \beta 1$  integrin or the utrophin-glycoprotein complex (UGC), rescues dystrophic pathology in the mdx mouse model of DMD by compensating for the loss of DGC function. Sarcospan (SSPN) ameliorates mdx muscular dystrophy by increasing abundance of both the UGC and  $\alpha 7 \beta 1$  integrin at the cell membrane. Here, we show that the rescue effect is dependent on  $\alpha 7$  integrin and that SSPN acts synergistically with both  $\alpha 7$  integrin and UGC complexes. We biochemically isolated a macromolecular complex containing  $\alpha 7 \beta 1$  integrin and the UGC. Using several double- and triple-knockout mice, we discovered that  $\alpha 7$  integrin and SSPN determine UGC laminin-binding and signaling functions. We show for the first time that  $\alpha 7 \beta 1$  integrin is required for rescue of mdx dystrophic pathology.

2097

**Tenascin-C aggravates myocardial inflammation in experimental autoimmune myocarditis in mice.**

T. Machino-Ohtsuka<sup>1,2</sup>, K. Tajiri<sup>2,3</sup>, M. Hiroe<sup>4</sup>, Y. Yasutomi<sup>3</sup>, K. Aonuma<sup>2</sup>, T. Yoshida<sup>1</sup>, K. Imanaka-Yoshida<sup>1</sup>; <sup>1</sup>*Mie University, Tsu, Japan,* <sup>2</sup>*Tsukuba University, Tsukuba, Japan,* <sup>3</sup>*Tsukuba Primate Research Center, Tsukuba, Japan,* <sup>4</sup>*National Center of Global Health and Medicine, Tokyo, Japan*

Tenascin-C (TN-C) is an extracellular matrix glycoprotein with high bioactivity, known to contribute to progression of various autoimmune diseases by mediating innate and adaptive immune responses. In normal adult heart, TN-C is sparsely detected but appears under various pathological conditions closely associated with active inflammation. In the present study, we examined a role of TN-C in regulation of immunoreaction in autoimmune myocarditis. Experimental autoimmune myocarditis (EAM) was induced by immunization with murine cardiac myosin peptide emulsified in complete Freund's adjuvant using knockout (TNKO) mice and comparing them with sibling wild-type (WT) mice. In WT-EAM, TN-C expression started to be upregulated at day 12 and peaked at day 14 after immunization in parallel to histological findings of inflammatory activity. At day 14, heart weight/body, weight myocardial troponin-I levels, severe infiltration of neutrophil, dendritic cell, activated CD4+ T-cells, Th17 cells infiltration, level of cytokines IL-6 and IL-17A in heart markedly elevated in WT-EAM to compare with the WT-control mice. These changes were significantly reduced in TNKO-EAM.

Next, we cultured dendritic cells derived from bone marrow of naive mice. In vitro, TN-C-induced expression of IL-6 which favors the generation of pathogenic Th17 cells and CCL17 that has chemotactic effect on Th17 cells. Silencing of  $\alpha 9$  integrin, a receptor for TN-C, by siRNA significantly reduced synthesis of IL-6 and CCL17. However, silencing of toll-like receptor 4, another receptor for TN-C did not show any effect to these cytokine production. These results

indicate that TN-C aggravates inflammatory response in the early stages of EAM by promoting Th17-related cytokine productions and Th17 cell generation via  $\alpha 9$  integrin-mediated signaling.

**Increased Collagen Production and Altered Integrin Expression by Fibroblasts in Drug-induced Gingival Overgrowth.**

*E. Uribe-Querol<sup>1</sup>, C. Rosales<sup>2</sup>; <sup>1</sup>Facultad de Odontología - UNAM, Mexico City, Mexico, <sup>2</sup>Instituto de Investigaciones Biomédicas - UNAM, Mexico City, Mexico*

Drug-induced gingival overgrowth is a side effect associated with 3 types of drugs: anticonvulsants (phenytoin), immunosuppressive agents (cyclosporine A), and various calcium channel blockers for cardiovascular diseases. Gingival overgrowth is characterized by the accumulation of extracellular matrix in gingival connective tissues, particularly collagenous components with various degrees of inflammation. About 30 % of patients treated with cyclosporine A develop gingival overgrowth. Although the mechanisms of this disorder are still unknown, recent studies in rat models suggest that this disorder seems to be induced by inhibition of collagen degradation in gingival connective tissue. However, in human gingival overgrowth collagen synthesis seems to be increased. In order to resolve how collagen is altered in human gingival overgrowth, collagen homeostasis and fibroblast functions were evaluated in cultures of fibroblasts derived from a cyclosporine A-treated patient. Collagen I and metalloproteinase type 1 (MMP-1) and the inhibitor for this metalloproteinase expression were increased. In addition, fibroblasts presented an exaggerated growth rate and a switch in integrin expression. Fibroblasts from a cyclosporine A-treated patient lost expression of  $\alpha 4$ ,  $\alpha 5$ , and  $\alpha v$  integrins, and increased expression of  $\alpha 6$  and  $\alpha L$  integrins. These data suggest that cyclosporine A-induced gingival overgrowth, in humans is caused in part by overproduction of collagen and at the same time by inhibition of collagen degradation. In addition, fibroblasts alter their phenotype showing an accelerated cell growth and alteration of integrin-dependent functions, such as adhesion and migration. Acknowledgements: This project was financed by grant IACOD IB200811 (to EUQ) and by grant IN205311-2 (to CR) from Dirección general de Asuntos del personal Académico, Universidad Nacional Autónoma de México.

**Binding of  $\alpha v \beta 1$  and  $\alpha v \beta 6$  integrins to tenascin-C induces epithelial-mesenchymal transition-like change of breast cancer cells.**

*T. Yoshida<sup>1,2</sup>, D. Katoh<sup>1</sup>, N. Shimojo<sup>1</sup>, K. Imanaka-yoshida<sup>1,2</sup>; <sup>1</sup>Pathology & Matrix Biology, Mie University Graduate School of Medicine, Tsu, Mie, Japan, <sup>2</sup>Matrix Biology Research Center, Tsu, Mie, Japan*

Tenascin-C (TNC), a large hexameric extracellular glycoprotein, has multiple domains and a variety of receptors mediating a wide range of cellular functions. We earlier reported its induction of epithelial-mesenchymal transition (EMT)-like change in breast cancer cells. In the present study, we clarified integrin receptors for involvement in this process. Among integrins previously reported as TNC receptors, substantial expression of  $\alpha 2$ ,  $\alpha v$ ,  $\beta 1$ , and  $\beta 6$  subunits was detected by quantitative polymerase chain reaction and immunoblotting. Integrin  $\beta 6$  mRNA was remarkably upregulated by transforming growth factor (TGF)- $\beta 1$  treatment, and protein expression was prominently increased by additional exposure to TNC. Immunofluorescence labeling demonstrated integrin  $\alpha v \beta 6$  in focal adhesions after TNC treatment, especially in combination with TGF- $\beta 1$ . The Immunoprecipitation showed increase in  $\alpha v \beta 1$  heterodimers, but not  $\alpha 2 \beta 1$ , after TNC treatment. Activated  $\beta 1$  subunits detected by an antibody against the  $Ca^{2+}$ -dependent epitope were co-localized with  $\alpha v$  in focal adhesion complexes, associated with FAK

phosphorylation at tyrosine 925. Binding analysis of integrins to TNC showed binding of  $\beta 1$ ,  $\beta 6$  and  $\alpha v$ , but not  $\alpha 2$ , in a divalent cations-dependent manner. Neutralizing antibodies against  $\alpha v$  and  $\beta 1$  blocked EMT-like change caused by TNC alone. In addition, combined treatment with anti- $\beta 1$  and anti- $\alpha v\beta 6$  inhibited TGF- $\beta 1$ /TNC-induced EMT. TNC could induce EMT-like change by signaling via integrin  $\alpha v\beta 1$  and  $\alpha v\beta 6$  recruited to focal adhesions.

### High Throughput Analysis of Mechanosensitive Stem Cell Differentiation.

A. W. Holle<sup>1</sup>, A. Engler<sup>1</sup>; <sup>1</sup>Bioengineering, UC San Diego, La Jolla, CA

Human mesenchymal stem cells (hMSCs) have the ability to differentiate based solely on the elastic modulus of the two-dimensional substrate upon which they are plated; substrates with a stiffness value mirroring that of a given tissue will cause hMSC differentiation toward that tissue's lineage. In order to accomplish this, hMSCs must be able to sample their environment for physical information and be able to convert that information into a biochemical signal in a process known as mechanotransduction. The role of mechanotransduction in cell fate decisions has been increasingly scrutinized, but a consensus on the necessary and sufficient signaling pathways for mechanosensitive stem cell differentiation has not yet been achieved. Focal adhesions, due to their position in proximity to the cell-matrix interface, have been proposed to play a role in this process. Linker proteins within focal adhesions have been shown to contain force-sensitive cryptic binding sites that are exposed under physiological strain. To analyze the force-resultant unfolding of focal adhesion proteins, a Cysteine Shotgun/Western Blot (CS/WB) technique was used to examine the extent of differential unfolding and exposure of cryptic kinase sites across focal adhesion proteins in response to substrate stiffness to identify novel stem cell mechanosensors. CS/WB revealed that in response to changes in substrate stiffness, hMSCs exhibit changes in talin unfolding. Talin, in turn, is responsible for the activation of vinculin, which activates MAPK1. In hMSCs, perturbing this pathway has been shown to affect myogenic differentiation of hMSCs on myogenically favorable substrates. Analysis of this system in the web-based proteomics tool Scansite reveals that vinculin contains an especially inaccessible binding domain for MAPK1. Scansite analysis of 47 potential focal adhesion-based mechanosensors further revealed a total of 465 cryptic binding domains. Of these, MAPK1 stood out for both its frequency and its inaccessibility, and was found to have inaccessible binding domains in a total of 21 potential mechanosensors. While force-dependent MAPK1 binding to vinculin specifically regulates myogenesis, monotonically increasing talin unfolding with stiffness suggests a broader, force-sensitive cell regulation. In order to address this, we utilized a 96 well plate polyacrylamide platform with varying stiffnesses to assess how a targeted siRNA screen of these other 21 proteins affects hMSC spreading, migration, proliferation, and differentiation. Combined, the data from both the bioinformatics analysis and the siRNA screen lend support to the heretofore unexplored role of MAPK1 in substrate-stiffness based hMSC differentiation, as well as the role of kinases in mechanically induced myogenesis.

**Matrix Stiffness Controls Nuclear Morphology of Human Mesenchymal Stem Cells in 2D and 3D.**

F. Rehfeldt<sup>1,2</sup>, M. Potyrala<sup>1</sup>, A. Zemel<sup>3</sup>, D. E. Discher<sup>2</sup>; <sup>1</sup>3rd Institute of Physics - Biophysics, Georg-August-University Goettingen, Goettingen, Germany, <sup>2</sup>Biophysical Engineering Lab, University of Pennsylvania, Philadelphia, PA, <sup>3</sup>Department of Dental Science, Hebrew University, Jerusalem, Jerusalem, Israel

It is now widely acknowledged that cells also mechanically interact and respond with their surrounding in multiple ways and that these physical cues can be as important as biochemical ones. Especially striking was the demonstration of mechanically guided differentiation of human mesenchymal stem cells (hMSCs) towards distinct lineages based on the stiffness of their native environment. While this process needs several days or weeks we focused on the early time interactions between cells and elastic substrates and analyzed cell morphology, cytoskeletal structure and nuclear morphology of cells cultured on novel hyaluronic acid hydrogels of different Young's moduli  $E$  in two and three dimensions. We find that the nuclear morphology is controlled by matrix elasticity via elastic coupling through acto-myosin stress fibers. Our experimental findings and the described theory offers an insight towards a direct mechanical pathway from the physical parameters of the extra-cellular matrix towards gene regulation in the nucleus.

**Integrated biochemical and functional characterization of the contribution of cellular architecture to ES- and iPS-derived cardiac tissue phenotype.**

S. P. Sheehy<sup>1</sup>, F. Pasqualini<sup>1</sup>, A. Grosberg<sup>1</sup>, S. Park<sup>1</sup>, Y. Aratyn-Schaus<sup>1</sup>, K. K. Parker<sup>1</sup>; <sup>1</sup>Disease Biophysics Group, School of Engineering and Applied Sciences, Harvard University, Cambridge, MA

Utilization of stem cell-derived cardiomyocytes for *in vitro* toxicity assessment applications is hampered by difficulties in driving them toward a physiologically-relevant phenotype. These challenges arise partly from a limited appreciation of the role played by the physical microenvironment during development, and a lack of rigorous, standardized metrics for evaluating the phenotypic state of stem cell-derived cardiac constructs *in vitro*. Traditionally, myocardial differentiation is evaluated using methodologies that provide poor predictions of tissue-level cooperative function, such as patch clamp recordings taken on individual cardiomyocytes. We hypothesized that the functional phenotype of stem cell-derived cardiomyocytes could be optimized and more readily assessed by culturing them in a microenvironment that recapitulates the laminar cellular organization of the native myocardium. To test this hypothesis, engineered cardiac tissues were fabricated using micro-contact printed fibronectin substrates seeded with either neonatal mouse ventricular myocytes (NMVM), murine ES-derived cardiomyocytes (mES), or murine iPS-derived cardiomyocytes (miPS). These myocardial tissue constructs were then subjected to quantitative cytoskeletal structure analysis, assessment of contractile performance, electrophysiological recordings, and gene expression measurements to compare and contrast the tissue-level, functional phenotype of the three types of cardiomyocytes tested. Examination of global sarcomere alignment as judged from immunohistochemically-labeled  $\alpha$ -actinin micrographs revealed that the mES and miPS-derived cardiac tissues possessed reduced sarcomere alignment due to the presence of less mature myofibrils relative to the NMVM tissues. Measurement of contractile stress output using our muscular thin film assay revealed that both the mES and miPS constructs generated significantly less contractile stress than the NMVM tissues. Optical mapping studies showed

that tissues constructed from all 3 cardiac cell types exhibited similar conduction velocities. However, the action potential duration at 90% of the amplitude (APD90) for mES-derived cardiac tissues was significantly shorter than that observed in NMVM tissues, whereas APD90 in miPS-derived cardiac tissues was not significantly different from either the mES or NMVM tissues. Statistical comparison of phenotype marker genes commonly used to distinguish ventricular from atrial myocytes revealed that the mES and miPS samples exhibit significantly greater expression of some atrial markers (*Myl4*, *Tbx5*, *Hcn4*) and significantly lower expression of some ventricular markers (*Pln*, *Irx4*, *Kcne1*) than the NMVM tissues. These results show that morphology and organization play an important role in the functional phenotype of myocardial tissues and allow physiologically-relevant characterization of contractile performance.

### Monitoring mouse iPS cell-derived cardiomyocytes behaviors using polypeptide multilayer-coated electrodes.

*P-Y. Wu<sup>1</sup>, C-C. Yang<sup>1</sup>, C-M. Lo<sup>2</sup>, H-S. Wang<sup>1</sup>; <sup>1</sup>Anatomy, Yang-Ming University, Taipei, Taiwan, <sup>2</sup>Biomedical Engineering, Yang-Ming University, Taipei, Taiwan*

Heart disease remains a leading cause of mortality in developed countries. Recently, one of the potential therapy approaches is to derive cardiomyocytes from induced pluripotent stem (iPS) cells. When iPS cells are cultured on gelatin-coated plates, however, the efficiency of cardiomyocyte differentiation rate is still too low. Therefore, to enhance the efficiency of iPS cell differentiation into cardiomyocytes remains challenging. In terms of molecular level, many biochemical assays are unable to describe cells without precluding their therapeutic potential at present. Electric cell-substrate impedance sensing (ECIS) is a real-time label-free noninvasive monitoring technology to characterize therapeutic potential of cells. Polyelectrolyte multilayer film is an emerging method for substrate coating to modulate cellular behaviors. It would be very useful for stabilizing the ECIS electrode coatings with these films for monitoring cell behaviors in real-time. In this study, we used the layer-by-layer assembly to build polyelectrolyte multilayer of cationic poly-L-lysine and anionic poly-L-glutamic acid on ECIS electrode arrays. After build-up, multilayer films were cross-linked with EDC/sulfo-NHS to modulate their stiffness, and were coated with gelatin to enhance cell adhesion. iPS cells were then cultured on gelatin-terminated PLL/PLGA multilayer-coated electrodes and cardiomyocyte differentiation was monitored with ECIS. The occurrences of appearing beating cardiomyocytes were observed when iPS cells were cultured on gelatin-terminated PLL/PLGA multilayer-coated electrodes and on gelatin-coated electrodes as well. In addition, the periodic fluctuations of measured impedance caused by cardiomyocyte beating were observed accordingly. Our results demonstrate that cross-linked and gelatin-coated polypeptide multilayer films can promote iPS cells toward cardiomyocyte differentiation and the cardiomyocyte beating can be monitored with impedance sensing techniques such as ECIS.

2104

### Novel 3D Porous Biodegradable Scaffolds for Stem Cell Based Tissue Regeneration.

*J-C. Wu<sup>1</sup>, K-J. Huang<sup>1</sup>, S. Li<sup>1</sup>, H. Lorenz<sup>1</sup>; <sup>1</sup>Surgery, Stanford University, Stanford, CA*

Herein we report a new method to make porous 3D scaffolds by enzyme crosslinking and microbead technology. Gelatin (Gel) conjugated with tyramine (Tyr) was synthesized as Gel-Tyr. Gel-Tyr can be crosslinked by oxidation using horseradish peroxidase to form biodegradable hydrogel scaffolds. In order to increase the porosity of the Gel-Tyr hydrogel scaffolds, we applied bead-leaching technology. Alginate microbeads with diameter of 100  $\mu\text{m}$  were mixed in the Gel-Tyr solution. After the hydrogel crosslinking was completed, alginate microbeads were dissolved by treating with the chelating reagent EDTA. The vacancy of

microbeads formed pores in the scaffold. The Gel-Tyr scaffolds were tested with bone mesenchymal stem cells (MSC). Cell viability and cell proliferation assays demonstrated good biocompatibility for MSCs adherence and proliferation. This approach provides a new straightforward way to fabricate 3D porous scaffolds for cell delivery and tissue regeneration.

2105

**Fibrillar collagen is equivalent to stiff matrix in driving marrow stromal cell differentiation into a matrix-deficient, myofibroblastic-like phenotype.**

*P. P. Dingal<sup>1</sup>, M. Raab<sup>1</sup>, P. Shah<sup>1</sup>, A. Buxboim<sup>1</sup>, J-W. Shin<sup>1</sup>, D. E. Discher<sup>1,2</sup>; <sup>1</sup>Molecular and Cell Biophysics Lab, University of Pennsylvania, Philadelphia, PA, <sup>2</sup>Cell and Molecular Biology Graduate Group, University of Pennsylvania, Philadelphia, PA*

Scars tend to be stiffer than normal tissue, which has prompted the use of stiff matrices as models of scars, but scars are also rich in fibrillar collagen-I. Here, we introduce a soft matrix embedded with distinctly fibrillar collagen type-I, and show that this is sufficient to drive bone marrow stromal cells (MSCs) into a contractile, myofibroblastic-like phenotype – ‘myo-MSCs’. These cells have been reported to minimize scarring in a unique wound healing response, exemplified by their application to myocardial infarcts. Transcriptome analysis in response to matrix rigidity points to an upregulation of genes that participate in the cellular contractile machinery, notably  $\alpha$ -smooth muscle actin (SMA), but a decreased expression of matrix protein genes for collagen types I and VI, and tenascin-C; TGF $\beta$ 1 and TGF $\beta$ RII, implicated in progressive fibrosis, are also downregulated. MSCs cultured on the embedded-fiber, soft matrix exhibit many similarities to cells on rigid substrates: higher SMA but lower collagen type I protein expression. Phosphorylation at serine-1943 (S1943) of non-muscle myosin IIA, which deactivates stress fiber assembly, is decreased on both fibrosis-like and rigid substrates but almost twice higher on a soft substrate. TGF $\beta$  is found to induce S1943 phosphorylation and SMA and collagen type I production. Surprisingly, inhibition of the TGF $\beta$  pathway perturbs matrix expression but not SMA, suggesting a response that is unique from those of myofibroblasts. Furthermore, these ‘myo-MSCs’ hint that, unlike myofibroblasts, they do not become hyper-contractile. This supports the notion that MSC engraftment into wounded tissues suppresses fibrosis, highlighting the promise of these cells in restoring normal tissue function.

2106

**Elongated Stem Cell Morphology and Matrix Stiffness Influences Lineage by Modulating Contractility.**

*L. G. Vincent<sup>1</sup>, C. Tay<sup>2</sup>, Y. Choi<sup>1</sup>, J. del Alamo<sup>3</sup>, L. Tan<sup>2</sup>, A. J. Engler<sup>1</sup>; <sup>1</sup>Bioengineering, University of California, San Diego, La Jolla, CA, <sup>2</sup>Material Science Engineering, Nanyang Technological University, Singapore, Singapore, <sup>3</sup>Mechanical and Aerospace Engineering, University of California, San Diego, La Jolla, CA*

Human adult mesenchymal stem cells (MSCs) “feel” the properties of their surrounding extracellular matrix (ECM) via myosin and differentiate in response to them, e.g. stiffness, porosity to direct cell shape, etc. Degenerative diseases, such as muscular dystrophies cause abnormal stiffening as a result of fibrosis, which misdirects stem cell lineage. When both stiffness and cell shape are present in a disparate fashion, e.g. highly elongated cells similar to muscle despite the presence of an abnormally stiff microenvironment, we hypothesized that a myosin contraction-dependent balance could induce a subset of MSCs to become myogenic despite residing in a dystrophic-like stiff niche, i.e. elongated MSCs on stiff ECM would maintain myosin activity similar to cells on normal ECM. MSCs on fibronectin patterned in shapes of varying aspect ratio but common area on polyacrylamide substrates expressed muscle specific

myosin heavy chain (MHC) most strongly on muscle like stiffness of 11 kiloPascal (kPa) and elongated patterns, i.e. 10:1 and 15:1 aspect ratio. In contrast on osteogenic-like matrices of 34 kPa, highest MHC expression corresponded to isotropic and circle shaped cells. Expression of vinculin scaled with cell shape for each stiffness tested and also with substrate stiffness but only on elongated cells. Cell strain energy as determined by traction force microscopy scaled with substrate stiffness and decreased as a function of cell elongation with isotropic cell patterns producing the highest contractile energy in contrast to our hypothesis. Interestingly, these data imply that focal adhesion formation and cell-generated traction stresses follow opposing trends as a function of cell shape. In addition these shape- and stiffness-dependent lineage changes with muscle markers and contractility-based observations suggest that muscle induction may be possible in non-permissive stiffer environments and could prove beneficial to treat fibrotic muscle diseases. Efforts to test the myogenic potential of this subpopulation of MSCs in the mdx mouse model of muscular dystrophy are ongoing.

### **Mechanically patterned matrices improve adipose-derived stem cells alignment and fusion**

Y. Choi<sup>1</sup>, L. G. Vincent<sup>1</sup>, A. R. Lee<sup>1</sup>, K. C. Kretchmer<sup>2</sup>, M. K. Dobke<sup>3</sup>, A. J. Engler<sup>1</sup>;

<sup>1</sup>Bioengineering, University of California, San Diego, La Jolla, CA, <sup>2</sup>Stem Cell Bridges Program, California State University San Marcos, San Marcos, CA, <sup>3</sup>Plastic Surgery, University of California, San Diego, La Jolla, CA

Adipose-derived stem cells (ASCs) more completely undergo extracellular matrix (ECM)-directed myogenesis than their bone marrow-derived counterparts (BMSCs) by expressing myogenic markers 40-fold higher and forming fused muscle in vitro; fusion rates, however, still produce too few myotubes to constitute a clinically viable cell source (~2%). To encourage end-on cell fusion to form aligned skeletal muscle, a mechanically patterned substrate with alternating neuronal- and muscle-like stiffness that mimicks innervated muscle may be a more physically appropriate environment. This mechanically patterned substrate or 'Zebraxis' matrix was fabricated with alternating regions of soft (neurogenic), firm (myogenic), and/or stiff matrix (fibrotic or osteogenic). ASCs, C2C12 myoblasts, and PC12 neuronal cells all differentially sorted themselves based on their stiffness preference: cardiomyocytes, myoblasts, and ASCs all durotaxed to the myogenic regions of the pattern whereas neurons had opposing behavior. With additional alignment, ASCs fused into multi-nucleated myotubes at a rate almost twice that on static hydrogels. Moreover, a great fraction of ASCs-derived myotubes underwent multiple rounds of fusion due to alignment of their cadherin-rich ends. Most importantly, the multi-nucleated myotubes that form are resistant to transdifferentiation when plated onto a stiffer matrix mimicking a more fibrotic-like stiffness. Singly nucleated ASCs are not, suggesting that additional strategies are necessary to achieve a pure myotube fraction. However differential sorting, enhanced fusion, and multiple fusion events supports using ECM to create spatially-patterned in vitro muscle for regenerative uses in fibrotic muscle diseases such as muscular dystrophy.

**A fibrous model of the tumor stromal microenvironment promotes mesenchymal morphology but not EMT in epithelial cells.**

J. S. McLane<sup>1</sup>, C. Rivet<sup>2</sup>, R. J. Gilbert<sup>2</sup>, L. A. Ligon<sup>1</sup>; <sup>1</sup>Biology, Rensselaer Polytechnic Institute, Troy, NY, <sup>2</sup>Biomedical Engineering, Rensselaer Polytechnic Institute, Troy, NY

It has become increasingly apparent that the tumor microenvironment is a key regulator of cancer progression. However, the role of the acellular, physical components of the microenvironment in tumorigenesis remains poorly understood. The stromal tissue surrounding most metastatic epithelial cancers is largely comprised of aligned, fibrous extracellular matrix primarily made up of type-I collagen. Here we developed an in vitro model system to test the effect of this aligned fibrous environment on cell morphology and behavior in the absence of physiological collagen. We grew cells on an acellular surface composed of electrospun poly-L-lactic acid (PLLA) and then examined the effect of the aligned fibrous environment upon growth rate, morphology, cytoskeletal arrangement, expression of epithelial to mesenchymal transition markers, adhesive strength and migratory capacity. We compared the phenotypically normal breast epithelial cell line MCF10A and the invasive breast cancer epithelial cell line MDA-MB-231 on three different types of substrates: common 2D culture (glass coverslips or plastic culture dishes), a thin film of PLLA (glass coverslips coated with PLLA) or PLLA fibers (glass coverslips onto which PLLA had been electrospun). Both cell types adopted a more mesenchymal morphology when grown on PLLA fibers, and this effect was exaggerated with the more metastatic MDA-MB-231. However, neither cell type underwent the changes in gene expression indicative of epithelial-mesenchymal transition (EMT), despite the changes in cell shape. Nor did they exhibit the decreased adhesive strength or increased migratory capacity typical of metastatic tumor cells. These results indicate that cells can be grown on electrospun PLLA fibers, and that they can undergo a morphological reorganization due to the topology of the substrate. However, they also suggest that changes in cell morphology alone do not promote a mesenchymal phenotype, and consequently that the aligned fibrous environment surrounding epithelial cancers does not, via topography alone, promote EMT.

2109

**CD44-based adhesion and mechanotransductive signaling on engineered hyaluronic acid matrices.**

Y. Kim<sup>1,2</sup>, B. Ananthanarayanan<sup>1</sup>, S. Kumar<sup>1,2</sup>; <sup>1</sup>Department of Bioengineering, University of California, Berkeley, Berkeley, CA, <sup>2</sup>UC Berkeley - UCSF Graduate Program in Bioengineering, Berkeley, CA

Glioblastoma multiforme is the most clinically aggressive primary brain tumor and is characterized by diffuse infiltration of glioma cells into brain parenchyma, which is rich in the glycosaminoglycan hyaluronic acid (HA). We present new evidence that the HA receptor CD44 may be responsible for supporting integrin-based adhesion and mechanotransduction of glioma cells. Additionally, under certain conditions, glioma cells are sensitive to the stiffness of HA-based matrices not functionalized with adhesive peptides, suggesting that HA receptors themselves are involved in sensing of the biophysical environment. While comparatively much is known about cell-matrix mechanosensing through integrins and the role it may play in tumor progression, our findings reveal a previously under-appreciated role of CD44 and possibly other HA-specific receptors in this process. These findings have broad implications for the field's fundamental understanding of how glioma cells interact with the tumor microenvironment and may suggest new therapeutic strategies.

2110

**In vivo surface reaction and microstructural degradation of hydroxyapatite in the dog.**

J. Lee<sup>1</sup>, D. Seo<sup>2</sup>; <sup>1</sup>Advanced Materials Engineering, Chosun University, Gwangju, Korea, <sup>2</sup>Jeonnam Technopark, Suncheon, Korea

Hydroxyapatite (HA) is widely used as a bioactive ceramics since it forms a chemical bonding to bone. The disadvantage of this material is its poor mechanical properties. In this research, the surface dissolution and disintegration of HA in the dog have been studied and the mechanism by which phase pure HA dissolves in vivo was investigated. The microstructural interactions of HA implant in vivo. is similar to the behaviour of in vitro. Biological properties of HA in in vivo are affected grain boundary dissolution followed by microstructural disintegration. It was caused by grain boundary dissolution initiated at the implant surface extended into bulk following these paths. This kind of dissolution process apparently evidenced grain boundary dissolving causes particle generation. This results indicates that long-term bone in-growth and mechanical properties could be dramatically decreased.

**Integrin involvement in the cell response to matrix-bound BMP2.**

L. Fourel<sup>1</sup>, R. Guillo<sup>2</sup>, E. Faurobert<sup>3</sup>, K. Ren<sup>2</sup>, E. Planus<sup>3</sup>, C. Picart<sup>2</sup>, C. Albiges-Rizo<sup>3</sup>; <sup>1</sup>Cnrs Grenoble Institute of Technology Inserm Ujf, Grenoble, France, <sup>2</sup>CNRS Grenoble Institute of Technology, Grenoble, France, <sup>3</sup>Cnrs Inserm Ujf, Grenoble, France

We have explored the concept that extracellular matrix proteins bind and present growth factors as “matrix-bound” ligands. As extracellular matrix is crucial for confinement by limiting diffusive range, accessibility, and ligand signaling direction, we have designed a biomaterial offering the characteristics of a permissive niche by combining growth factor presentation with appropriate mechanical properties. The BMP2-containing soft films appear as an appropriate substrate to further investigate the specificity of BMP2 signaling and to decipher the associated signaling cascade. Our results support that signaling can be enhanced by the spatial organization of different type of receptors and that receptor cooperativity is necessary for the achievement of a coordinated cell response leading ultimately to cell differentiation. We show that cross-talk between BMP2 receptors and integrins is required to drive Smad signaling through specific reorganization of the actin cytoskeleton.

**Tuning cellular mechanics and motility through genetic manipulation of Rho GTPase and myosin activity.**

J. L. MacKay<sup>1</sup>, S. Kumar<sup>2</sup>; <sup>1</sup>Chemical and Biomolecular Engineering, University of California, Berkeley, Berkeley, CA, <sup>2</sup>Bioengineering, University of California, Berkeley, Berkeley, CA

The structural and mechanical properties of cells such as cell size, shape, and stiffness have recently been recognized as important regulators of cell behavior. For example, cells cultured on small areas of adhesive extracellular matrix (ECM) grow slowly and apoptose more frequently than cells spread on large areas (Chen et al., 1997 *Science* **276**: 1425-1428), and cells confined to one-dimensional lines of ECM elongate their cell bodies and can migrate faster than cells cultured on standard unconfined two-dimensional substrates (Doyle et al., 2009 *J Cell Biol.* **184**: 481-490). While there are many strategies to indirectly control such cell behaviors through manipulation of the extracellular environment, there is a marked lack of strategies for controlling these behaviors in more direct and precise ways. To address this unmet need, we have developed a genetic strategy for directly tuning the mechanical properties of cells. Specifically, we have placed genetic mutants of intracellular mechanotransductive signaling

proteins, including RhoA GTPase and myosin light chain kinase (MLCK), under a tetracycline-repressible promoter and introduced a single copy of these constructs into human glioblastoma cells using viral gene delivery. By expressing these proteins from a tetracycline-repressible promoter, we can vary their expression by simply changing the concentration of tetracycline in the cell culture medium. RhoA and MLCK are both known to activate myosin II, which is the motor protein responsible for cellular force generation, and with constitutively active (CA) mutants of these proteins, we demonstrate that we can modulate cytoskeletal architecture, traction force generation, and cellular stiffness in a graded fashion. Moreover, by reversibly switching expression of CA RhoA on and off over time (by adding and removing tetracycline), we can dynamically control cell spreading, migration, and ECM remodeling. We believe that this strategy will serve as a valuable tool for developing quantitative relationships between intracellular signaling pathways, cellular physical properties, and complex cell behaviors. Furthermore, such precise control over cell behavior could allow us to directly control how cells physically interact with their microenvironment and could potentially allow one to “re-engineer” how cells respond to ECM properties, which would be particularly useful in tissue engineering applications that interface cells with synthetic materials.

2113

**Structured substrates for the investigation of shape-mediated behavior.**

*K. E. Broaders<sup>1</sup>, Z. Gartner<sup>1</sup>; <sup>1</sup>Pharmaceutical Chemistry, UCSF, San Francisco, CA*

The communal behavior of cells in tissues is influenced by the physical arrangement of matrix, cells, and diffusible factors in the microenvironment. The phenotypic dependence of cells on their surrounding environment is important in the context of tumorigenesis, where an initially organized tissue is disrupted and transitions to a less structured but nonetheless reorganized cancerous "pseudo-organ". It has long been appreciated that genetic injury is, in many cases, not sufficient to elicit tumor growth. Furthermore, disrupting tissue integrity has been shown to enable tumor growth in cases where no growth is observed within a formed tissue. Thus, an important question is: what kinds of structural perturbations are involved the breakdown of tissue homeostasis? In this work, I begin an investigation of the effects of tissue structure on mechanical integration on the tissue integrity. To do this, I fashion substrates from polydimethylsiloxane (PDMS), a biocompatible silicone rubber, by casting them on photochemically patterned curved ridges. The resulting channels and intervening flat substrate portions range between 25 and 500  $\mu\text{m}$  in width and have a depth of 50  $\mu\text{m}$ . These PDMS substrates can be made amenable to cell culture by plasma treating them and treating with collagen I. When seeded at high concentration with Madin Darby canine kidney (MDCK) cells, a model epithelial cell line, confluence is achieved within 1 d for all geometrical configurations. Interestingly, over the course of 5 days, cells were observed to clear out of the channels or form bridges over the channels. This effect is not observed when actomyosin activity is inhibited with either blebbistatin or ML-7, indicating that tissue contractility is necessary for the observed clearance to occur. Additionally, decreasing the area of non-channel flat portions of the substrate decreases the cell-clearing phenomenon. This may indicate that the observed clearance of cells from areas of negative curvature is the result of pulling by mechanically integrated cells on a continuous flat zone of the substrate. Although the system investigated is artificial in nature, it may have strong implications for the maintenance of homeostasis in healthy tissues and the steps necessary or sufficient to disrupt it. In addition to tumorigenesis, diseases of epithelial tissues in general often have characteristic structural components such as blistering or flattening of structures. Understanding what degrees of structural perturbation are sufficient to disrupt mechanical integration or initiate tissue reorganization may be important to understanding and eventually treating these illnesses.

**Elucidating the mechanism of durotaxis using a novel cell-on-a-chip assay.**

S. Wong<sup>1</sup>, W-H. Guo<sup>1</sup>, Y-L. Wang<sup>1</sup>; <sup>1</sup>Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA

Rigidity sensing is widely recognized as an important element of wound healing, tissue engineering, and cancer treatment. However, it has been challenging to study rigidity sensing experimentally due to difficulties in locating a sufficient number of isolated cells at a sharp rigidity border. We sought to address this problem by developing a highly efficient model experimental system that confines cells to a simulated rigidity border. To this end, we fabricated a micropatterned composite material of photoresist islands grafted on top of non-adhesive polyacrylamide hydrogels. The design consists of one large adhesive island, which provides the rigid domain, juxtaposed with two rows of small islands that provide the soft domain when grafted on soft gels, due to the minimal force required to deform this region. The objective of the present study was to analyze conditions that cause defects in rigidity sensing using this novel approach. As expected, the majority of NIH 3T3 fibroblasts were confined to the large island after culturing overnight on the composite substrate with a soft underlying hydrogel, while cells on composite substrates with a stiff underlying hydrogel were able to occupy most of the small islands. Interestingly, FAK knockout cells (FAK <sup>-/-</sup>) and cells treated with nocodazole, both shown to have elevated activities of the small GTPase Rho, were able to spread across most of the islands regardless of the stiffness of the underlying hydrogel. In addition, treatment of FAK <sup>+/+</sup> cells with a Rho activator was sufficient to cause these cells to spread across the rigidity border. Cells expressing F397-FAK, a mutation preventing autophosphorylation without increasing Rho activities, exhibited a normal response comparable to control cells. In summary, our novel model experimental system allowed highly efficient analyses of rigidity sensing for both motile and non-motile cells. Our results indicate that the regulation of Rho activity is critical for rigidity sensing, and we propose that the loss of Rho regulation is responsible for the rigidity sensing defect observed in FAK<sup>-/-</sup> cells and in cells depleted of microtubules.

**Analysis of cellular responses of MC3T3-E1 mouse osteoblast-like cells to rough surfaced substrates.**

T. Saito<sup>1</sup>, K. Teraoka<sup>1</sup>; <sup>1</sup>Advanced Manufacturing Research Institute, National Institute of Advanced Industrial Science and Technology, Nagoya, Japan

Precise understandings of cell-material interactions are essential for designing biomaterials for clinical applications. It has been recognized that the behavior of cell adhesion, proliferation and differentiation on materials mainly depends on their surface physico-chemical properties including hydrophilicity, roughness, texture, and morphology. In this study, in order to obtain better understandings of the regulatory mechanisms of osteoblast responses to the surface roughness, we focused on the cellular responses such as adhesion, morphology, and proliferation of mouse osteoblast-like MC3T3-E1 cells plated and cultured on the rough-surfaced substrates, and investigated how these early responses influence the subsequent cellular development of osteoblastic differentiation and mineralization. The cellular responses of MC3T3-E1 cells to the surface roughness were examined in the sequential events of cell adhesion, proliferation, differentiation, and mineralization. The MC3T3-E1 cells were plated and cultured on sandblasted borosilicate glass slideslips with different surface roughness. DNA synthesis at day 1 after plating and the cell number at day 5 significantly decreased as the surface roughness increased. The suppressed cell proliferation on the rough-surfaced substrates, closely related to the round cell morphology, caused underdeveloped cell-cell contacts via the gap junction due to the low population of neighboring cells. Expressions of the

representative osteoblastic genes at day 14, alkaline phosphatase activity at day 21, and mineralization at day 28 were markedly reduced on the rough-surfaced substrates. These results clearly indicated that the reduced cell differentiation and mineralization resulted from the early cellular responses of the suppressed cell proliferation depending on the surface roughness and the consequent poor intercellular communication. Furthermore, specific early changes in the gene expression profiles dependent on the surface roughness were analyzed using a mouse DNA chip in order to obtain a better understanding of the regulatory mechanism of the early cellular responses stimulated by the surface roughness. The specific changes in the early gene expression profiles at day 1, depending on the surface roughness, were examined by a large-scale analysis of the gene expression using a mouse DNA chip. As the results, the ribosomal protein S6 kinase polypeptide 1 gene, known to be a cell growth-related gene involved in the PI3-kinase/Akt pathway, was found to be the most down-regulated among the 4277 screened genes by the DNA chip analysis.

### **Nanometer Scale Surface Protein Patterns for Spatially Controlled Cell Adhesion.**

*D. Vurmaz<sup>1</sup>, G. Oyman<sup>1</sup>, W. F. Heinz<sup>2</sup>, J. L. Werbin<sup>2</sup>, J. H. Hoh<sup>2</sup>, D. B. Haviland<sup>3</sup>, D. Pesen Okvur<sup>1</sup>; <sup>1</sup>Izmir Institute of Technology, Izmir, Turkey, <sup>2</sup>Johns Hopkins University School of Medicine, Baltimore, MD, <sup>3</sup>KTH Royal Institute of Technology, Stockholm, Sweden*

Cell adhesion is an important process in both health and disease states such as wound healing and cancer as well as tissue engineering and biosensor fabrication. Electron beam lithography (EBL) is widely used in applied physics to fabricate integrated circuits, waveguides and photomasks; due to its nanometer scale resolution, ability to pattern large areas and design flexibility. We have developed an EBL-based approach to fabricate surface patterns of proteins at the nanometer scale in order to study cell adhesion. We used atomic force, scanning electron and immunofluorescence microscopies to characterize the EBL generated protein patterns and cell adhesion on them. We showed that proteins respond to a focused electron beam and can directly be used as EBL resists without the need for conventional polymers. When we exposed a silicon surface with immobilized protein of interest to a highly focused electron beam with doses ranging from 0.01 to 100 pC, the exposed areas were 'activated' and a second protein of interest selectively bound to these areas in a dose dependent manner as detected by antibody staining. Accelerating voltage dependence indicated that nanometer scale protein patterns are formed by both back and forward scattered electrons, and two dose thresholds define the formation and shape of the patterns (dot or ring). We were able to pattern (i) cell adhesion promoting proteins such as fibronectin or laminin on an anti-cell adhesion background of BSA or K-casein, (ii) hybrid surfaces with laminin nanopatterns on a fibronectin background, with smallest feature size of 100 nm. Furthermore, we demonstrated biofunctionality at the cellular level where fibroblasts, endothelial and epithelial cells formed pattern specific focal adhesions and organized their immediate cytoskeleton accordingly. Our results suggested that a minimum of  $\approx 40$  fibronectin molecules is required for a cell to form a focal adhesion. Finally, we successfully adopted our EBL based approach for patterning proteins on indium tin oxide (ITO) coated glass surfaces, which, unlike silicon, are transparent and thus make various downstream light microscopy applications possible.

**Nanostructured conducting polymer devices for tissue engineering.**

*E. Moyer<sup>1</sup>, E. Ismailova<sup>1</sup>, A. Hama<sup>1</sup>, I. Ozerov<sup>2</sup>, M. Hanbücken<sup>2</sup>, G. G. Malliaras<sup>1</sup>, R. M. Owens<sup>1</sup>; <sup>1</sup>Bioelectronics, Ecole des Mines de St. Etienne, Gardanne, France, <sup>2</sup>UMR 7325, Université Aix-Marseille; CNRS, Marseille, France*

The ability to control the microenvironment around a cell offers tremendous value in understanding life processes. Cell–cell and cell-microenvironment interactions regulate cell behavior, however, the underlying biological mechanisms remain poorly understood. Cells cooperate with their environment by interacting with neighbouring cells, with their surrounding extracellular matrix and by communicating through secreted soluble factors. Typically, these interactions are well-coordinated, but perturbation of the underlying cellular and molecular interplay may affect intracellular signalling pathways, immunological reactions and tissue homeostasis.

The triggering of the eventual fate of the cell is mediated through chemical cues from the adsorbed proteins and physical cues such as surface energy, stiffness and topography. For example, it has recently been shown that a gradient of surface energy, obtained by applying a bias to conducting polymer, can lead to a gradient in cell density [1]. It is also known that nano-topography [2] and stiffness variations [3] affect cell proliferation, death, differentiation or migration. Interestingly, stiffness modifications can be induced by nano-topography, the ability of nano-pillars to bend defining an effective stiffness [4]. We have achieved the fabrication of such nanotopography by fabricating pores or pillars in conducting polymers over large areas, using porous aluminum oxide membranes as a template. This enables the development of electrically active devices combining topography, stiffness and surface energy control to investigate cell-substrate interactions and cell migration. We report on the fabrication of such devices and show the results of their interactions with cells.

**Nanophysical properties of scaffolds induce cerebral cortical astrocyte response.**

*V. M. Ayres<sup>1</sup>, V. M. Tiryaki<sup>1</sup>, K. Xie<sup>1</sup>, I. Ahmed<sup>2</sup>, D. I. Shreiber<sup>2</sup>; <sup>1</sup>Department of Electrical & Computer Engineering, Michigan State University, East Lansing, MI, <sup>2</sup>Department of Biomedical Engineering, Rutgers, The State University of New Jersey, Piscataway, NJ*

Astrocytes cultured on electrospun polyamide nanofibers whose nanophysical properties may reproduce key aspects of native extracellular matrices have demonstrated promising results in both in-vitro and in-vivo situations. In vitro, astrocytes cultured on nanofibrillar scaffolds assumed morphologies that appeared to recapitulate those observed in native tissues and also demonstrated increased neurite outgrowth by co-cultured neurons. In vivo, the same scaffolds introduced into spinal cord wound sites promoted accelerated hindlimb recovery measured by standardized observational scoring with aligned and fasciculated axon development and revascularization throughout wound sites. Furthermore, low levels of astrocytic scarring were observed in comparison to injury-only controls. The in-vitro and in-vivo results suggest that

nanofibrillar scaffolds could induce preferential astrocyte differentiation leading to minimized glial scar formation, which has positive implications for improved treatment options for central nervous system injury repairs.

The present investigation examined the hypothesis that external physical cues of the nanofibrillar scaffolds can trigger specific signaling cascades with morphological consequences. The nanophysical cues of surface polarity, surface charge and surface roughness were investigated in this study. The morphological response of cerebral cortical astrocytes to nanophysical properties of the nanofibrillar scaffolds was investigated at high-resolution using AFM. The three-dimensional capability of AFM was also used to characterize cell spreading. An initial study of the corresponding activation of GTPase upstream regulators was performed using immunocytochemistry, focusing on investigation of the main GTPase regulators for the observed morphological responses: filopodia, lamellipodia, stress fiber formation, and stellation. The results support the hypothesis that the nanophysical extracellular environment can trigger preferential activation of members of the Rho GTPase family with demonstrable morphological consequences for cerebral cortical astrocytes.

### **Microenvironmental Stiffness and Cell Shape Co-Regulate Work Output of Cardiac Myocytes.**

*M. L. McCain<sup>1</sup>, P. H. Campbell<sup>1</sup>, K. K. Parker<sup>1</sup>; <sup>1</sup>Wyss Institute for Biologically Inspired Engineering, School of Engineering and Applied Sciences, Harvard University, Cambridge, MA*

Disease progression in the heart is associated with marked extracellular and intracellular structural remodeling, which compromises the functional output of the heart. For example, many cardiomyopathies are characterized by increased tissue stiffness due to extracellular matrix deposition and fibrosis. On the cellular level, changes in myocyte aspect ratio commonly result from different pathological states. For example, concentric hypertrophy, which is caused by increased ventricular afterload, decreases myocyte aspect ratio from approximately 7:1 to 5:1. We hypothesized that remodeling of cell shape during concentric hypertrophy optimizes force generation in stiff pathological microenvironments. To test this, we performed traction force microscopy on isolated neonatal rat ventricular myocytes cultured on polyacrylamide gels with physiological (13 kPa) and pathological (90 kPa) stiffness. Gels were micropatterned with fibronectin rectangles ranging in aspect ratio from 2:1 to 12:1 to mimic myocyte shapes characteristic of health and disease. Myocytes on pathological substrates generated more force, but not more work, than myocytes on physiological substrates. On physiological substrates, peak systolic work generation was optimized at aspect ratio 8:1. Conversely, on pathological substrates, peak systolic work was optimized at aspect ratio 2:1. Time to peak systole was similar on both substrates, but relaxation time was prolonged on pathological substrates, suggesting that increased microenvironmental stiffness could be an important contributing factor to diastolic dysfunction. Actin alignment increased with aspect ratio, but was not a function of substrate stiffness. These results suggest that cardiac myocytes remodel their shape to optimize systolic work output in response to changes in the compliance of the microenvironment and reveal potentially important relationships between extrinsic mechanical factors and intrinsic structure-function relationships.

**Substratum topography alters YAP-mediated mechanotransduction response in corneal epithelial cells.**

V. Raghunathan<sup>1</sup>, B. Dreier<sup>1</sup>, J. T. Morgan<sup>1</sup>, P. Russell<sup>1</sup>, C. J. Murphy<sup>1,2</sup>; <sup>1</sup>Dept of Surgical and Radiological Sciences, School of Veterinary Medicine, University of California Davis, Davis, CA, <sup>2</sup>Dept of Ophthalmology, School of Medicine, University of California Davis, Davis, CA

Corneal wound healing is influenced by the extracellular environment both through soluble signals and from biophysical cues such as topography and matrix stiffness. These cues profoundly influence phenotypic characteristics of cells including adhesion, migration, shape, size and proliferation. These changes are mediated by activation/inhibition of specific signaling pathways. Human corneal epithelial cells have been demonstrated to remodel their cytoskeleton and orient differentially on anisotropically ordered topographically patterned substrates. However, there still remains a considerable knowledge gap in understanding the role of cell signaling pathways in response to biophysical cuing and mechanotransduction. YAP (Yes-associated protein) and TAZ (WWTR1; transcriptional coactivator with PDZ-binding motif), two important signaling molecules of the Hippo pathway, have recently been implicated as nuclear relays to mechanical cues sensed by cells. We investigated the effects of nano through micron scale topographic features in altering the YAP/TAZ pathway in human corneal epithelial cells. Primary and immortalized (hTERT) corneal epithelial cells (hTCEpi) were cultured on planar or topographically patterned substrates with biologically relevant dimensions (pitch sizes of 400, 1400 and 4000 nm; pitch = ridge width + groove width) for 12 hr. The role of substratum topography in modulating gene expression following (a) transcriptional activation of YAP via inhibition of HSP90, or (b) knockdown of YAP/TAZ in hTCEpi cells was investigated. RNA was isolated and the expression of YAP, TAZ, 14-3-3 $\sigma$  and Transforming Growth Factor beta-2 (TGF $\beta$ 2) was determined by qPCR. Alignment of cells to topography was determined after knockdown.

A differential response to topographic cues was observed. Corneal epithelial cells were most responsive to (biomimetic) 400 nm pitch topography with up-regulation in YAP, 14-3-3 $\sigma$ , and TGF $\beta$ 2. Inhibition of HSP90 induced translocation of YAP to the nucleus implying transcriptional activation. Translocation of YAP to the nucleus was associated with increases in YAP, CTGF, and TGF $\beta$ 2; this expression was independent of topographic cues. In contrast, knockdown of YAP resulted in significantly lower expression of CTGF but not TGF $\beta$ 2. Interestingly, YAP, CTGF and TGF $\beta$ 2 were significantly upregulated with increasing pitch after knockdown of TAZ. Also, TAZ knockdown led to a significantly greater number of cells aligning parallel with the long axis of underlying ridges and grooves on pitch sizes greater than 1600 nm compared with control or YAP knockdown cells.

The biophysical attributes of the microenvironment of corneal cells cause changes in cell morphology and are capable of altering cell signaling. Our results strongly suggest that YAP, TAZ, 14-3-3 $\sigma$  and TGF $\beta$ 2 play fundamental roles in regulating how corneal cells respond to their biophysical microenvironment.

2121

### Substratum Compliance and Latrunculin B Regulate the Gene Expression of YAP/TAZ in Human Trabecular Meshwork Cells.

S. M. Thomasy<sup>1</sup>, J. A. Wood<sup>1</sup>, C. J. Murphy<sup>1</sup>, P. Russell<sup>1</sup>; <sup>1</sup>University of California, Davis, Davis, CA

**Objective:** The compliance of the human trabecular meshwork (HTM) has been shown to dramatically stiffen in glaucomatous patients. Latrunculin-B (Lat-B) is an actin cytoskeleton disruptor that directly targets HTM cells and is currently in clinical trials as a treatment for glaucoma. The purpose of this study was to determine the impact of substratum compliance and Lat-B, on the expression of the mechanotransducers, Yes-associated protein (YAP) and transcriptional co-activator with PDZ-binding domain (TAZ), in HTM cells. In addition, the effects of substratum compliance and Lat-B on the expression of 14-3-3 $\sigma$  (a protein important in YAP/TAZ degradation), and connective tissue growth factor (CTGF), a gene that is highly regulated by YAP, were also examined.

**Methods:** Primary HTM cells were cultured on hydrogels possessing compliance values mimicking those found in normal (5 kPa) and glaucomatous (75 kPa) meshworks, or on tissue culture polystyrene (TCP >1 GPa) as a control substrate. Cells were treated with 2.0  $\mu$ M Lat-B in DMSO or DMSO alone. RT-PCR was used to determine the impact of substratum stiffness and/or Lat-B treatment on the expression of YAP, TAZ, 14-3-3 $\sigma$  and CTGF.

**Results:** Substratum compliance modulated YAP and TAZ mRNA expression such that both genes were upregulated on the 75 kPa hydrogels in comparison to the 5 kPa hydrogels and TCP. Treatment with Lat-B resulted in a marked decrease of YAP and TAZ mRNA on the 75 kPa hydrogels. Lat-B treatment of HTM cells on the 75 kPa hydrogels also increased 14-3-3 $\sigma$  mRNA. In addition, Lat-B treatment decreased CTGF mRNA on the 75 kPa hydrogels.

**Conclusions:** Substratum stiffness modulates YAP/TAZ activity which then may alter the expression of ECM proteins important in glaucoma. In addition to disrupting the actin cytoskeleton, Lat-B may decrease intraocular pressure by modulating 14-3-3 $\sigma$ . Therefore, YAP and TAZ may represent new therapeutic targets in the treatment of glaucoma.

### Mechanotransduction in Trabecular Meshwork Cells and the Progression of Glaucoma.

P. Russell<sup>1</sup>, J. Morgan<sup>1</sup>, C. Reilly<sup>1</sup>, V. Raghunathan<sup>1</sup>, C. J. Murphy<sup>1</sup>; <sup>1</sup>University of California, Davis, Davis, CA

**Background and Aims:** Two Yorkie homologues, YAP1 and TAZ, have been identified as important mechanotransducers of extracellular cues to the cell nucleus. These proteins relay changes from the extracellular matrix to induce changes in gene and protein expression. Both proteins are co-activator of transcription factors. The trabecular meshwork in the outflow pathway of aqueous humor is thought to be the site of regulation of intraocular pressure. YAP has been shown to increase the levels of TGF- $\beta$ , CTGF, transglutaminase 2, serpine 1 and thrombospondin, proteins shown to increase in glaucoma or when human trabecular meshwork (HTM) cells are treated with dexamethasone (DEX). Since the glaucomatous meshwork is stiffer than the normal meshwork, we wished to determine how changes in matrix stiffness would influence YAP and TAZ and the expression of genes in HTM cells. Both YAP and TAZ can be phosphorylated in the cytoplasm. After phosphorylation at specific sites, the protein 14-3-3 $\sigma$  can bind to them and mark them for degradation. We also wished to determine how substrate stiffness would influence 14-3-3 $\sigma$ .

**Methods:** Immunohistochemical staining for YAP and TAZ was done on donor HTM. HTM cells from normal donors were cultured on hydrogels with stiffnesses of 5 kPa (mimicking normal

HTM) and 75 kPa (mimicking glaucomatous HTM). The changes in expression of YAP and TAZ on the different substrates were determined. Levels of mRNA for CTGF and 14-3-3 $\sigma$  were measured.

**Results:** YAP and TAZ were present in the HTM cells in sections from donor corneoscleral rims. Both YAP and TAZ were present in the cytoplasm as well as the nucleus of HTM cells. TAZ mRNA expression was upregulated on stiffer hydrogels; however, YAP was down regulated. The amount of 14-3-3 $\sigma$  was lower on the stiffer hydrogels. The level of CTGF mRNA was higher on both hydrogels after DEX treatment.

**Conclusions:** The mechanotransducers YAP and TAZ may play key roles in HTM cells particularly when the extracellular matrix becomes stiffer as it does in glaucoma. These proteins have the ability to cause upregulation of several of the proteins found to be increased in glaucoma and may influence the progression of disease.

#### **A plate-and-cone bioreactor method to measure cell attachment on artificial graft material.**

*L. Dreyer<sup>1</sup>, H. Zernetsch<sup>2</sup>, A. Ngezahayo<sup>1</sup>, B. Glasmacher<sup>2</sup>; <sup>1</sup>Institute for Biophysics, Leibniz Universität, Hannover, Germany, <sup>2</sup>Institute for Multiphase Processes, Leibniz Universität, Hannover, Germany*

Artificial vascular implants with diameters smaller than 6 mm have a high risk of occlusion, caused by early thrombosis or long-term intimal hyperplasia. As the availability of autologous grafts is often limited, there is a high demand for improving artificial prostheses. As a solution, a confluent inner lining of endothelial cells could (i) avoid the blood contact of the material, (ii) prevent hyperplasia and therefore offers a solution for improving vessel grafts. Currently, there is no biomaterial in clinical use that is designed for endothelial cell attachment [Ravi et al., 2010]. Electrospun polymer fiber mats offer a promise to fulfill both the mechanical properties for a surgically usable implant and the topographic surface structure for optimal cell attachment. To test different surface topologies and material compositions for the attachment of endothelial cells, we applied the principle of a plate-and-cone rheometer as a bioreactor. Here, a uniform wall shear stress up to 10 dyn/cm<sup>2</sup> can be applied on a defined, ring-shaped region of a culture dish bottom that has been coated by the test materials and cells seeded. To obtain statistical relevant data, six cone-and-plate systems can be used in parallel, either inducing the same or varying shear rates, adjusted by the rotational speed of the cones. The effects on cell proliferation, migration and cell morphology are monitored during stimulation using a laser scanning microscope. Flow conditions of the reactor have been shown to be laminar with uniform wall shear stress on a defined area.

In our experiments, endothelial cells (GFP-labeled HPMECs) were seeded on protein-coated PCL/PLGA (polycaprolactone/polylactic-co-glycolic acid) fiber mats with 1.4 to 1.7  $\mu$ m mean fiber diameter (95% CI) resulting in a porosity of 80%  $\pm$  2%. As coating proteins, collagen, fibronectin or gelatine were used. Cell proliferation could be quantified and migration could be observed using live cell imaging. Collagen-coated fiber mats showed best results for cellular attachment under shear stresses of 10 dyn/cm<sup>2</sup>. Modifications of three-dimensional fiber structure and surface topology are ongoing to achieve a confluent lining of endothelial cells.

## Focal Adhesions and Invadosomes

2124

### Specific protein-interactions regulate the three-dimensional nanoscale organization of vinculin within focal adhesions.

L. B. Case<sup>1,2</sup>, G. Shtengel<sup>3</sup>, H. F. Hess<sup>3</sup>, C. M. Waterman<sup>1</sup>; <sup>1</sup>NHLBI, NIH, Bethesda, MD, <sup>2</sup>Univeristy of North Carolina, Chapel Hill, NC, <sup>3</sup>HHMI Janelia Farm, Ashburn, VA

Vinculin is a ubiquitously expressed protein that localizes to focal adhesions (FAs) in a myosin II-dependent manner, and is important for regulating FA functions including adhesion strength, actin dynamics, and signaling. Vinculin has at least 10 putative binding partners at FAs including actin, talin, Arp2/3, and paxillin. Thus, vinculin may regulate specific FA functions via interaction with particular binding partners. Interferometric photoactivated localization microscopy ("iPALM") is a superresolution light microscopy technique that allows for 20nm lateral resolution and 10nm axial resolution. We previously used iPALM to show that FAs have a conserved stratified structure. We are currently using iPALM to test the hypothesis that the vertical position of vinculin within the FA is dictated by specific protein-protein interactions that modulate its function in reinforcing FA strength, signaling, and regulating actin dynamics. We have focused first on vinculin's interactions with paxillin and actin. The vinculin-paxillin interaction requires FAK-mediated phosphorylation of paxillin, and the vinculin-actin interaction requires vinculin activation. We showed previously that paxillin is located ~5nm axially from the plasma membrane within FAs, while actin is located 30-40nm higher, suggesting that two spatially and functionally distinct populations of vinculin may exist in FAs. Here we found that phosphomimic mutations in paxillin promote vinculin accumulation near the plasma membrane, while FAK inhibition or non-phosphorylatable paxillin mutants shift vinculin localization 30-40nm higher within FAs. We conclude that vinculin interacts with phospho-paxillin near the plasma membrane within FAs. Furthermore, we show that iPALM allows high-resolution measurements of changes in vinculin's 3D localization within the FA structure, suggesting that iPALM is a valid technique to understand the contribution of vinculin binding interactions to vinculin's nanoscale organization and function within FAs. We are currently mapping the 3D nanoscale organization of various vinculin mutants and correlating this nanoscale organization with vinculin's FA function.

### Vinculin interaction with activated $\alpha$ -actinin.

H. Shams<sup>1</sup>; <sup>1</sup>Applied Science and Technology, UC Berkeley, Berkeley, CA

Vinculin and  $\alpha$ -actinin are two major focal adhesion players, whose interaction entails several important aspects in cytoskeletal reorganization at the adhesion sites. Vinculin is one the most crucial proteins functioning in both formation and maturation of focal adhesions. It binds actin in its activated conformation. The structure is composed of a head (Vh) and a tail domain (Vt) that are connected by a neck region. The head and tail domains are associated in the inhibited conformation covering the actin binding domains. It has been postulated that interaction with some binding partners such as talin and  $\alpha$ -actinin induces critical conformational changes in the vinculin head domain that leads to activating the molecule for actin binding.  $\alpha$ -Actinin acts as a cross-linker for both parallel and anti-parallel F-actin. This rod-shaped molecule is an anti-parallel homodimer. Each monomer has an actin binding domain at the N-terminal that is followed by four spectrin repeats (R1-R4) and a CaM domain at the C-terminal. Vinculin binding site ( $\alpha$ VBS) is placed in R4 and is shown to be inhibited in the full-length structure of the

molecule available in the Protein Data bank. The hydrophobic interactions stabilize  $\alpha$ VBS in the rod domain in that structure.

In a previous study, we have successfully achieved the activated structure of  $\alpha$ -actinin for vinculin binding that was used in the present study. The full length vinculin molecule was prepared using homology modeling. The head domain was placed in the vicinity of  $\alpha$ VBS in such a way that the closest atoms are farther than 10 Angstroms. We used all-atom molecular dynamics methods to model the interaction between  $\alpha$ -actinin and vinculin. Explicit water model was used to enhance the accuracy. Our results showed that  $\alpha$ -actinin has a high affinity for vinculin binding. The helices in the vinculin head domain rearranged their conformation to allow for  $\alpha$ VBS insertion. The energy and root mean square deviation (RMSD) plots illustrated a stable interaction. Our MD simulations were used to explore the effect of this binding on vinculin activation. The vinculin head domain was monitored and several conformational changes were detected during the trajectory. Specifically, the interface between head and tail domains weakened but not completely dissociated throughout the equilibration simulation. Finally, the key interactions in stabilizing the inhibited conformation of vinculin were mapped to later be used for therapeutic applications.

Migrating cells form integrin-based focal adhesions (FA) near their leading edges in association with rapid filamentous actin (F-actin) assembly and retrograde flow. How F-actin flow is coupled to FA is unclear, and thus it is not known how F-actin engagement to FA regulates actin cytoskeleton and FA dynamics. We analyzed the role of vinculin in integrating FA and actin dynamics by vinculin gene disruption in primary fibroblasts. Vinculin promotes nascent FA formation and turnover in lamellipodia, establishes a lamellipodium-lamellum border and engages F-actin flow in maturing FA to generate high ECM traction forces. Characterization of a vinculin point mutation that specifically disrupts F-actin binding shows that vinculin F-actin interaction is critical for these cellular functions. However, FA maturation rate correlates with F-actin flow rate independently of vinculin. Thus, vinculin functions as molecular clutch organizing leading edge F-actin, generating ECM traction and promoting FA formation and turnover, while FA maturation is regulated by F-actin flow independently of vinculin.

**CAS interacts with vinculin to control mechanosensing and focal adhesion dynamics in cells.**

*R. Janostiak<sup>1</sup>, D. Rosel<sup>1</sup>, V. Auernheimer<sup>2</sup>, Z. Tatarova<sup>1</sup>, L. Lautscham<sup>2</sup>, T. Dey<sup>2</sup>, P. Jedelsky<sup>1</sup>, W. H. Goldmann<sup>2</sup>, B. Fabry<sup>2</sup>, J. Brabek<sup>1</sup>; <sup>1</sup>Department of Cell Biology, Faculty of Science, Charles University, Prague, Czech Republic, <sup>2</sup>Biophysics Group, Department of Physics, University of Erlangen-Nuremberg, Erlangen, Germany*

Focal adhesions (FAs) are cellular structures through which both mechanical forces and regulatory signals are transmitted. FA-associated proteins, CAS and vinculin were both independently shown to be crucial for cells to transmit mechanical forces and generate cytoskeletal tension. We identified a novel direct interaction between CAS and vinculin, independent of focal adhesion kinase (FAK). This interaction is mediated by the CAS SH3 domain and the proline-rich sequence in the hinge region of vinculin. We found that CAS localization in FAs is partially dependent on vinculin and that CAS-vinculin association is required for stretch-induced phosphorylation of the CAS substrate Y410 domain and ERK1/2 phosphorylation. Moreover, CAS-vinculin interaction significantly affects the dynamics of CAS and vinculin within FAs as well as the size of adhesion structures, but not the cellular adhesion strength. Finally, disruption of CAS binding to vinculin negatively impacts cell stiffness and traction force generation, but increases cell migration and cell fluidity. Taken together, these findings strongly implicate a crucial role of the CAS-vinculin interaction in mechanosensing, force transmission, and focal adhesion dynamics.

**Focal adhesion kinase, isometric tension generation, and extracellular matrix organization.**

*K. M. Arnold<sup>1,2</sup>, Z. M. Goeckeler<sup>2,3</sup>, N. Galvin<sup>4</sup>, R. B. Wysolmerski<sup>2,5</sup>; <sup>1</sup>Physiology and Pharmacology, West Virginia University School of Medicine, Morgantown, WV, <sup>2</sup>Center for Cardiovascular and Respiratory Sciences, West Virginia University School of Medicine, Morgantown, WV, <sup>3</sup>Neurobiology and Anatomy, West Virginia University School of Medicine, Morgantown, WV, <sup>4</sup>Pathology, St. Louis University School of Medicine, St. Louis, MO, <sup>5</sup>Mary Babb Randolph Cancer Center, West Virginia University School of Medicine, Morgantown, WV*

Focal adhesions (FA) are specialized cell contact sites of distinct molecular composition and structure that provide for efficient bidirectional transmission of biochemical and mechanical signals between the intra- and extracellular compartments. Focal adhesion kinase (FAK) is a soluble cytoplasmic protein kinase that is essential for the organization, assembly, stabilization, and basal physiological activity of FA. FAK has been proposed to be a key component of FA downstream of integrins that regulate the organization of actin for transduction of cellular forces from inside to outside of the cell. From isometric tension experiments using FAK knockout (KO) mouse embryonic fibroblasts (MEFs) embedded in three-dimensional (3-D) collagen constructs, we found that loss of FAK decreased basal isometric tension and virtually abolished agonist induced force development compared to wild type (WT) MEFs. Gel-compression assays revealed FAK KO MEFs did not compress the 3-D collagen matrix to the same extent as WT controls. Loss of FAK had no effect on basal myosin II regulatory light chain phosphorylation. This data suggested the loss of tension development might be due to the inability of KO cells to interact/organize the extracellular matrix. WT and FAK KO MEFs exhibited distinct morphology in 3-D collagen constructs. FAK KO MEFs are round and over time formed large multicellular spheres while WT MEFs spread forming an interconnected sheet of cells. Second harmonic generation and SEM studies showed WT MEFs generate a highly organized, uniform, dense

fibril collagen network whereas FAK KO MEFs form a loose matrix lacking a distinct organizational pattern. Expression of either WT-FAK or constitutively active FAK in FAK KO MEFs rescued force development, cell spreading, and matrix organization in 3-D collagen constructs. Inhibition of FAK kinase activity with the small molecule inhibitor PF-573,288 or expression of a FAK kinase dead mutant in FAK KO cells had little effect on basal or agonist induced force generation suggesting FAK kinase activity may not be necessary for tension development. Taken together, our findings indicate FAK is an important molecular player in FA facilitating transduction of cellular forces from inside to outside of the cell.

2129

**Actin dynamics and organization drive focal adhesion maturation at vanishing tension**

*J. D. Stricker<sup>1</sup>, Y. Beckham<sup>1</sup>, M. L. Gardel<sup>1</sup>; <sup>1</sup>Department of Physics, James Franck Institute, Institute for Biophysical Dynamics, University of Chicago, Chicago, IL*

Cell adhesion to the extracellular matrix (ECM) must be dynamically regulated during directed cell migration, tissue morphogenesis and wound healing. Focal adhesions mediate the attachment between the cell and ECM and play an important role in regulating cell morphology, cell-ECM force transmission and ECM-mediated signaling. Adhesions assemble in an actin polymerization-dependent manner within the lamellipodium and stabilize to the ECM near the lamellipodial base. Myosin II motors within the lamella drives changes in focal adhesion morphology and composition in a “maturation process” that is crucial for regulating focal adhesion dynamics. Understanding the mechanisms regulating focal adhesion maturation has been complicated by the intermingled effects of myosin II on lamellar actin architecture, dynamics and force transmission during focal adhesion maturation. Stresses generated by myosin II drive retrograde flow of lamellar actin networks and bundles as well apply tension to focal adhesions. Myosin-generated stress and cross-linking also facilitate the reorganization of the lamellar actin network into a dense radial stress fiber at the adhesion plaque. It is widely presumed that focal adhesion maturation is a tension-dependent process, although very few studies have been done to decipher the distinct roles of myosin II activity in focal adhesion maturation. However, the extent to which tension is a direct regulator of focal adhesion elongation and stabilization is not well understood. Here, we show that focal adhesion elongation rate stays constant even when the tension build up is reduced by 75%. Instead, focal adhesion elongation rate is correlated with actin retrograde flow, and focal adhesion elongation only halts at stress sufficiently low to impair retrograde flow. The stability of elongated focal adhesions is impaired at low tension, and a critical tension of ~100 Pa is necessary for adhesion stability. However, this force requirement can be bypassed by overexpression of  $\alpha$ -actinin 1 or constitutively active Dia1. Our work identifies a minimal threshold of myosin activity required to drive actin retrograde flow that is sufficient to permit focal adhesion elongation. This work further identifies the stresses associated with both focal adhesion elongation and stabilization. However, rather than acting directly, we believe these stresses are those required to drive retrograde flow dynamics and actin stress fiber assembly demonstrating the important role of actin dynamics and organization in controlling focal adhesion morphology.

2130

**Cells exert rotational moments about focal adhesions**

C. K. Choi<sup>1</sup>, W. R. Legant<sup>1</sup>, L. Shao<sup>2</sup>, L. Gao<sup>2</sup>, J. S. Miller<sup>1</sup>, E. Betzig<sup>2</sup>, C. S. Chen<sup>1</sup>;  
<sup>1</sup>Bioengineering, University of Pennsylvania, Philadelphia, PA, <sup>2</sup>Howard Hughes Medical  
 Institute, Janelia Farm Research Campus, Ashburn, VA

Anchorage-dependent cells maneuver the extracellular matrix (ECM) by exerting traction stresses, which are generated by myosin II contracting on actin filaments and transmitting tension to integrin-mediated adhesions. Forces at adhesions regulate key molecular processes, including cytoskeletal reorganization and adhesion-mediated signaling, and fundamental cellular processes, such as migration, proliferation, and differentiation. Traditional traction measurement methods have assumed that cells apply only shear forces, and only recently, studies have reported significant vertical deformations on the ECM. However, the dynamics and the subcellular locations of multi-dimensional tractions remain unclear. In this study, we developed a multi-dimensional traction force microscopy (2.5D TFM) with high spatio-temporal resolutions to measure the full nature of traction stresses and investigate their relationship to focal adhesions and the actin cytoskeleton. Mouse embryonic fibroblasts (MEFs) expressing GFP-tagged focal adhesion protein (paxillin), actin, or a membrane-marker (farnesyl) were plated on RGD-conjugated synthetic hydrogels. Sub-resolution fluorescent beads embedded in the hydrogels were tracked over time to obtain the 3D deformation field within the substrate. Finite element method was used to generate discretized Green's function to compute cellular traction stresses from the substrate displacements. The dynamics of shear and normal traction stresses relative to the cell body, actin stress fibers, and focal adhesions were determined by co-analyzing volumetric cell images. Cells on planar ECM substrates exert maximum shear tractions directly along focal adhesions, whereas maximum upward and downward normal tractions are generated around focal adhesions and the termini of actin stress fibers. The net effect of these forces produces rotational moments around focal adhesions with a characteristic radius of 10  $\mu\text{m}$ . These moments form only in cell peripheries, where focal adhesions elongate. The moments are also highly dynamic, as they propagate outward with protruding leading edges in migrating and spreading cells over time. Finite element modeling incorporating empirical data and key cytoskeletal components shows that actomyosin contraction on  $\sim 150$  nm tall focal adhesions induces 1  $\mu\text{m}$  lateral displacements and 150-300 nm vertical displacements on the pliable ECM substrate. These findings reveal that cellular interactions with the ECM involve more complex traction stresses, consisting of shearing and compressive forces at focal adhesions.

2131

**Do cancer cells have distinct adhesions in 3D collagen matrices and *in vivo*?**

A. Simon<sup>1</sup>, S. Geraldo<sup>1</sup>, N. Elkhatab<sup>1</sup>, D. Louvard<sup>1</sup>, L. Fetler<sup>1</sup>, D. M. Vignjevic<sup>1</sup>; <sup>1</sup>Institut Curie,  
 Paris, France

During metastasis, cancer cells breach the basement membrane and migrate through the stroma mostly composed of a network of collagen I fibers. Cell migration on 2D is initiated by the formation of protrusions of the cell membrane followed by adhesions at the cell front that link the actin cytoskeleton to the underlying extracellular matrix (ECM). Cells then move forward by exerting traction forces on the adhesions at its front and by disassembling adhesions at the rear. In 2D, only the ventral surface of a migrating cell is in contact with the ECM, where cell-matrix adhesions are assembled. In 3D matrices, even though the whole surface of a migrating cell is interacting with the ECM, it is unclear whether discrete adhesion structures actually exist. Using high-resolution confocal microscopy, we imaged the endogenous adhesome proteins in three different cancer cell types embedded in non-pepsinized collagen type I, polymerized at a slow

rate to allow formation of a network resembling the organization of ECM observed *in vivo*. In MDA-MB-231 cells, vinculin, zyxin and paxillin aggregates were detected in the cellular protrusions, frequently colocalizing with collagen fibers, implying they correspond to adhesion structures in 3D. In colon cancer cells HCT116 and CT26, as the distance from the substrate bottom increases, adhesion aggregates become smaller and almost undetectable. This suggests that the distance from hard substrates, and thus the elasticity of the ECM, is a key factor on the formation of cell-matrix adhesions. Using intravital imaging we observed adhesion protein aggregates *in vivo*. These aggregates share similarities with the ones found in 3D collagen matrices. It still remains to be determined if adhesions assembled in 3D and *in vivo* share functional similarities to the well-described adhesions in 2D. This would provide a major step forward in understanding cell migration in more physiological environments.

2132

**Physiological type I collagen organization induces the formation of a novel class of linear invadosomes.**

A. Juin<sup>1</sup>, C. Billotet<sup>2</sup>, V. Moreau<sup>1</sup>, O. Destaing<sup>3</sup>, C. Albiges-Rizo<sup>3</sup>, J. Rosenbaum<sup>1</sup>, E. Genot<sup>4</sup>, F. Salte<sup>1</sup>; <sup>1</sup>U1053, Inserm, Bordeaux, France, <sup>2</sup>U1029, Inserm, Talence, France, <sup>3</sup>U823, Institut Albert Bonniot, Grenoble, France, <sup>4</sup>U1023, IECB, Pessac, France

Invadosomes are F-actin structures capable of degrading the extracellular matrix through the activation of matrix metalloproteases. Invadosomes is a global term including podosomes found in normal cells and invadopodia observed in cancer cells. As fibrillar type I collagen promotes pro-matrix metalloproteinase 2 activation by membrane type 1 matrix metalloproteinase, we aimed at investigating the functional relationships between collagen I organization and invadosome induction. We found that fibrillar collagen I induced linear F-actin structures, distributed along the fibrils, on endothelial cells, macrophages, fibroblasts, and tumor cells. These structures share features with conventional invadosomes, as they express cortactin and N-WASP and accumulate the scaffold protein Tks5, which proved essential for their formation. On the basis of their ability to degrade extracellular matrix elements and their original architecture, we named these structures "linear invadosomes." Interestingly, podosomes or invadopodia were replaced by linear invadosomes upon contact of the cells with fibrillar collagen I. However, linear invadosomes clearly differ from classical invadosomes, as they do not contain paxillin, vinculin, and  $\beta 1/\beta 3$  integrins. Using knockout mouse embryonic fibroblasts, blocking antibody and RGD peptide, we demonstrate that linear invadosome formation and activity are independent of  $\beta 1$  and  $\beta 3$  integrins. This study demonstrates the existence a new type of invadosomes specifically induced by physiological type I collagen organization.

2133

**Profilin1 regulates invadopodium maturation in human breast cancer cells.**

A. Valenzuela-Iglesias<sup>1</sup>, J. J. Bravo-Cordero<sup>2,3</sup>, V. P. Sharma<sup>2,3</sup>, B. T. Beaty<sup>2</sup>, Z. Ding<sup>4</sup>, L. E. Gutierrez-Millan<sup>1</sup>, P. Roy<sup>4,5</sup>, J. S. Condeelis<sup>2,3</sup>; <sup>1</sup>Department of Scientific and Technologic Investigations, University of Sonora, Hermosillo, Mexico, <sup>2</sup>Department of Anatomy and Structural Biology, Albert Einstein College of Medicine of Yeshiva University, Bronx, NY, <sup>3</sup>Gruss Lipper Biophotonics Center, Albert Einstein College of Medicine of Yeshiva University, Bronx, NY, <sup>4</sup>Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, <sup>5</sup>Department of Pathology, University of Pittsburgh, Pittsburgh, PA

Metastasis is the dissemination of tumor cells from the primary tumor to distant organs. Invadopodia are actin-based membrane protrusions with proteolytic activity. The formation of invadopodia is a multistep process. First, invadopodium precursors are assembled and actin

polymerization induces the formation of mature invadopodia which are capable of matrix degradation upon delivery of MMPs. Profilin1 (Pfn1) regulates actin polymerization in various ways: it can sequester G-actin and inhibit actin polymerization, or it can promote actin polymerization by supplying actin monomers to the barbed end of the actin filaments. Pfn1 can also bind to a number of proteins containing proline-rich sequences that are important for cell migration as well as several phosphoinositides (PI(4,5)P<sub>2</sub>, PI(3,4)P<sub>2</sub>, PI(3,4,5)P<sub>3</sub>), at least, *in vitro*. Seemingly contrary to the essential role of Pfn1 in cell migration in the physiological contexts, Pfn1 is downregulated in several adenocarcinomas and furthermore, loss of Pfn1 expression increases invasiveness of breast cancer cells raising the possibility that its downregulation enhances invadopodium formation. To investigate the role of Pfn1 in the invadopodium formation, we studied the effect of Pfn1 depletion on invadopodium in MDA-MB-231, a metastatic human breast cancer cell line. Depletion of Pfn1 leads to an increase in the number of mature invadopodia and matrix degradation. Consistent with a previous report of Pfn1's negative regulation of membrane PI(3,4)P<sub>2</sub> at the leading edge, we found that loss of Pfn1 expression enhances the level of PI(3,4)P<sub>2</sub> and as a result, the recruitment of PI(3,4)P<sub>2</sub> interacting adaptor protein Tks5 (an invadopodial protein) to the invadopodium. Thus, our results suggest a role for Pfn1 in invadopodia by controlling the levels of PI(3,4)P<sub>2</sub> and accessibility of Tks5 to promote invadopodium formation.

2134

#### **Intracellular Trafficking of Src and Initiation of Invadopodium Formation.**

*K. Williams<sup>1</sup>, M. G. Coppolino<sup>1</sup>; <sup>1</sup>Molecular and Cellular Biology, University of Guelph, Guelph, ON, Canada*

During invasion of an extracellular matrix (ECM), tumour cells can form small, finger-like membrane protrusions called invadopodia. Invadopodia extend into the ECM, and contain on their surface both integrins and matrix metalloproteinases (MMP), suggesting these structures participate in the degradation of the ECM while still allowing cells to adhere to it. The formation of invadopodia involves cytoskeletal rearrangement, attachment to the ECM, and secretion of MMP to degrade the ECM facilitating further protrusion of the cell membrane. Intracellular trafficking of invadopodium-associated proteins is hypothesized to contribute invadopodium formation and to support cell invasion of ECM. SNAREs (soluble N-ethylmaleimide-sensitive factor attachment protein receptors) play a major role in intracellular vesicular traffic, wherein they function to localize vesicles to target membranes. We have begun to characterize the function of SNAREs during the formation of invadopodia in the tumour cell lines HT-1080 and MDA-MB-231. Using a gelatin-based *in vitro* invadopodium formation assay, we have found that inhibition of SNAREs impedes cell invasion and impairs the formation of invadopodia at an early stage, prior to the assembly of actin-based structures at the core of the invadopodia. Expression of a membrane targeted form of Src (Src-CAAX) rescued invadopodium formation, to the point that actin punctae could be detected, but did not restore cell invasion. In addition, SNARE function was required for the formation of a  $\beta$ 1 integrin-Src-containing complex that was observed early during cell invasion of ECM. Our observations suggest that SNARE-dependent trafficking of factors, including  $\beta$ 1 integrin and Src, contributes to both initiation of invadopodium formation and later events in cell invasion.

2135

**Analysis of myosin 1e role in invadopodia dynamics.**

*J. L. Ouderkirk<sup>1</sup>, J. Bi<sup>1</sup>, M. Krendel<sup>1</sup>; <sup>1</sup>Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY*

Cell migration and adhesion are essential for both physiological and pathological processes. Embryonic development, tissue repair and the inflammatory response rely on cell migration, while abnormal migration and invasion can cause bone defects, autoimmune disorders and tumor formation or metastasis in cancer. The actin cytoskeleton and its dynamics are crucial for proper cytoskeletal remodeling associated with cell migration and adhesion. Regulation of actin containing structures, such as lamellipodia and invadopodia, relies on coordination and turnover of a variety of proteins involved in cell adhesion. Unconventional myosins 1e (myo1e) and myosin 1f (myo1f) have been implicated in cell adhesion through proteomic studies that detected these proteins in the integrin-containing cell adhesion complexes.

While the functional role for myo1f in regulation of cell adhesion in neutrophils has been confirmed (Kim et al., Science, 2006), the role of myo1e in cell adhesion has not been analyzed. Since myo1e is expressed in a wide range of tissue and cell types, we hypothesized that it may play an important role in regulation of cell-substrate contacts in a variety of cells. We found that myo1e was enriched in invadopodia rather than in focal adhesions. Using v-Src transformed BHK cells as a model of invadopodia formation, we observed that myo1e localized to the actin-rich core of invadopodia. Enlargement of invadopodia rosettes in response to inhibition of tyrosine phosphatase activity was associated with an increase in the concentration of myo1e at the periphery of the expanding rosettes. Our observations suggest a role for myo1e in invadopodia dynamics and turnover. Thus, myo1e may serve as an important target in diseases where abnormal cell migration and invasion caused by defects in cell adhesion result in pathologies.

**Structure and Function of the Extracellular Matrix**

**Stem Cell-Derived Matrix is Necessary for Lineage Induction.**

*H. Taylor-Weiner<sup>1</sup>, J. E. Schwarzbaue<sup>2</sup>, A. J. Engler<sup>1</sup>; <sup>1</sup>University of California, San Diego, La Jolla, CA, <sup>2</sup>Princeton University, Princeton, NJ*

While differentiation methods often rely exclusively on growth factors to direct mouse embryonic stem cell (mESC) fate, the ESC niche also contains fibrillar extracellular matrix (ECM) proteins, including fibronectin (FN), collagens, and laminins. Many soluble factors used in ESC differentiation are known to increase ECM expression, e.g. Activin A and FN, yet the ECM's ability to direct ESC fate alone is not well understood and likely occurs at points during development. We examined whether ECM proteins were necessary and/or sufficient to direct mESC differentiation. mESCs, grown as embryoid bodies in the absence of serum FN, maintained pluripotency marker expression unlike those in complete serum. Embryoid bodies also showed a spatiotemporal correlation between expression of FN and GATA4, an endodermal marker, and an inverse correlation between FN and Nanog, a pluripotency marker. Maintenance of mESC pluripotency via leukemia inhibitory factor (LIF) prevented fibrillar matrix production, but mESCs created a fibrillar ECM containing FN and laminin depending on the specific inductive conditions. This mESC-derived matrix was unlike conventional fibroblast-derived matrix, which almost exclusively contained fibronectin. Analysis of naïve mESCs plated

onto mESC- and fibroblast-derived matrix indicated lineage specific differences: cells were more receptive to neuro-ectoderm induction on laminin-containing matrix, but in the presence of endodermal growth factors, cells were more receptive to endoderm induction. Fibroblast-derived matrix with exogenously added laminin lacks any residual growth factors that mESC-derived matrix may contain, and appears to indicate a similar requirement. These data appear to indicate that some lineages require a specific combination of matrix and soluble cues, e.g. endoderm, whereas matrix is sufficient to begin lineage commitment for others, e.g. neuro-ectoderm. Regardless of lineage, these data imply that fibrillar FN is necessary for and can enhance and/or direct mESC differentiation.

**Cross-linked collagen nanofilms stiffen the nuclei of mesenchymal stem cells and promote osteogenesis.**

*I. L. Ivanovska<sup>1</sup>, J. Swift<sup>1</sup>, D. E. Discher<sup>1</sup>; <sup>1</sup>University of Pennsylvania, Philadelphia, PA*

Matrix elasticity has been shown in culture to direct lineage specification of MSCs, with mechanisms based in part on forces applied to matrix by the cell's actin-myosin contractility system (Engler et al., 2006). MSCs were cultured on highly ordered collagen nanofilms, in which the mechanical properties had been tuned by enzymatic crosslinking with Transglutaminase. In the absence of cross-linking, cells pulling on the films visibly deformed the collagen fibrils. However, cells cultured on cross-linked films responded by altering their morphology, actomyosin organization, and nuclear shape. Mechanically anisotropic, pristine collagen films promoted strong polarization and orientation along the highly aligned fibrils, whereas cross-linked films caused cells to spread isotropically and stiffen their nuclei with increased lamin-A/C expression. Cell morphology on cross-linked films appeared osteoblastic and the early osteogenic transcription factor RUNX2 and the later marker osteonectin were indeed found to be upregulated relative to cells on pristine collagen. Lamin-A/C over-expression was found to enhance osteogenesis and we discovered a positive correlation between matrix and nuclear mechanics on cell differentiation potential. Conversely, low levels of lamin-A,C favor a soft tissue fate. We found that soft matrix, mimicked here with a soft gel (0.3kPa), increased adipogenesis compared to stiff gels (40kPa), while partial knockdown of LMNA more than doubled adipogenesis on soft matrix. Our results demonstrate the exquisite sensitivity of stem cells and their nuclei to the mechanical properties of their matrix and microenvironment.

**A Continuously Expanding Silicone Culture Surface Provides High Yields of Non-Fibrotic Primary Human Dermal Fibroblasts for iPSC Reprogramming.**

*S. Chaudhry<sup>1</sup>, H. Majd<sup>2</sup>, G. Pietramaggiori<sup>2</sup>, B. Alman<sup>1</sup>, T. Quinn<sup>3</sup>, B. Hinz<sup>1</sup>; <sup>1</sup>University of Toronto, Toronto, ON, Canada, <sup>2</sup>EPFL, Lausanne, Switzerland, <sup>3</sup>McGill University, Montreal, QC, Canada*

Background: The expansion of primary autologous dermal fibroblasts in culture is a pivotal step to obtain sufficiently high numbers for applications where large surface area tissue destructions exceed the body's repair capacity and demand grafting of regenerative cells. Stimulated by the stiff surface of conventional culture plastic, a substantial percentage of fibroblasts spontaneously differentiate into fibrotic myofibroblasts by producing excessive amounts of collagen, de novo expressing  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA), and consequently developing high contractile force. Myofibroblasts cause pathological tissue contractures characteristic of hypertrophic scars and fibrosis. Hence, suppressing this phenotype during cell culture expansion is crucial for the success of subsequent grafting. We hypothesize that culture on highly elastic surfaces will deliver better quality fibroblasts for iPSC reprogramming by inhibiting

myofibroblast development. Method: To rapidly produce high numbers of fibroblasts for cell therapy we implement a novel method combining dynamic enlargement of the culture surface with fibroblast growth on a highly compliant, and extendable, silicone rubber (HESR). Results: 1) Attachment and proliferation of human dermal fibroblasts on functionalized HESR is similar to conventional tissue culture plastic. 2) Repeated passaging on plastic augments the percentage of fibrogenic myofibroblasts. 3) HESR fibroblast cultures show differential gene expression of putative markers for fibrosis. 4) The pro-fibrotic cytokine TGF- $\beta$ 1 fails to activate myofibroblast differentiation on HESR. 5) HESR polymer rheology and not polymer chemistry is responsible for the mechanically-induced gene expression changes and 6) HESR dynamic expansion culture generates a multi-fold increase in daily cell yield while retaining the anti-fibrotic properties of static HESR. Conclusions: The low elastic modulus of the HESR membrane provides anti-fibrotic mechanical cues to primary dermal fibroblasts while dynamic expansion culture using the iris-like expansion device maintains a proliferative cell density by preventing contact inhibition of growth.

### **Mechano-sensing of cells on viscoelastic biomembrane-mimicking substrates.**

L. A. Lautscham<sup>1</sup>, C. Yu-Hung Lin<sup>2</sup>, V. Auernheimer<sup>1</sup>, D. Minner<sup>2</sup>, W. H. Goldmann<sup>1</sup>, C. Naumann<sup>2</sup>, B. Fabry<sup>1</sup>; <sup>1</sup>*Biophysics, University of Erlangen-Nuremberg, Erlangen, Germany,* <sup>2</sup>*Chemistry and Chemical Biology, Indiana University-Purdue University, Indianapolis, IN*

Cells have been shown to sense the mechanical properties of their environment with substantial impact on cellular fate and function. To probe the mechano-sensitivity of cells, previous studies mainly focused on polymeric cell substrates of adjustable elasticity with immobilized cell-substrate linkers. Here, we report on an alternative way of cell substrate design based on a polymer-tethered multi-lipid bilayer system with distinct material properties. Complementary single molecule tracking and magnetic tweezer experiments show that polymer-tethered lipids in the fluid lipid bilayer matrix do not hinder the lateral mobility of individual cell linker molecules, nor obstruct or even prevent the free lateral diffusion of clusters of cell linkers (as determined from focal adhesions). As a consequence, the presented biomembrane-mimicking substrate exhibits a viscous response with respect to individual linkers and a rather elasto-plastic response in the presence of linker clusters. Importantly, the material properties of the multi-bilayer cell substrate can be tuned by altering the number of bilayers in the stack. Experiments using mouse embryonic fibroblasts confirm the mechano-sensitivity of plated cells in response to altered material properties in the multi-bilayer substrate. Mouse embryonic fibroblasts cultured on triple bilayer substrates show an about 50 % reduced spreading area compared to cells cultured on glass. Furthermore, the cell stiffness and tractions decrease by approximately 25 % and 80 %, respectively. Similarly, the focal adhesion size is reduced with increasing number of stacked bilayers. These results illustrate that mouse embryonic fibroblasts are susceptible to changes in substrate elasto-plasticity and linker mobility by changing their morphological and mechanical properties.

### **Self-Assembling Peptide Gels Enable Comprehensive Phenotypic and Molecular Characterization of Cellular Responses to Extracellular Stiffness Cues in 3D.**

Y. Yui<sup>1,2,3</sup>, R. Bainer<sup>1,2,3</sup>, J. Lakins<sup>1,2,3</sup>, S. Mumenthaler<sup>4</sup>, P. Mallick<sup>4</sup>, C. Bilgin<sup>5</sup>, B. Parvin<sup>5</sup>, V. M. Weaver<sup>1,2,3,6</sup>; <sup>1</sup>*Department of Surgery, University of California, San Francisco, San Francisco, CA,* <sup>2</sup>*Center for Bioengineering and Tissue Regeneration, University of California, San Francisco, San Francisco, CA,* <sup>3</sup>*Bay Area Physical Sciences-Oncology Center, San Francisco,*

CA, <sup>4</sup>Center for Applied Molecular Medicine, University of Southern California, Los Angeles, CA, <sup>5</sup>Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, <sup>6</sup>Department of Anatomy, Department of Bioengineering and Therapeutic Sciences, Eli and Edythe Broad Center of Regeneration Medicine and Stem Cell Research, UCSF Helen Diller Comprehensive Cancer Center, University of California San Francisco, San Francisco, CA

The stiffness of the extracellular matrix (ECM) stimulates mechanotransduction pathways that regulate tissue development and tumor progression. We previously showed that a stiff ECM potentiates cell growth and survival and enhances cell migration to drive tumor cell invasion (Paszek et al., *Cancer Cell* 2005). We also reported that the ECM progressively stiffens during malignant progression and that ECM tension drives malignant progression of the mammary gland in culture and in vivo (Levant et al. *Cell*. 2009; Lopez et al., *J Integ Biol* 2011). To identify molecular mechanisms whereby ECM stiffness could modulate the malignant behavior of cells, we have been using nonmalignant and oncogenically-modified human mammary epithelial cells (MECs) cultured in either collagen/reconstituted basement membrane gels in three-dimensions (3D) or on top of protein-laminated polyacrylamide gels. While sufficient in many experimental contexts, polyacrylamide gels fail to accurately recapitulate the 3D interstitial ECM, and collagen gels exhibit a limited dynamic range of stiffness and are non-uniform with respect to ligand availability, pore size, and topology, severely complicating data interpretation. To address this issue we established an alternative 3D culture system using self-assembling peptide (SAP) gels that significantly extends the experimental dynamic range of stiffness conditions while limiting topological changes in the ECM, and in which cells broadly maintain biological phenotypes observed in comparable collagen and matrigel systems (Miroshnikova et al. *Phys. Biol.* 2011). We used this technique to identify a critical ECM stiffness that promotes progressive changes in mammary acini growth, morphology and invasion. While mammary acini interacting with a highly compliant ECM (80 Pa) maintained acini integrity, mammary acini embedded within a highly stiff ECM (5,000 Pa) collapsed and invaded into the SAP gel. These changes in mammary tissue phenotype were accompanied by differences in levels of genes implicated in tumorigenesis, including significant induction of fibronectin. To identify additional force-regulated molecular pathways involved in tumor progression we used Affymetrix expression microarrays to characterize the gene expression profiles of mammary acini exposed to increasing ECM tension (80-5000 Pa). In parallel, we identified changes in protein expression using mass spectrometry-based quantitative proteomics. These studies highlight the significant advantage SAP gels offer over existing 3D systems and provide biological insight into the divergent cellular responses to distinct stiffness environments.

**Coordinated regulation of epithelial cell invasion by the ECM and actomyosin contractility.**

*K-V. Nguyen-Ngoc<sup>1</sup>, A. J. Ewald<sup>1</sup>; <sup>1</sup>Cell Biology, Johns Hopkins School of Medicine, Baltimore, MD*

The extracellular matrix (ECM) provides the signals and scaffold for tissue development and is also hijacked in cancer. Abnormal changes in collagen type I, the most abundant ECM component in the stroma, are particularly correlated with poor prognosis in breast cancer. To determine the effect of fibrillar collagen on epithelial cell invasion and dissemination, we explanted epithelial fragments from tumor and normal murine mammary epithelium and cultured them in 3D gels of collagen I. We observed that tumor cells persistently invaded with protrusions

and disseminated into collagen I. Despite initiating with a similar response, myoepithelial cells in normal epithelium went through cycles of extension and retraction, but maintained a directional growth along progressively aligned collagen fibers. Eventually, normal epithelium restored simple epithelial organization and underwent branching morphogenesis. Ceasation of protrusions correlated with reestablishment of basement membrane.

We next sought to identify molecular changes that would induce persistent invasion of myoepithelial cells. We chose to target actomyosin contractility, which plays an important role in cell-matrix adhesion and collagen remodeling. Using pharmacological perturbation, we found that inhibition of actomyosin contractility resulted in an excess of long, thin invasive protrusions of myoepithelial cells. Time-lapse microscopy revealed that cellular extension was normal but retraction was blocked. We also observed a complete inhibition of fiber alignment and a failure to reorganize into an epithelial structure. In addition, inhibition of Rho kinase, an upstream regulator of actomyosin contractility, completely disrupted the myoepithelial cell layer, allowing a direct access of luminal epithelial cells into the ECM. We next asked whether actomyosin contractility is required for the maintenance of epithelial architecture. When we inhibited actomyosin contractility after protrusions had ceased, we observed rapid initiation of basal protrusions. These data suggest a functional role of actomyosin contractility in maintenance of epithelial integrity and prevention of local invasion of epithelial cells into a collagen-rich ECM.

Actomyosin filaments generate contractile force via Myosin II motors, whose properties and functions are mainly determined by myosin heavy chain (MHC) domains. Myoepithelial cells express two MHC isoforms, namely MHCIIA and MHCIIIB. We next aim to use Cre-lox based deletion to unravel the specific contribution of each isoform to the epithelial cell contractility and invasion.

**Epithelial-mesenchymal crosstalk mediates tissue fibrosis.**

*C. Jamora<sup>1,2</sup>, T-L. Tan<sup>1,2</sup>, M. Nakasaki<sup>1,2</sup>; <sup>1</sup>University of California, San Diego, La Jolla, CA, <sup>2</sup>IFOM-inSTEM Joint Research Laboratory, Bangalore, India*

The formation of excess fibrous connective tissue (fibrosis) adversely affects the function of many organs and can result from a variety of conditions including aging and inflammation. A central player in fibrosis is the activation of fibroblasts that secrete excessive amounts of extracellular matrix proteins. Despite their pivotal role in fibrogenesis, the molecular mechanisms regulating fibroblast activation remains elusive and is a major roadblock in the development of effective therapeutics against this debilitating pathology. Previous work in a variety of organs has demonstrated that the transcription factor Snail is capable of inducing tissue fibrosis. Its developmental role in mediating an epithelial-mesenchymal transition (EMT) during embryogenesis is widely extrapolated to be the mechanism by which activated fibroblasts are produced from neighboring Snail expressing epithelial cells. However, we have found that transgenic expression of Snail in epidermal keratinocytes of the skin is capable of leading to dermal fibroblast activation and fibrosis without utilizing an EMT. Instead, the Snail expressing keratinocytes secrete factors capable of activating dermal fibroblasts to induce overproduction and reorganization of the extracellular matrix. This new paradigm of epithelial-mesenchymal crosstalk as a mediator of fibrosis will illuminate novel targets for clinical intervention to combat fibrosis, which accounts for up to 45% of deaths worldwide.

**The role of tissue elasticity in the formation of cutaneous fibrosis.**

*M. Nakasaki<sup>1,2</sup>, Y. Hwang<sup>2</sup>, T. Tan<sup>1,2</sup>, C. Xie<sup>2</sup>, T. Nakamura<sup>3</sup>, S. Varghese<sup>2</sup>, C. Jamora<sup>1</sup>; <sup>1</sup>IFOM-inSTEM Joint Research Laboratory, Bangalore, India, <sup>2</sup>Bioengineering, University of California, San Diego, La Jolla, CA, <sup>3</sup>Pharmacology, Kansai Medical University, Osaka, Japan*

Fibrosis is the formation of excess fibrous connective tissue and is the cause of life-threatening fibrotic diseases in multiple organ systems, including the skin, blood vessels, heart, lungs, and kidneys. However, the mechanism of fibrosis formation remains to be clarified. We established a fibrotic skin model using conditional transgenic mice which exogenously express the transcription factor Snail in the epidermis of the skin, leading to severe inflammation and fibrosis in dermal tissue. We also established a method to evaluate the mechanical properties of the skin tissue including tissue stiffness and elasticity and identified the Snail transgenic skin demonstrated a significantly higher elastic modulus and stiffness compared to the wild-type skin. The Snail transgenic skin contained increased amount of elastic fibers and exhibited up-regulated expression of fibrosis signature genes such as smooth muscle actin and SPARC. We also observed an increased deposition of Fibulin-5 which is a component of elastic fiber and essential for elastic fiber formation in the fibrotic dermis of the Snail transgenic skin. To investigate the contribution of altered elasticity with accumulated elastic fibers in fibrosis formation, we crossed the Snail transgenic mice with fibulin-5 knock-out mice. The obtained Snail transgenic/fibulin-5 KO skin demonstrated not only a reduced elastic modulus but also a reduced expression level of the fibrosis and inflammation signature genes in the affected skin. These findings suggest that tissue elasticity regulates the formation of skin fibrosis.

2144

**Regulation of cell-generated forces during phenotypic reversion by a novel laminin chain in 3D culture of human breast tumor cells.**

*K. Tanner<sup>1,2</sup>, W. Orellana<sup>1,2</sup>, E. Chen<sup>3</sup>, M. J. Bissell<sup>1</sup>; <sup>1</sup>Life Sciences, LBNL, Berkeley, CA, <sup>2</sup>Center for Cancer Research, National Cancer Institute, Bethesda, MD, <sup>3</sup>Department of Pharmacological Sciences & Proteomics Center, Stony Brook University School of Medicine, Stony Brook, NY*

Laminins are heterotrimeric extracellular glycoproteins found in, but not confined to, basement membranes (BMs). They are important components in formation of the molecular networks of BMs as well as in cell & tissue polarity, differentiation and morphogenesis. They are secreted by cells and serve to initiate the template required for multicellular assembly. Mass spectroscopy of the isolated membrane fractions revealed a differential expression of an unexpected laminin chain where human malignant breast cells have a higher expression than that of non malignant cells in 3D IrECM. We thus asked the question what is the role of this endogenously produced laminin for 3D acinar morphogenesis. Recently, we reported that non-malignant cells in a 3D laminin-rich gel generate a centripetal force resulting in coherent angular motion (CAMo) to establish acini[1]. On the other hand, malignant cells are randomly motile but regain the ability to rotate during phenotypic reversion [2]. We show that there is a differential deposition of this laminin in the BM in malignant tissues from human patient biopsies. Modulation of expression via shRNA reveals that malignant cells regain the ability to generate centripetal forces and thus re-enter the acinar morphogenetic program. We determine that the cells' ability to perform CAMo is in part due to both the expression and localization of this particular laminin chain. These data show the intimate dynamic reciprocity between the cells and the ECM to establish polarity and form tissue architecture.

**Functional characterization of tissue inhibitor of metalloproteinase-1 (TIMP-1) N- and C-terminal domains during early *Xenopus laevis* development.**

M. Nieuwesteeg<sup>1</sup>, M. Cepeda<sup>1</sup>, J. A. Willson<sup>1</sup>, S. Damjanovski<sup>1</sup>; <sup>1</sup>Biology, University of Western Ontario, London, ON, Canada

Extracellular matrix (ECM) remodeling facilitates processes such as cell migration and angiogenesis, and is therefore necessary for proper development. ECM remodeling is mediated by the enzymatic activity of matrix metalloproteinases (MMPs), which cleave the various components of the ECM, and by their endogenous inhibitors, tissue inhibitors of metalloproteinases (TIMPs). TIMP proteins contain two structurally and functionally distinct domains. The N-terminal domains bind to and inhibit MMPs, while the C-terminal domains may have cell signaling activity. *In vitro* studies have indicated that TIMP-1 may play important roles in regulating apoptosis and cell growth pathways through its C-terminal domain, however, its role *in vivo* remains unclear. The objective of this study is to examine the individual roles of TIMP-1 N- and C-terminal domains *in vivo*, as they pertain to early *Xenopus laevis* development. Semi-quantitative RT-PCR analysis shows that endogenous TIMP-1 is expressed throughout early *X. laevis* development, with the highest level of expression during organogenesis. RNA microinjection was used to overexpress full-length TIMP-1 or its individual N- or C-terminal domains. Overexpression of each TIMP-1 construct produced unique developmental defects; however, full-length and N-terminal TIMP-1 resulted more similar phenotypic abnormalities (axis defects) and increased lethality compared to C-terminal TIMP-1. Additionally, RT-PCR analysis and zymography showed that overexpression of N- or C-terminal TIMP-1 resulted in unique changes in the expression of axial and proteolytic genes, as well as MMP activity, respectively. Together, this indicates that the individual N- and C-terminal domains of TIMP-1 can play distinct roles during development, which are moderated in the full-length TIMP-1 molecule.

2146

**Tissue inhibitor of metalloproteinase-2 (TIMP-2) with a non-functional N-terminal domain decreases the invasiveness of MCF-7 and MDA-MB231 breast cancer cells.**

M. A. Cepeda<sup>1</sup>, M. Nieuwesteeg<sup>1</sup>, J. Willson<sup>1</sup>, S. Damjanovski<sup>1</sup>; <sup>1</sup>University of Western Ontario, London, ON, Canada

The tissue inhibitors of metalloproteinases (TIMPs) are the natural inhibitors of matrix metalloproteinases (MMPs), a family of proteins primarily involved in the proteolytic degradation and remodeling of the extracellular matrix (ECM). By virtue of their activity, TIMPs and MMPs play an important role in the migration and invasion of cells both *in vivo* and *in vitro*. TIMPs possess functionally distinct N- and C-terminal domains. While the N-terminal domain of TIMPs is largely involved in inhibiting specific MMPs, the C-terminal domains of the different TIMPs are capable of different functions depending on the TIMP. The N-terminal domain of

TIMP-2 is an excellent inhibitor of MMP-2, -9 and MT-1 (Membrane Type-1) MMP, while the C-terminal domain has been shown to signal inside the cell through MT-1 MMP and alpha3beta1 integrin. The C-terminal domain of TIMP-2 has been shown to modulate migration through the ERK (Extracellular Regulated Kinase) pathway, and induce expression of RECK (REversion inducing Cysteine rich protein with Kazal motifs), a novel MMP regulator, amongst other functions. The objective of my study was to see how TIMP-2 or ALA+TIMP-2 conditioned media affects the invasion and gene expression of MCF-7 and MDA-MB231 breast cancer cells. ALA+TIMP-2 is a TIMP-2 mutant with a non-functional N-terminal domain, which allows for the isolation of the effect the C-terminal domain of TIMP-2 has on invasion and gene expression. MDA-MB231 cells express much higher levels of MT-1 MMP and MMP-2 than MCF-7 cells and as such are significantly more invasive. Treatment of MCF-7 and MDA-MB231 cells with TIMP-2 and ALA+TIMP-2 conditioned media decreased invasiveness, with ALA+TIMP-2 treatment showing the highest decrease in invasiveness for both cell lines. Treatment of both cell lines with TIMP-2 or ALA+TIMP-2 conditioned media did not change expression of RECK, TIMP-2, beta-1 integrin or MT-1 MMP. However, MDA-MB231 cells show a significant decrease in the expression of MMP-2 after treatment with TIMP-2 and ALA+TIMP-2 conditioned media. These data indicates that the C-terminal domain of TIMP-2 can decrease the invasion of MCF-7 and MDA-231 cells, as well as affect MMP-2 expression.

2147

**Analysis of RECK expression in dorsalized and ventralized *Xenopus laevis* embryos.**

J. A. Willson<sup>1</sup>, M. Nieuwesteeg<sup>1</sup>, M. Cepeda<sup>1</sup>, S. Damjanovski<sup>1</sup>; <sup>1</sup>University of Western Ontario, London, ON, Canada

Remodeling of proteins within the extracellular matrix (ECM) is crucial during the development of multicellular organisms. Degradation of ECM components occurs through the combined action of matrix metalloproteinases (MMPs) and their endogenous inhibitors, tissue inhibitors of metalloproteinases (TIMPs). The reversion-inducing cysteine-rich protein with kazal motifs (RECK) gene encodes a membrane-anchored protein and has recently been found to play an important role in mediating ECM remodeling by inhibiting MMPs. To date, however, few *in vivo* studies exist examining the role of RECK during early development. My research focuses on cloning and examining the expression pattern of RECK during *Xenopus laevis* development. A full-length cDNA clone of the RECK gene was generated and sequence analysis confirmed its identity relative to other species. RT-PCR analysis was used to examine the temporal expression of RECK during early development. Results showed that RECK was expressed at lower levels during gastrulation, and then increased during neurulation and organogenesis. Whole mount *in situ* hybridization was used to examine the spatial expression of RECK. Results showed that RECK expression was localized to the neural regions of the developing embryo, including the brain, neural tube, and notochord. RECK expression was also observed in the blood precursors and the otic placode. Treatment of *Xenopus* embryos with lithium chloride (LiCl) and ultraviolet (UV) irradiation revealed that RECK expression decreased in LiCl-treated (dorsalized) embryos and increased in UV-treated (ventralized) embryos. These results suggest that RECK expression is temporally and spatially restricted during early *Xenopus* development.

2148

**The role of polycystins in the maintenance of extracellular matrix integrity.**

S. Le Corre<sup>1</sup>, I. A. Drummond<sup>1</sup>; <sup>1</sup>Nephrology Division, Massachusetts General Hospital, Charlestown, MA

Mutations in Polycystin1 and Polycystin2 account for Autosomal Dominant Polycystic Kidney Disease (ADPKD), the most frequent heritable human genetic disease. ADPKD is characterized by the presence of multiple cysts in both kidneys. In addition to cystic pathology, ADPKD is also associated with vascular aneurysm, cardiac valve defects, and abdominal wall hernia; all pathologies linked to extracellular matrix defects. We have modeled ADPKD in zebrafish by polycystin1 and polycystin2 mutation or knockdown and shown that the strong dorsal axis curvature mutant/morphant phenotype was caused by overproduction of cross-linked collagen II alpha1 protein in the notochord sheath since col2a1 knockdown rescued dorsal axis curvature in polycystin-deficient embryos. Surprisingly, overproduction of notochord collagens was not due to over-expression of col2a1, col9a2, or col27a1 mRNA (qRT-PCR). Instead, over-accumulation of collagen protein is more likely linked to enhanced collagen translation, secretion, or reduced degradation.

Polycystin1 is localized to focal adhesions and interacts with focal adhesion kinase (FAK). Over-expression of Polycystin-1 can activate downstream targets of FAK such as PI3K. Interestingly, we find that inhibition of PI3K with a reversible inhibitor (LY294002) phenocopies the polycystin-deficiency dorsal axis curvature in zebrafish, suggesting that inhibition of the PI3K pathway leads to dorsal axis curvature. Further experiments demonstrated that the PI3K targets phospho-Akt and phospho-GSK3 $\beta$  are downregulated in polycystin2-deficient embryos. Consistent with a role for PI3K in regulating collagen synthesis or turnover, col2a1 knockdown rescued the dorsal axis curvature in embryos treated with the PI3K inhibitor LY294002, strengthening the idea that over-expression of collagen is necessary to induce this phenotype. Taken together, our results support a model where Polycystins 1 and 2 are required for full activity of the PI3K/AKT pathway. In polycystin-deficient or PI3K inhibitor treated embryos, extracellular matrix synthesis or turnover is dysregulated, leading to axial curvature in zebrafish. A similar mechanism may contribute to disease pathogenesis in human ADPKD patients.

**Tenascin C protects aorta from acute dissection in mice.**

H. Aoki<sup>1</sup>, T. Kimura<sup>2</sup>, K. Yoshimura<sup>3</sup>, K. Shiraishi<sup>3</sup>, K. Imanaka-Yoshida<sup>4</sup>, T. Yoshida<sup>4</sup>, Y. Ikeda<sup>3</sup>, T. Miyamoto<sup>1</sup>, M. Hiroe<sup>5</sup>, K. Hamano<sup>3</sup>, K. Aonuma<sup>2</sup>, M. Matsuzaki<sup>3</sup>, T. Imaizumi<sup>1</sup>;  
<sup>1</sup>Cardiovascular Research Institute, Kurume University, Kurume, Japan, <sup>2</sup>Cardiovascular Medicine, University of Tsukuba, Tsukuba, Japan, <sup>3</sup>Yamaguchi University, Ube, Japan, <sup>4</sup>Mie University, Tsu, Japan, <sup>5</sup>National Center for Global Health and Medicine, Tokyo, Japan

Acute aortic dissection (AAD) is caused by an abrupt destruction of the aortic medial layer that is life-threatening and more prevalent than the rupture of abdominal aortic aneurysm (AAA), another common destructive aortic disease. While recent studies including ours have deciphered the molecular pathogenesis of AAA, that of AAD is largely unknown. During the investigation on pathogenesis of AAA focusing on a matricellular protein tenascin C (TNC) that is associated with tissue destruction in various diseases including AAA, we serendipitously discovered that Tnc-null, but not wild type mice developed AAD by the combination of angiotensin II infusion and periaortic CaCl<sub>2</sub> treatment. CaCl<sub>2</sub> treatment caused the stiffening of aorta, a known risk factor of AAD in human, and augmented the AngII-induced hemodynamic stress and TNC expression in aorta. TNC expression, in turn, was essential to tissue reinforcement by expression of extracellular matrix proteins, and to ameliorating an excessive

inflammatory response both in aortic tissue *in vivo* and aortic smooth muscle cells *in vitro*. Our findings indicate that stress-induced TNC expression is a previously unrecognized protective mechanism in aortic walls, and the failure of the protective mechanism underlies the pathogenesis of AAD.

2150

**Roles of the heterotypic CCN2-CCN3 and homotypic CCN2-CCN2 interactions in matrix synthesis in chondrocytes.**

M. Hoshijima<sup>1</sup>, T. Hattori<sup>1</sup>, E. Aoyama<sup>2</sup>, T. Nishida<sup>1</sup>, T. Yamashiro<sup>1</sup>, M. Takigawa<sup>1</sup>; <sup>1</sup>Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama, Japan, <sup>2</sup>Okayama University Dental School, Biodental Research Center, Okayama, Japan

In healthy tissue CCN family member 2 / connective tissue growth factor (CCN2/CTGF) is highly expressed in cartilage and modulates chondrocyte differentiation and proliferation. Since ectopic overexpression of CCN2 is observed in several pathological states such as fibrosis or cancer, regulation of protein level and activity of CCN2 are required for normal development and maintenance of the physiological conditions in the living organisms. To understand the regulating mechanism of CCN2 activity, we, in the present study, identified CCN2-interactive proteins and investigated the effects of interaction on CCN2 activity in chondrocytes.

To identify CCN2-interactive proteins, we carried out GAL4-based yeast two-hybrid screening using a cDNA library derived from a chondrocytic cell line, HCS-2/8. CCN2/CTGF and CCN3/NOV polypeptides were picked up as CCN2-binding proteins, and CCN2-CCN2 and CCN2-CCN3 binding domains were identified. CCN family members have 4 characteristic domains: insulin-like growth factor binding protein-like (IGFBP), von Willebrand factor type C (VWC), thrombospondin type 1 repeats (TSP-1) and C-terminal cystine knot (CT). Among the four domains of CCN2, IGFBP, VWC and CT domains interact directly with full length CCN2, while only VWC and CT domains, but not IGFBP, of CCN2 bound to CCN3. Furthermore direct binding between CCN2 and CCN3 was confirmed by coimmunoprecipitation *in vitro* and *in vivo* and surface plasmon resonance, and the calculated dissociation constant (Kd) was  $1.17 \sim 10^{-9}$  M between CCN2 and CCN2 and  $1.95 \sim 10^{-9}$  M between CCN2 and CCN3, respectively. Ectopically overexpressed GFP-CCN2 and Halo-CCN3 in COS7 co-localized as determined by direct fluorescence analysis. In addition indirect immunostaining of endogenous CCN2 and CCN3 with specific antibodies showed subcellular co-localization of these proteins. We also present evidence that CCN2-CCN3 interactions modulated CCN2 activity such as enhancement of *aggrecan* and *col2a1* expression. Curiously, CCN2 enhanced, whereas CCN3 inhibited, the expression of *aggrecan* and *col2a1* mRNA in HCS-2/8 cells; and the combined treatment with CCN2 and CCN3 abolished the inhibitory effect by CCN3. These effects were neutralized with an antibody against the VWC domain of CCN2 (11H3). This antibody diminished the binding between CCN2 and CCN2, but enhanced that between CCN3 and CCN2. Our results suggest that CCN2 could form homotypic and heterotypic dimers with CCN2 and CCN3, respectively. Strengthening the binding between CCN2 and CCN3 with the 11H3 antibody had an enhancing effect on *aggrecan* expression in chondrocytes, suggesting that CCN2 had an antagonizing effect by binding to CCN3.

**Identification of Genes Necessary for Neuronal Attachment.**

*E. G. Njie<sup>1</sup>, D. Cabrera<sup>1</sup>, B. Colbitz<sup>1</sup>, M. Chalfie<sup>1</sup>; <sup>1</sup>Biological Sciences, Columbia University, New York, NY*

The extracellular matrix (ECM) is an essential network of proteins that surrounds cells. The interaction between ECM proteins and cells has been of great interest because cellular attachment is lost in several diseases, such as tumor malignancies. Furthermore, the biology of how cells interact with the ECM has been a subject of intense research in the past years, yet the exact mechanism is not fully understood. Previous work from our lab demonstrated that genes including the epidermal growth factor (EGF) and Kunitz domain containing gene *mec-1* and the collagen-like gene *mec-5* encode proteins localized to the ECM and are needed for the attachment in the touch-sensitive neurons to *C. elegans* epidermis; therefore, the attachment of touch neurons to surrounding tissue is a proven approach to identify new genes of the ECM. In the present study, we aim to find genes important for the attachment in the touch neurons by mutagenizing *C. elegans* with ethyl methanesulfonate (EMS) and screening for animals with defective attachment. These screens have led to the identification of 51 mutant strains that show defective attachment. We have also observed great variability in the mutant phenotype, which suggests that multiple genes have nuanced effects in the attachment of neurons to the ECM. The mutant strains that we have found may carry lesions in genes previously associated with attachment defects or in novel genes. We are currently working on characterizing the genes that carry the mutations in these novel strains. The identification of new genes and alleles responsible for neuronal attachment will shed light on the dynamic interaction of cells with their surrounding tissues.

**Defining Therapeutic Targets and New Therapeutics II**

**Nanoparticles-emitted light attenuates beta amyloid-induced inflammation and oxidative stress.**

*B. Bungart<sup>1</sup>, J. Lee<sup>1</sup>; <sup>1</sup>Biological Engineering, University of Missouri, Columbia, MO*

Alzheimer's disease (AD) is the sixth leading cause of death in Americans over 65 with no effective intervention yet available to aid in changing this fact. Lower level light therapy (LLLT) has been shown to be an efficacious treatment for many diseases involving inflammation, such as rheumatoid arthritis. Our lab was the first to show the potential of LLLT to serve as a remedy in AD through its ability to prevent the inflammation and oxidative stress induced by amyloid- $\beta$  (A $\beta$ ) in vitro. However, the low penetration of light into deep tissues is still the major challenge of LLLT. Therefore, new and innovative light delivery methods without relying upon external energy to produce light should be explored. Here we demonstrate the use of Bioluminescence Resonance Energy Transfer (BRET) Quantum Dots (BRET-Qdots) as an alternative near infrared (NIR) light source. BRET-Qdots are conjugated on their surface with luc8, a mutant luciferase which is 4 times as efficient. Exposure of luc8 to its substrate, coelenterazine-h (i.e. luciferin), induces the emission of light of peak wavelength 480 nm through an enzymatic reaction. By the principle of fluorescent resonance energy transfer (FRET), the light energy of luc8, in turn, excites the quantum dot to emit NIR light; thus, no external light source is required for light emission. Our results show that BRET-Qdot-emitted NIR suppresses oxidative stress and inflammatory responses induced by A $\beta$  in primary rat astrocytes. These data provide a proof of concept using quantum dots to carry out light therapy for neurodegenerative diseases, and

should ultimately initiate a new research direction applying nano-medicine approaches as AD therapeutic strategies.

2153

**Construction of different clones of sC3 transferase prior to testing the effectiveness on growth of cells.**

*F. Norflus<sup>1</sup>, C-A. Gutekunst<sup>2</sup>, R. E. Gross<sup>2</sup>; <sup>1</sup>Natural Sciences, Clayton State University, Morrow, GA, <sup>2</sup>Neurosurgery, Emory University, Atlanta, GA*

Reconstruction of neural circuits using cell replacement therapies remains high on the lists of potential treatments for neurodegenerative diseases including Parkinson's Disease (PD) and other CNS injuries. New approaches need to be developed to assist implanted cells in regenerating their axons and to guide that growth for proper connectivity. RhoA mediates the effects on growth cones of diverse extracellular cues present after injury. Biochemical blockade of RhoA activity, conversely, leads to axon growth on inhibitory molecules. C3 transferase, a Clostridial Botulinum exotoxin, irreversibly inhibits RhoA and thus holds great promise for regenerative therapeutics. C3 has been shown to increase axon regeneration in the CNS after injury, and is in clinical trials for the treatment of SCI (spinal cord injury).

More recently, a small peptide of 29 amino acids (residues 154-182, sC3) from the C-terminal region of C3 was capable of promoting both axonal and dendritic growth, as well as branching of hippocampal neurons independently from Rho inhibition. The same peptide was shown to enhance axon regeneration in an animal model of spinal cord injury.

The main goal of this project was to generate GFP plasmids containing a short fragment of the C3 gene (sC3). The control contained GFP with no C3. The 0 bridge plasmid contained the sC3 fused directly to GFP and the last plasmid contained a 25 amino acid bridge between sC3 and GFP. These plasmids were transfected into HEK393 cells as a preliminary system. All the plasmids expressed GFP. In addition, both the 0 and 25 bridge constructs enhanced process length of the cells compared to the control plasmid. Future studies will examine these plasmids in neuronal cells grown on inhibitory substrates. These in vitro studies will provide pilot data for subsequent in vivo studies.

2154

**P12, a novel fibronectin peptide, promotes cell survival by augmenting survival signals PDGF-BB.**

*J. Zhu<sup>1</sup>, M. Mctigue<sup>1</sup>, R. Clark<sup>1</sup>; <sup>1</sup>State University of New York at Stony Brook, Stony Brook, NY*

Objective: P12 is a small cationic peptide derived from the first type III repeat of human fibronectin with platelet derived growth factor-BB (PDGF-BB) binding activity. P12 limits injury progression in both rat and porcine burn injury models. Previous experiments demonstrated that P12 has synergistic effects with PDGF-BB to prolong adult human dermal fibroblast (AHDF) survival and that P12 alone can enter cells in a temperature and energy dependent manner, like a cell penetrating peptide. Our global hypothesis is that P12 functions by augmenting PDGF-BB survival signals. Results: Here we demonstrate that P12 slows the uptake of PDGF-BB by human dermal fibroblast under starvation. Nevertheless, P12 in the presence of PDGF-BB enhances PDGFR phosphorylation at Y751 (the docking site of PI3K), enhances ERK1/2 phosphorylation, prolongs Akt phosphorylation. Furthermore, we demonstrated by confocal microscopy co-localization between P12 and PDGF-BB. Conclusion/speculation: P12 promotes

cell survival by augmenting survival signals from PDGF-BB through shifting the distribution of PDGF internalization from Clathrin-mediated endocytosis to macropinocytosis.

2155

**Oxytocin is expressed in epidermal keratinocytes and released upon stimulation with ATP in vitro.**

*S. Denda<sup>1,2</sup>, K. Take<sup>2</sup>, J. Kumamoto<sup>2</sup>, M. Goto<sup>1</sup>, M. Tsutsumi<sup>1</sup>, M. Denda<sup>1</sup>; <sup>1</sup>Shiseido Innovative Science Research & Development Center, Yokohama, Japan, <sup>2</sup>CREST, Japan Science and Technology Agency, Tokyo, Japan*

Various similarities have been found between brain and epidermis, as might be expected, because both of them have a common embryonic origin. For example, epidermal keratinocytes synthesize a variety of neuropeptides and neurotransmitters. Oxytocin is a neuropeptide produced primarily in the hypothalamus and is secreted from the posterior pituitary into blood. It contracts smooth muscle during parturition and lactation. It also influences behavior, memory, and mental state. Systemic oxytocin infusion reduced the repetitive behavior of patients with autism and Asperger's syndrome. Moreover, tactile stimuli increased plasma oxytocin level and influenced emotional state. Thus, oxytocin might be a mediator between tactile sensation and emotional state. Here we show that oxytocin is expressed in both human epidermis and cultured epidermal keratinocytes. We also show that oxytocin is released from keratinocytes after application of ATP, in a dose-dependent manner. ATP is an important signaling molecule for keratinocytes and epidermis, and secreted from these cells in response to external stimuli such as heat and pressure. The oxytocin release was inhibited by removal of extracellular calcium, or by the P2 receptor antagonists. These results suggest that oxytocin is produced in human epidermal keratinocytes and is released in response to calcium influx via P2X receptors. Tactile stimuli might induce ATP secretion from epidermis, leading to oxytocin release from epidermal keratinocytes. Further investigation of the roles of epidermis-derived oxytocin may lead to new treatment methodologies for both skin and mental disorders.

2156

**Cannabinoid receptor ligand blocks abnormal hemichannel activity and emerges as a potential treatment for EKV disease.**

*J. Chi<sup>1,2</sup>, C. Tang<sup>1</sup>, D. Yang<sup>1</sup>, L. Li<sup>1</sup>, J. Tan<sup>1</sup>, Q. Pan<sup>1</sup>, Z. Zhang<sup>1</sup>, D. Wang<sup>1</sup>; <sup>1</sup>The State Key Laboratory of Medical Genetics, Changsha, China, <sup>2</sup>The Affiliated Hospital of Medical College Qingdao University, Qingdao, China*

Connexins form gap junction channels between adjacent cells to mediate direct exchange of small cytoplasmic molecules and metabolites less than 1KD. They can also form hemichannels on unopposed plasma membrane to allow the passage of small molecules, such as ATP and glutamine. Mutations in connexin 31 (Cx31) are associated with a variety of genetic disorders, including erythrokeratoderma variabilis (EKV), deafness and peripheral neuropathy. Previous studies suggest that EKV associated Cx31 mutants mistraffic and lead to ER stress associated cell death. Our recent study suggests that Cx31R42P forms constitutive-active hemichannels leading to hemichannel activity-dependent necrotic cell death. Using electronic microscopy, we here provide direct evidence of hemichannel formation by Cx31R42P. We have also identified that WIN55212-2 and SR141716, two cannabinoid receptor ligands, suppress Cx31R42P-induced cell death via small molecule screening. Both compounds inhibit hemichannel activity but via distinct mechanisms. Results from this study suggest that abnormal hemichannel activity is the main reason for Cx31R42P associated cell death and identify cannabinoid receptor ligands as potential treatments for EKV disease.

**Stimulant Effects of Guarana Versus Caffeine on *Dugesia dorotocephala*.**

*D. Moustakas*<sup>1</sup>, *E. Pineda*<sup>1</sup>, *M-A. Constable*<sup>1</sup>, *J. G. Golfinos*<sup>2</sup>, *K. Higgins*<sup>1</sup>, *E. B. Voura*<sup>1,2</sup>;  
<sup>1</sup>Dominican College, Orangeburg, NY, <sup>2</sup>New York University Langone Medical Center, New York, NY

The planarian is an ideal model organism for both developmental and behavioral studies. Planarians prefer darkness and use photoreceptors to detect and avoid light. This behavioral feature provides one means for the associative conditioning or training of these organisms. Further, the locomotor activity (pLMV) and convulsive (c-type) response of planarians with drug exposure has been shown to provide an excellent system to gauge the effects of drug stimulation, addiction and withdrawal. Caffeine is a natural stimulant found in the nuts, leaves and berries of many plants, and prior studies have documented the effects of caffeine on planarian behavior. Guarana is a climbing plant native to the Amazon and Brazil whose seeds contain approximately four times the amount of caffeine found in coffee beans. The mix of other natural chemicals unique to Guarana is suggested to heighten the tonic-type effects of Guarana over caffeine alone. Because of this additive stimulation, the use of Guarana seed extracts is on the rise. Yet, despite the growing use of Guarana as an additive in energy drinks, and a burgeoning market for it as a nutritional supplement, the scientific literature documenting the short-term and long-term effects purportedly attributed to the chemicals they contain is limited. To demonstrate the effects of Guarana, the locomotor activity and reaction time of the planarian species *Dugesia dorotocephala* was tested to gauge the alertness and activity of the flatworms cultured in the presence of the stimulant. Studies examining the physiological effects of Guarana in contrast to, and in combination with, caffeine and glucose were also begun. This work provides an important background for further experimentation using maze learning and memory tests to assess the longer-term effects of Guarana stimulation.

2158

**Cigarette Smoke Toxins on Surfaces are a Major Health Threat for Children and the Elderly.**

*M. Martins-Green*<sup>1</sup>, *N. Adhami*<sup>1</sup>, *M. Valdez*<sup>1</sup>, *M. Frankos*<sup>1</sup>, *B. Goodwin*<sup>1</sup>, *B. Martinez*<sup>1</sup>, *S. Dhall*<sup>1</sup>, *P. Jacob*<sup>2</sup>, *C. Havel*<sup>2</sup>, *L. Yu*<sup>2</sup>, *M. Curras-Colazzo*<sup>1</sup>; <sup>1</sup>Cell Biology & Neuroscience, UC Riverside, Riverside, CA, <sup>2</sup>Department of Psychiatry, UC San Francisco, San Francisco, CA

Although at least the western nations are making extensive efforts to reduce cigarette smoking, it remains a major health threat for smokers and nonsmokers alike. Moreover, it becomes increasingly clear that the threat is not only during the act of smoking but also to those who share closed spaces with smokers. It is now well known that Second Hand Smoke (SHS) is much more toxic than directly-inhaled smoke and recently, a new and potentially even greater threat has been discovered – Third Hand Smoke (THS) – the accumulation of SHS on environmental surfaces. THS ages with time, becoming progressively more toxic and making it a serious health threat to children, the elderly and those who work in environments where smoking is or has been allowed. We present here the results in vivo showing the effects of THS on multiple organs. We show that significant damage occurs to liver, lung and healing of wounds and that the THS-exposed animals display altered behavior that resembles hyperactivity in humans. In the liver, exposure of mice to THS leads to enhanced lipid concentrations and nonalcoholic fatty liver disease (NAFLD), a precursor to cirrhosis and cancer and potentially a contributor to cardiovascular disease. In lung, THS stimulates excess collagen production and deposition and high levels of inflammatory cytokines, suggesting propensity for fibrosis with implications for Chronic Obstructive Pulmonary Disease (COPD). Mice exposed to

THS show impaired healing of skin wounds that have many characteristics of the poor healing of surgical incisions in human smokers. Lastly, mice exposed to THS become hyperactive and show reduced ability to socialize, as delineated by several behavioral tests. These data are of broad importance because they demonstrate the need for policies governing cleaning of hotel rooms, rental cars, re-rented apartments, etc. and education of parents who smoke.

2159

**The role of redox stress in the development of chronic wounds.**

S. Dhall<sup>1,2</sup>, M. Martins-Green<sup>1,2</sup>; <sup>1</sup>Bioengineering Interdepartmental Graduate Program, UC Riverside, Riverside, CA, <sup>2</sup>Cell Biology & Neuroscience, UC Riverside, Riverside, CA

Cutaneous wound healing is a complex event consisting of sequential, overlapping, phases: hemostasis, controlled oxidative stress response, inflammation, re-epithelialization, granulation tissue formation, and remodeling. When wounds do not progress through these stages, the course of healing derails and problematic healing ensues. Chronic wounds, such as diabetic foot, pressure and venous ulcers, have a significant impact on human health, affecting ~5.7M people and costing ~\$20B/year in the US alone. Advancing knowledge of chronic wound development requires animal models. We have shown recently that absence of the gene for Tumor Necrosis Factor Superfamily Member 14 (TNFSF14/LIGHT) in mice results in abnormal healing that can develop into chronic wounds that mimic chronic ulcers in humans. We hypothesized that oxidative stress is increased in the LIGHT<sup>-/-</sup> wounds and that it is critically involved in the LIGHT<sup>-/-</sup> impaired healing. In chronic human wounds, the levels of reactive oxygen species (ROS) and reactive nitrogen species (RNS) are high and lead to deleterious effects because they cause oxidative stress, with consequent significant cell damage and increased inflammation. We show that the level of H<sub>2</sub>O<sub>2</sub> is high in adult LIGHT<sup>-/-</sup> mice and increases with age much like in humans. However, the levels of the anti-oxidant enzymes catalase and glutathione are not elevated, hence these wounds have excessive ROS. Nitrotyrosine is also high, suggesting elevated peroxynitrite anion, a highly reactive nitrogen species and nitrating agent that damages a wide array of molecules. As a result of high oxidative stress, cell death by necrosis is high, further enhancing inflammation and impaired healing. Perturbation of critical parameters in these wounds leads to chronicity. In conclusion: By modifying the wound environment, *we have successfully produced the first model of chronic wounds*. We are using this model to understand mechanisms involved in chronic wound development to identify potential targets for treatment of humans.

**TP508, a novel peptide, rescues loss of stemness in the colonic crypts of mice in response to radiation damage.**

C. Kantara<sup>1,2</sup>, D. Ambriz<sup>2</sup>, P. Singh<sup>1</sup>, D. Carney<sup>2</sup>; <sup>1</sup>Neuroscience and Cell Biology, University of Texas Medical Branch, Galveston, TX, <sup>2</sup>Biochemistry and Molecular Biology, University of Texas Medical Branch, Galveston, TX

Background: In recent years, the threat of radiation exposure has significantly increased worldwide. In 2011, Japan was hit with a series of earthquakes, damaging the nuclear reactors and exposing thousands of people to high levels of radiation. More recently, nuclear threats against the US and other countries are becoming a concern. Therefore, it is crucial to develop effective medicinal countermeasures to mitigate the effects of radiation exposure and prevent calamitous death rates wherever an accidental or intentional nuclear event may occur. TP508, also known as Chrysalin®, developed by Dr. Darrell Carney, is an investigational drug which has been shown to mitigate the effects of whole body nuclear radiation (8Gy) in mice, and to

reduce mortality and morbidity of the irradiated mice. In addition, TP508 treatment post-exposure delayed mortality of mice exposed to lethal doses of radiation (12Gy), and prevented radiation-induced apoptosis. We now have examined possible protective effects of TP508 on stemness/phenotype of intestinal crypts, which may contribute to the previously observed reduction in mortality of irradiated mice treated with TP508. Methods: CD-1 (IRC) mice (in groups of 5) were either exposed to whole body gamma radiation (9Gy), or not irradiated, followed by i.p treatment of  $\pm$  500  $\mu$ g TP508, 24 hrs post-irradiation. Group 1 received no radiation+saline, group 2 received no radiation+TP508, group 3 received a lethal dose (9Gy) of radiation+saline and group 4 received radiation+TP508. Mice were euthanized 12 days post exposure and colonic crypts were isolated and analyzed for their length and architecture. Colons were also processed for immunofluorescence and Western blot analysis for stem cell populations, expressing DCLK1, LGR5 and CD44. Results: Our results demonstrated that lengths of colonic crypts were significantly decreased in irradiated versus non-irradiated mice; however, treatment with TP508 reversed the deleterious effects of irradiation on the morphology and lengths of colonic crypts. Western blot analysis for the indicated stem cell markers, strongly suggested that TP508 effectively protects against the loss of stem cell populations in the colonic crypts of irradiated mice. Conclusions: These findings suggest that TP508 may protect stem cell populations from deleterious effects of irradiation, and thus contribute towards reversing the damaging effects of irradiation on length/morphology of colonic crypts. We therefore postulate that TP508 can be developed as an effective novel drug for mitigating effects of radiation exposure.

### **Stem cell expansion, characterization and health monitoring in a scalable bioreactor system.**

*M. Aysola<sup>1</sup>, S. Punreddy<sup>1</sup>, A. Verma<sup>1</sup>, K. Mann<sup>1</sup>, E. Binder<sup>2</sup>, D. Jing<sup>1</sup>, D. Kehoe<sup>1</sup>, N. Sunil<sup>1</sup>, K. Niss<sup>1</sup>, M. Rook<sup>1</sup>, J. Murrell<sup>1</sup>; <sup>1</sup>EMD Millipore, Bedford, MA, <sup>2</sup>Merck Millipore, Darmstadt, Germany*

Progenitor cells are an attractive target for clinical study as therapeutic agents. However, current multilayer flatbed culture expansion paradigms are cumbersome, time consuming, costly and typically limited in the ability to monitor cell quality attributes during the growth process. We demonstrated a new expansion paradigm that uses a three liter, single use, stirred tank bioreactor with a microcarrier scaffold for suspension expansion of human mesenchymal stromal/stem cells (hMSCs), one example of progenitor cells. The bioreactor is a scalable system that enables sampling throughout the expansion run so cells can be monitored for quality and to ensure they maintain the desired undifferentiated state. We describe implementation of a panel of assays that characterize the cell state and the identity and purity of the cells during expansion and purification. Cell state assays include cell cycle, viability and apoptosis. Identity and purity were assessed using both the standard recommended ISCT panel of positive and negative markers in addition to markers indicative of hMSC properties. We demonstrated that positive markers such as Thy-1 (CD90), Endoglin (CD105) and SH3/4 (CD73) were expressed in >95% of viable cells, markers of hematopoietic origin such as CD34, CD45, CD11b and other markers such as HLA-DR were expressed in <2% of cells per the ICST guidelines. We also demonstrated the use of additional hMSC markers such as H-Cam (CD44), PD-L1 (CD274), V-CAM (CD106) for characterizing the hMSCs with respect to their age and induction state. When we intentionally change the system, an increased fraction of apoptotic cells (34% versus 10% control) correlated to poor cell yield (50 million cells versus 300 million

cells at day 12). In a perturbed system, deviations from the expected percentages for ISCT panel and expanded marker panel clearly identify poor cell/process quality. The combination of cell state and marker panels for identity and purity can be considered a process monitoring tool for expansion of hMSCs in addition to a quality control assessment following expansion. As processes scale, establishing a validation window within which the process should operate is critical; using markers such as these allows one to establish the boundary conditions. Thus, we have demonstrated use of a scalable bioreactor system to expand, monitor and characterize progenitor cells.

### **Efficacy Evaluation of #101 pills on Indomethacin Induced Gastric Mucosal Damage in Rats.**

*S. Lee<sup>1</sup>, J. Jung<sup>1</sup>, J. Kim<sup>2</sup>, D. Kim<sup>1</sup>, H. Jang<sup>1</sup>, J. Kim<sup>3</sup>, W. Lee<sup>1</sup>; <sup>1</sup>Inha university, Incheon, Korea, <sup>2</sup>NCEED, Inha Hospital, Incheon, Korea, <sup>3</sup>Sadang Oriental Medical Clinic, Seoul, Korea*

#101 pills were used in clinically for digestive problems including gastritis. But its efficacy does not evaluated and confirmed on scientific methods such as in vivo approach with animal models. In the present study we have investigated the efficacy of #101 pills on its anti-ulcer effect using indomethacin induced gastric mucosal damage in rats.

We divided the animals into 4 groups as follows: (1) vehicle control, (2) 25 mg/kg indomethacin, (3) 25 mg/kg indomethacin + 250 mg/kg #101 pills [repetitive administration], (4) 25 mg/kg indomethacin + 500 mg/kg #101 pills [single administration]. In groups 2, 3 and 4, indomethacin was given at 30 minutes after #101 pills administration. 25 mg/kg indomethacin was given to all rats (n=10) by oral gavage in 3% sodium bicarbonate. Seven hours after, the entire rats were sacrificed and confirmed gastrointestinal erosions and ulcers.

Pretreatment with #101 pills at 30 minutes before administration of indomethacin resulted in a decrease score in gastric damage areas in the entire group treated. And also, gastric acid volume was decreased in as well. Based on H&E staining and its scoring on histopathology, single administration group with #101 pills had more effective on the reducing of gastric mucosal damage. Our data suggests that #101 pills accomplish the protective effect on indomethacin-induced gastric mucosal damage.

### **Autoantibodies in Senear-Usher syndrome are the result of inter-molecular epitope spreading.**

*E. Pérez-Pérez<sup>1</sup>, E. Avalos-Díaz<sup>1</sup>, R. Herrera-Esparza<sup>1</sup>; <sup>1</sup>Immunology, Universidad Autónoma de Zacatecas, Zacatecas, Mexico*

Senear Usher syndrome is a pathology that overlaps clinical and serological data of pemphigus foliaceus and lupus erythematosus. Skin biopsies of these patients exhibit acantholysis and immunoglobulin's deposition at desmosomes, together with positive lupus band test. Given that Senear-Usher patients have pemphigus and lupus autoantibodies and the disease clinically behaves as benign variant of pemphigus and cutaneous lupus, the major issues that we attempt to address are the following: It is possible that Senear Usher autoantibodies were connected with a single antigen? If so, such poly-reactivity might result of cross-reactivity or instead: Are the antibodies the result of stimulus to independent B cell clones by different antigens? In such case, the poly-reactivity could result of inter-molecular epitope spreading. Sera from patients

with Senear Usher were studied using immunofluorescence and ELISA against recombinant desmogleins 1 and 3, and RNP/Sm, Ro and La ribonucleoproteins and nDNA to determine the fine antigenic specificity. Bound specific autoantibodies to cow nose (used as antigenic substrate and previously digested with nucleases or trypsin) were eluted by 0.2M glycine and recovered, and then tested by double fluorescence assays to tag desmosome in green or nucleus-cytoplasmic antigens in red.

Our present investigation demonstrates that patients with Senear Usher disease share anti-epithelial antibodies specific to desmoglein 1 or 3, together with anti-nuclear antibodies specific to Ro, La, Sm or double-stranded DNA antigens. By double fluorescence assays using specific anti-epithelial or anti-nuclear antibodies recovered after elution, a lack of cross-reactivity between desmosomes and nuclear or cytoplasmic lupus antigens was demonstrated, therefore this result suggests that Senear-Usher auto antibodies are directed against different antigens and they are produced by independent B cell clones. Additionally, the molecular evolution of the immune specificity response was tracked through ten years, the result of this analysis yield the conclusion that desmoglein complex (Dsg 1) was the initial target, because anti-epithelial antibody appeared several months or years before than the anti-nuclear response. Finally, considering the clinical and serology data we suggest that Senear Usher syndrome behaves as a multiple autoimmunity disease. It is accepted that different disease co-exist in a single patient by multiple autoimmunity, the involved mechanisms are largely unknown however some clues have been arising of certain MHC alleles who define the clinical expression of autoimmunity; for instance in blistering autoimmune diseases the DQB1\*0301 allele may drive two simultaneous autoimmune responses that under different stereo chemical conditions can bind two T-dependent epitope residues, like desmogleins or BP 180 and under other condition might bind ribonucleoprotein's, such peculiar antigenic driving would result in a dual autoimmune response one organ-specific for pemphigus and another to express another disease phenotype like the cutaneous lupus erythematosus (Clin Exp Immunol 162:224), such kind of dual response might induce inter-molecular epitope spreading this could be the case of Senear Usher disease.

2164

**Hydrogen sulfide inhibits preoptic prostaglandin E2 production during endotoxemia.**

*L. S. Branco<sup>1</sup>, R. N. Soriano<sup>1</sup>, M. Kwiatkoski<sup>1</sup>, E. C. Carnio<sup>1</sup>; <sup>1</sup>Physiology, University of Sao Paulo, Ribeirão Preto, Brazil*

Hydrogen sulfide (H<sub>2</sub>S) is a gaseous neuromodulator endogenously produced in the brain by the enzyme cystathionine β-synthase (CBS). We tested the hypothesis that H<sub>2</sub>S acts within the anteroventral preoptic region of the hypothalamus (AVPO) modulating the production of prostaglandin (PG) E<sub>2</sub> (the proximal mediator of fever) and cyclic AMP (cAMP). To this end, we recorded deep body temperature (T<sub>b</sub>) of rats before and after pharmacological modulation of the CBSH<sub>2</sub>S system combined or not with lipopolysaccharide (LPS) exposure, and measured the levels of H<sub>2</sub>S, cAMP, and PGE<sub>2</sub> in the AVPO during systemic inflammation. Intracerebroventricular (icv) microinjection of aminoxyacetate (AOA, a CBS inhibitor; 100 pmol) did not affect basal PGE<sub>2</sub> production and T<sub>b</sub>, but enhanced LPS-induced PGE<sub>2</sub> production and fever, indicating that endogenous H<sub>2</sub>S plays an antipyretic role. In agreement, icv microinjection of a H<sub>2</sub>S donor (Na<sub>2</sub>S; 260 nmol) reduced the LPS-induced PGE<sub>2</sub> production and fever. Interestingly, we observed that the AVPO levels of H<sub>2</sub>S were decreased following the immunoinflammatory challenge. Furthermore, fever was associated with decreased levels of AVPO cAMP and increased levels of AVPO PGE<sub>2</sub>. The LPS-induced decreased levels of cAMP were reduced to a lesser extent by the H<sub>2</sub>S donor. The LPS-induced PGE<sub>2</sub> production was potentiated by AOA (the CBS inhibitor) and inhibited by the H<sub>2</sub>S donor. Our data are consistent

with the notion that the gaseous messenger H<sub>2</sub>S synthesis is downregulated during endotoxemia favoring PGE<sub>2</sub> synthesis and lowering cAMP levels in the preoptic hypothalamus.

2165

**Spontaneous Hypertension Is Associated With Inflammatory Response In The GI Tract: Effects of Captopril.**

*I. Khan<sup>1</sup>, A. A. Ghefreh<sup>1</sup>; <sup>1</sup>Biochemistry, Kuwait University, Kuwait, Kuwait*

Hypertension is associated with oxidative stress and inflammatory responses in the target organs however the status of intestine remains to be elucidated. In this study we employed spontaneously hypertensive rats (SHR) to examine the level of myeloperoxidase as a marker of inflammation. Twelve weeks old SHR and their genetic counterparts Wistar Kyoto rats (WKY) as controls were used in this study. Groups of animals were also treated with captopril, an ACE inhibitor starting from week 4 of age until week 12 through water ad libitum (300 mg/L). Hypertension was characterized in terms of BP, kidney and heart hypertrophy and proteinuria. Animals were sacrificed at the end of week 12, ileum and colon were taken out, cleaned with ice cold PBS and stored at -70°C until use. Myeloperoxidase activity was measured using standard spectrophotometric method. SHR animals showed significant increase in blood pressure, weights of heart and kidney and proteinuria in SHR as compared to WKY controls. In both colon and ileum myeloperoxidase activity was increased significantly in SHR as compared to WKY controls. These changes were significantly reversed by captopril treatment of SHR. Captopril under the experimental condition did not affect these parameters in WKY controls. These findings demonstrate development of ileal and colonic inflammation due to hypertension, and suggests an antiinflammatory action of captopril.

**Telomere Dysfunction in Naïve CD4 T cells in Rheumatoid Arthritis.**

*P. J. Hohensinner<sup>1</sup>, J. Grisar<sup>1</sup>, Z. Yang<sup>1</sup>, J. Goronzy<sup>2</sup>, C. Weyand<sup>1</sup>; <sup>1</sup>Stanford University, Stanford, CA, <sup>2</sup>Palo Alto Department of Veterans Affairs Health Care System, Palo Alto, CA*

Background: Telomeres are the natural ends of chromosomes. Naïve CD4 T cells of patients suffering from rheumatoid arthritis (RA) display a premature aging phenotype and a loss of telomeric length. The aim of our study was to determine, if telomeres from RA patients display more telomere damage and DNA damage protein localization and if this can be seen in healthy aging or if telomere dysfunction is a disease specific phenomenon.

Methods: CD4 naïve T cells were isolated from RA patients, age and sex matched controls, and old (mean age 80) and young individuals (mean age 30) using magnetic beads. Telomere damage was measured in metaphase spreads treated with colcemid and subsequent FISH staining. DNA damage foci at the telomere were analyzed with double staining for 53BP1, ATR or BRCA1 and TRF2.

Results: Four parameters of telomere damage are used, a doubling of a signal, apposition of the long chromosome arm, fusion of telomeres and loss of telomeric signal. Naïve CD4 T cells show an increase of double signals (42% versus 32.4% of events) and apposition (22.2% versus 12.4% of events) compared to healthy controls. In addition, we only observed telomeric fusion and telomere loss in nuclei from RA patients (2.9% and 1% of events respectively). In addition, DNA damage foci are increased at telomeres in CD4 naïve T cells from patients with RA including 53BP1 foci (8% in control versus 17% in RA, p<0.05), ATR foci (15% in control versus 33% in RA, p<0.05) and BRCA1 foci (20% in control versus 39% in RA, p<0.05). An

increase of DNA damage repair protein 53BP1 at the telomere is not observed in old healthy individuals (10% versus 8% for young individuals,  $p=0.44$ ). To determine, whether the ATR pathway is activated in RA T cells, we determined the number of pChk1 positive cells. In resting conditions, we did not observe a difference between the amount of pChk1 positive cells between healthy controls and RA patients. However, after 3 days of stimulation we only observed pChk1 positive cells in the RA group (6%), indicating an increased activation of the ATR pathway.

Conclusion: We provide evidence, that naïve CD4 T cells from patients with RA have dysfunctional telomeres and increased localization of DNA damage signaling molecules to the telomere. We did not find a similar response in cells from aging individuals, indicating a disease specific phenotype rather than an age specific phenotype.

### **Galectin-8 knockout mice have sex-dependent altered homeostasis of T and B lymphocytes and autoimmune features.**

*E. Pardo<sup>1,2</sup>, C. Curkovic<sup>1,2</sup>, D. Valenzuela<sup>3</sup>, A. González<sup>1,2</sup>, A. Soza<sup>1,2</sup>; <sup>1</sup>Departamento de Inmunología Clínica y Reumatología, Fac. Medicina, Pontificia Universidad Católica de Chile, Santiago, Chile, <sup>2</sup>Centro de Envejecimiento y Regeneración (CARE), Fac. Ciencias Biológicas, Pontificia Universidad Católica de Chile, Santiago, Chile, <sup>3</sup>Regeneron Pharmaceuticals Inc, New York, NY*

Galectin-8 (Gal-8) regulates a variety of cellular activities interacting with beta-galactosides of cell surface glycoproteins. Its effects in the immune system include stimulation of apoptosis of thymocytes and activated T cells, proliferation of “naïve” T cells and differentiation of B lymphocytes into plasma cells. We have also described function-blocking autoantibodies in patients with systemic lupus erythematosus (SLE) and rheumatoid arthritis. However, the requirement of Gal-8 in immunological functions has not been studied “in vivo”. Here we analyze the expression of Gal-8 in spleen and lymph nodes and lymphocyte subpopulations in a Gal-8-null/LacZ knock-in mice (Gal-8<sup>-/-</sup>). LacZ histochemistry and immunohistochemistry show Gal-8 expressing at specific sites of the spleen and lymph nodes. Strikingly, only female Gal-8<sup>-/-</sup> mice, examined at 8-12 weeks, have increased spleen populations of CD4 and CD8 T lymphocytes and decreased population of B-lymphocytes, without differences in dendritic cells. By the age of 14 months, these female Gal-8<sup>-/-</sup> mice develop alopecia and splenomegaly accompanied by a significant decrease in the population of CD4 and CD8 T lymphocytes and B-lymphocytes. These mice also generate anti-ANA and anti-dsDNA autoantibodies. These features suggest an autoimmune disease such as SLE. These results reveal an important contribution of Gal-8 to the homeostasis of T and B cells, with sexual differences, such that alterations in its function might lead to autoimmunity. ### **Examining the Role of mTOR in T Cell Proliferation and Migration Under Immunosuppression by Rapamycin.**

*M. J. Gregg<sup>1</sup>, M. J. Billard<sup>2</sup>, T. K. Tarrant<sup>3</sup>, Y. J. Miyamoto<sup>1</sup>; <sup>1</sup>Department of Biology, Elon University, Elon, NC, <sup>2</sup>Thurston Arthritis Research Center, University of North Carolina at Chapel Hill, Chapel Hill, NC, <sup>3</sup>Department of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC*

mTOR (mammalian target of rapamycin) is a serine/threonine protein kinase that has a role in cell growth and metabolism. mTOR also is the core of two functional distinct complexes, mTORC1 and mTORC2. mTORC1 has a prominent role in cell growth and proliferation while

mTORC2 has been shown to affect cell proliferation and cytoskeletal organization. However, the role of mTOR signaling in T cell migration is not fully understood. Studies were conducted to determine the effects of rapamycin, an immunosuppressant that targets mTOR, on Jurkat T cell proliferation and migration. Rapamycin treatment of Jurkat cells was expected to inhibit cell proliferation and cell migration due to its inhibition of normal mTOR signaling. Jurkat T cells were stimulated with PMA (50 ng/ml) and PHA (5 $\mu$ g/ml) in the presence or absence of rapamycin (5, 10, 20, 50 nM; 12, 24, and 48 hours). Cell counts at 12, 24, and 48 hours showed a concentration-dependent inhibition of cell proliferation by rapamycin; no significant effects were seen beyond 20 nM of rapamycin. Phosphorylated ERK was also decreased in activated T cells treated with rapamycin as determined by Western blot analysis. Rapamycin also inhibited Jurkat T cell migration toward CXCL12. Results show that even in combination with activating agents, rapamycin inhibits T cell proliferation and migration, suggesting that mTOR signaling may also have an effect on ERK signaling and T cell chemotaxis.

### **TNC Microenvironment Reduces IL-12 Responsiveness In Triple Positive Thymocytes.**

S-A. Miller<sup>1</sup>, S. V. Mills<sup>2</sup>, S. C. Henley<sup>1</sup>, F. R. Davis<sup>1</sup>, R. H. Lewis<sup>2</sup>, M. T. Martinez<sup>2</sup>; <sup>1</sup>Integrative Biosciences, Tuskegee University, Tuskegee Institute, AL, <sup>2</sup>Biology, Tuskegee University, Tuskegee Institute, AL

Interleukin-12 (IL-12) is a heterodimeric, pro-inflammatory cytokine released by antigen presenting cells (APCs) such as macrophages and dendritic cells as well as activated T cells. IL-12 is well documented to favor T-helper differentiation into Th1 effector cells in the periphery. However, IL-12 is also reported to promote apoptosis among the CD4<sup>+</sup>CD8<sup>+</sup> TCR<sup>lo</sup> triple positive (TP) thymocyte subset known to undergo restriction to self major histocompatibility (MHC) proteins in the thymus. Thymic nurse cells (TNCs) are cortical epithelial cells of the thymus that express both class I and class II (MHC) proteins on their cell surfaces. Although TNCs appear to be significant participants in the negative selection of TP thymocytes, they have been shown to rescue a small proportion of these thymocytes from apoptosis. We hypothesized that TNC mediated rescue of TP thymocytes from apoptosis is due to the down regulation of IL-12 responsiveness by these thymocytes. To demonstrate this, timed co-cultures were prepared containing thymocytes and TNCs with and without recombinant IL-12. Thymocytes were harvested from co-cultures and stained with fluorescently-labeled anti-CD4 and anti-CD8 antibodies to identify cells that were double positive for these co-receptors. These thymocytes were also labeled with FITC-conjugated Annexin V for the detection of apoptosis. Labeled cells were analyzed by flow cytometry. As expected apoptosis was found to be severely reduced among double positive thymocytes in all co-cultures containing TNCs. Remarkably, thymocyte rescue from apoptosis was also observed in cultures that included recombinant IL-12, and this rescue was found to be greater than that seen in cultures which did not include the cytokine. Additionally, it was noted that thymocyte rescue from apoptosis in cultures containing recombinant IL-12 did not translate into thymocyte maturation as it did in cultures that did not contain IL-12. Together these observations led to the theory that IL-12 responsiveness among double-positive thymocytes may be down-regulated in the TNC microenvironment. Current experiments are in progress to test this theory.

**RB controls size and cellularity of the mouse thymus.**

*P. M. Garfin<sup>1</sup>, P. Viatour<sup>1</sup>, D. Min<sup>1</sup>, J. Bryson<sup>2</sup>, K. Weinberg<sup>1</sup>, N. Manley<sup>2</sup>, J. Sage<sup>1</sup>; <sup>1</sup>Pediatrics, Stanford University, Stanford, CA, <sup>2</sup>Developmental Biology, University of Georgia, Athens, GA*

The establishment of the thymic microenvironment early in life is crucial for the production of functional T cells. Conversely, thymic involution results in a decreased T cell output. Thymic involution has important health implications especially following bone marrow transplant. Our objective is to determine molecular and cellular mechanisms that will allow for regeneration of involuted thymic tissue, restore production of naïve T cells, and improve immune function. In this pursuit, we have focused on the Retinoblastoma family of tumor suppressor proteins. The main function of the RB pathway is to restrict passage through the G1/S transition of the cell cycle. RB and its two family members, p107 and p130, mediate the action of a broad range of cellular signals to control the proliferation, survival, and differentiation status of a large number of mammalian cell types. We found that inactivation of the RB pathway in the thymus by early deletion of RB family genes prevents thymic involution, promotes expansion of functional thymic epithelial cells (TECs), and increases thymic T cell output. Moreover, we have identified a direct regulatory relationship between RB and the Foxn1 transcription factor. Via E2F transcription factors, where RB/E2F complexes directly repress the Foxn1 promoter, thereby promoting involution. Thus, the RB family is a critical mediator of extra- and intra-cellular signals to regulate thymic epithelial cells and thymus function, and decreasing RB pathway function may promote regeneration of the involuted thymus and restoration of naïve T cell production in patients.

**Gene expression profile of monocytes from patients with chronic kidney disease reveals canonical Wnt signaling activation.**

*H. Al-Chaqqmaqchi<sup>1</sup>, A. Moshfegh<sup>2</sup>, E. Dadfar<sup>3</sup>, J. Paulsson<sup>4</sup>, M. Hassan<sup>1</sup>, S. Jacobson<sup>5,6</sup>, J. Lundahl<sup>4</sup>; <sup>1</sup>Laboratory Medicine, Karolinska Institutet, Stockholm, Sweden, <sup>2</sup>Oncology Pathology, Karolinska Institutet, Stockholm, Sweden, <sup>3</sup>Department of Medicine, Karolinska Institutet, Stockholm, Sweden, <sup>4</sup>Clinical Immunology and Transfusion Medicine, Karolinska Institutet, Stockholm, Sweden, <sup>5</sup>Department of Nephrology, Danderyd University Hospital, Stockholm, Sweden, <sup>6</sup>Department of Clinical Sciences, Karolinska Institutet, Stockholm, Sweden*

**Objectives:** Patients with chronic kidney disease (CKD) have an increased susceptibility to infections and one contributing factor is dysfunctional leukocytes. Monocytes play a central role in immunity as a link between the innate and the adaptive immune responses. This study was conducted to investigate the gene expression profile of monocytes to understand the underlying molecular mechanism behind CKD.

**Methods:** Monocytes from CKD patients with glomerular filtration rate (GFR) < 20 ml/min were obtained from peripheral blood by density centrifugation and purified with anti-CD14 Mini-MACS beads. Samples from healthy subjects were run in parallel. Microarray gene expression profile was performed using Affymetrix human Gene Chips U133A. Data were interpreted by GeneSpring™ software. Genes demonstrated a differential expression of 1.5 Fold (F) or more and were statistically significant (P<0.05), further analyzed. The on line PANTHER classification system website was used for pathway analysis.

**Results:** The gene expression profile demonstrated up regulation of 487 genes and down regulation of 258 genes in the CKD group compared to healthy controls. Pathway analysis revealed that Wnt signaling has the highest score among the pathways affected in the CKD group. Several genes demonstrated up regulation including Wnt5a (3.6 F), FZD4 (2 F), LEF1 (1.6 F),

TCF3 (2.2 F) and TCF7 (1.6 F) respectively. Typically, Wnt5a through FZD4 leads to canonical Wnt signaling pathway activation with inhibition of  $\beta$ -catenin degradation.

Conclusions: This study demonstrates crucial difference in the monocyte gene expression profile between CKD patients and healthy subjects. The canonical Wnt signaling pathway is activated in monocytes from CKD patients which leads to lesser  $\beta$ -catenin degradation and hence its accumulation in the cytoplasm. Since  $\beta$ -catenin affects monocyte adhesion and transmigration, our finding may contribute to monocyte dysfunction and to the pathogenesis of complications observed in CKD. Therefore developing strategies to interfere with this pathway could improve prognosis regarding general immunity and prevention of complications.

**Individual platelet contraction dynamics stimulated via two distinct signaling pathways.**

*G. Ramirez-San Juan<sup>1</sup>, P. Oakes<sup>1</sup>, M. Gardel<sup>1</sup>; <sup>1</sup>University of Chicago, Chicago, IL*

Platelet adhesion to sites of vascular injury occurs when extra cellular matrix components become exposed to the bloodstream. After adhesion, activation of platelets can be mediated by two independent signaling pathways. One involves the exposure of subendothelial matrix collagen, while another relies on the release of tissue factor and its downstream effectors for platelet activation. Surprisingly, much of the previous work studying platelet force generation relied on bulk assays that calculated individual platelet contraction from macroscopic measurements. These results give little insight into how single platelets contribute to the overall force generation of an aggregate. Here we analyzed individual platelet activation dynamics using traction force microscopy, mapping the stress fields of isolated platelets adhered to polyacrylamide substrates coated with physiologically relevant ECM proteins (collagen, fibrinogen and fibronectin). We find that for all substrates, platelets are capable of generating forces of  $\approx 100$  nN upon contraction. Interestingly, interaction with collagen and fibrinogen coated substrates was sufficient to induce immediate platelet activation, while on fibronectin coated surfaces, platelets would adhere and spread without contracting. Contraction could then be stimulated on fibronectin coated substrates through the addition of epinephrine. These data suggest that we can successfully activate platelets through inside-out and outside-in signaling pathways, which is consistent with previous in vivo thrombus formation studies that identified two independent signaling pathways for platelet activation. Furthermore, since platelets produced the same amount of force on each substrate, these data indicate that the force response of individual platelets is independent of the mechanism of activation. Together these findings highlight the promising new research avenues that can be explored by studying isolated platelet adhesion and contraction.

## Establishing and Maintaining Organelle Structure

**Obscurin is Required for AnkyrinB-dependent Localization of Dystrophin and Sarcolemmal Integrity in Skeletal Muscle Fibers.**

*D. Randazzo<sup>1</sup>, E. Giacomello<sup>1</sup>, S. Lorenzini<sup>1</sup>, C. Reggiani<sup>2</sup>, S. Lange<sup>3</sup>, A. K. Peter<sup>3</sup>, J. Chen<sup>3</sup>, V. Sorrentino<sup>1</sup>; <sup>1</sup>University of Siena, Siena, Italy, <sup>2</sup>University of Padova, Padova, Italy, <sup>3</sup>University of California, San Diego, San Diego, CA*

Obscurin is a recently identified sarcomeric giant protein that participates in the organization of the sarcomere at the M band. In addition to interact with sarcomeric proteins, obscurin can also bind some muscle-specific ankyrins. Interaction between obscurin and the muscle-specific

ankyrin sAnk1.5 has been found to regulate the organization of the sarcoplasmic reticulum in striated muscles. Additional muscle-specific ankyrin isoforms, namely ankB and ankG, are localized at the sub-sarcolemma level and have been shown to contribute to the organization of dystrophin and  $\beta$ -dystroglycan at costameres. Accordingly, we investigated whether obscurin might be involved in the sub-sarcolemmal localization of ankB and ankG and eventually in the assembly of dystrophin and  $\beta$ -dystroglycan at costameres in skeletal muscle fibers. In vitro experiments indicated that obscurin can bind to ankB and ankG. Furthermore, we found that in mice deficient for obscurin, ankB was displaced from its localization at the M-band, while localization of ankG at Z-disk was not affected. In obscurin KO mice, localization at costameres of dystrophin, but not of  $\beta$ -dystroglycan, was altered and the sub-sarcolemma microtubule cytoskeleton was disrupted. In addition, these mutant mice displayed sarcolemmal fragility and reduced muscle strength. Altogether, these results support a model where obscurin, by targeting ankB at the M-band, contributes to the organization of sub-sarcolemma microtubules, localization of dystrophin at costameres and to maintenance of sarcolemmal integrity. These results add a new twist to obscurin function due to interaction with proteins of the extra-sarcomeric cytoskeleton. Accordingly, obscurin appears to represent a multifunctional anchoring protein that on one hand establishes interactions with sarcomeric proteins and on the other hand enables complex formation with extra-sarcomeric proteins, like the muscle-specific ankyrin isoforms, that help to connect the sarcomeres with the SR and with the sub-sarcolemmal cytoskeleton.

2174

#### **ELP1 connects Endoplasmic Reticulum to Mitochondria.**

S. Sonn<sup>1</sup>, S-J. Jeong<sup>1</sup>, C-J. Lim<sup>1</sup>, G. Oh<sup>1</sup>; <sup>1</sup>Division of Life and Pharmaceutical Science, Ewha Womans University, Seoul 120-750, Seoul, Korea

Intercommunication between the endoplasmic reticulum (ER) and mitochondrion is important for  $Ca^{2+}$  signaling and cell viability. However, the molecular mechanisms controlling this interaction are largely unknown. The ER supplies  $Ca^{2+}$  directly to mitochondria via inositol 1, 4, 5-trisphosphate receptors (IP3Rs). Here we found new ER protein ELP1 (endoplasmic reticulum localizes protein 1), is enriched at ER-mitochondria connection. Removal of ELP1 in mouse embryonic fibroblasts or silencing of ELP1 in HeLa cells show ER abnormal morphology and disconnect ER-mitochondria interactions, for this reason leading to a reduced  $Ca^{2+}$  signaling into mitochondria via IP3Rs. ELP1 form a complex at ER-mitochondria connection with prohibitin and chaperone, BiP (GRP78). The ER chaperones are important in maintaining cellular  $Ca^{2+}$  level, majority of ER chaperones, including BiP, calreticulin, and calnexin, serve to store ER  $Ca^{2+}$  as high-capacity  $Ca^{2+}$ -binding proteins. Therefore, ELP1 connects ER to mitochondria and regulates ER-mitochondrial  $Ca^{2+}$  signaling.

2175

#### **Plasma membrane tethering of the cortical ER necessitates its finely reticulated architecture.**

D. Zhang<sup>1,2</sup>, A. Vjestica<sup>1,2</sup>, S. Oliferenko<sup>1,2</sup>; <sup>1</sup>Temasek Life Sciences Laboratory, Singapore, Singapore, <sup>2</sup>Department of Biological Science, National University of Singapore, Singapore, Singapore

The cortical endoplasmic reticulum (ER) is an intricate network of tubules and cisternae tightly associated with the plasma membrane (PM) in plants, yeast and the excitable cell types in metazoans. How the ER is attached to the cell cortex and what necessitates its highly reticulated architecture remain unknown. Using a combination of mutants where the cortical ER

is detached from the PM and a set of artificial ER-PM tethers suppressing this phenotype we show that the footprint of the cortical ER is functionally insulated from the cellular interior in the fission yeast *Schizosaccharomyces pombe*. Conversion of the reticulated ER structure to the sheet-like morphology blocks large areas of the cellular cortex from interaction with the peripherally associated protein complexes. Importantly, our work provides a mechanistic explanation for the severe division site positioning defects in fission yeast cells lacking the ER membrane tubulating proteins. We propose that fine reticulation of the ER network may have emerged as a critical adaptation enabling access of protein complexes to the inner surface of the plasma membrane.

2176

**Type 1 inositol 1,4,5 tri phosphate receptor is required for Endoplasmic reticulum clustering and Calcium oscillation in mouse oocyte maturation.**

S-Y. Yoon<sup>1</sup>, H. Lee<sup>2</sup>, D. Lee<sup>3</sup>, R. Fissore<sup>2</sup>; <sup>1</sup>CHA university, Seoul, Korea, <sup>2</sup>University of Massachusetts, Amherst, MA, <sup>3</sup>Department of Biomedical Science, College of Life Science, CHA university, Seoul, Korea

Type 1 inositol 1,4,5 tri phosphate receptor (IP3R1) and Endoplasmic reticulum (ER) become redistributed during mouse oocyte maturation from the germinal vesicle (GV) stage to the metaphase II (MII) stage. We investigated is the impact of redistribution of IP3R1 on ER clustering during oocyte maturation by first degrading endogenous IP3R1 with injection of GV oocytes with Adenophostin A (AdA), a non-hydrolyzable analogue of IP3, then expressing exogenous IP3R1 with injection of IP3R1 cDNA. To examine IP3R1 redistribution, we used immunofluorescence and for ER clustering, we used DiIC. There is no effect of injection of AdA and IP3R1 cDNA on the in vitro maturation rate. Western blot analysis of the IP3R1 in eggs after in vitro maturation demonstrated a 85% decrease in immunoreactive mass of the IP3R1 in AdA-injected eggs compared to control eggs. In eggs injected with IP3R1 cDNA following Ada injection, immunoreactive mass of IP3R1 was increased 1.5 fold from that of control eggs. Immunofluorescence of IP3R1 and ER staining of In vitro matured MII egg demonstrated that cortical clusters localize near plasma membrane in control eggs, but Ada injection inhibits cortical cluster formation of IP3R1 and ER. On the other hand, eggs injected with IP3R1 cDNA after Ada injection recovered cortical cluster formation of IP3R1, but ER clusters. Knockdown IP3R1 eggs showed low [Ca<sup>2+</sup>]<sub>i</sub> responses to mPLCzeta cRNA injection, but IP3R-1 overexpressing eggs demonstrated persistent, albeit delayed, [Ca<sup>2+</sup>]<sub>i</sub> responses to the injection of the mPLCzeta cRNA.

We therefore hypothesize that IP3R-1s are required for ER cluster formation during mouse oocyte maturation via homotypic and heterotypic interactions. From these results, we hypothesize that IP3R1s are required for ER cluster formation during mouse oocyte maturation via homotypic and heterotypic interactions. This research was supported by Basic Science Research Program through the National Research Foundation of Korea(NRF) funded by the Ministry of Education, Science and Technology(2012R1A1A3010811)

**Contacts between the endoplasmic reticulum and the plasma membrane mediated by Extended-Synaptotagmins are regulated by PI(4,5)P<sub>2</sub>.**

Y. Saheki<sup>1</sup>, F. Giordano<sup>1</sup>, O. Idevall-Hagren<sup>1</sup>, N. Borgese<sup>2</sup>, P. De Camilli<sup>1</sup>; <sup>1</sup>Yasunori Saheki and Francesca Giordano equally contributed to this work (See also abstract by Giordano, Saheki et al.). Department of Cell Biology, Program in Cellular Neuroscience, Neurodegeneration and Repair, and Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT, <sup>2</sup>CNR Institute of Neuroscience, University of Catanzaro, Milan, Italy

The endoplasmic reticulum (ER) forms a complex network of cisternae and tubules that extends throughout the cell and participates in multiple contacts with virtually all other membranes, including the plasma membrane (PM). Direct contacts between the ER and the PM have long been known to participate in depolarization-contraction coupling in muscle cells via their regulation of Ca<sup>2+</sup> fluxes. More recently, a general role of ER-PM contact sites in the regulation of Ca<sup>2+</sup> homeostasis and in other functions, such as lipid transfer and phosphorylation-dephosphorylation of proteins and lipids in the PM by ER-anchored proteins, has been appreciated. However, evolutionary conserved molecular mechanisms that mediate such contacts have remained elusive. In a companion Abstract (Giordano, Saheki et al.), we report that a family of multiple C2 domain-containing proteins, the Extended-Synaptotagmins (E-Syt1, E-Syt2 and E-Syt3), are cortical ER-enriched proteins that mediate such bridges (see also Abstract by Manford et al. on the tricalbins, the yeast homologue of the E-Syts). E-Syts had been proposed to be transmembrane proteins with a single transmembrane span. However, E-Syts lack a signal sequence, and analysis of the membrane topology of the E-Syts revealed that both the N- and C-terminus are localized in the cytosol, suggesting a hairpin-insertion. Accordingly, the single hydrophobic stretch predicted to represent the membrane anchor is longer than a typical transmembrane span and is reminiscent of hydrophobic amino acid stretches shown to form hairpin in the ER membrane such as those of the reticulons and of REEP. The property of E-Syt2 and E-Syt3 to bind the PM, and thus to generate ER-PM contact sites, depends on C2 domains and requires presence of PI(4,5)P<sub>2</sub> in the PM. Acute dephosphorylation of plasma membrane PI(4,5)P<sub>2</sub> via the recruitment of an inositol-5 phosphatase using an optogenetic approach recently developed in our laboratory (Idevall-Hagren et al., PNAS 2012) resulted in the dissociation of the E-Syts from the PM and in their dispersion throughout the entire ER.

Regulated binding of C2 domains to the PI(4,5)P<sub>2</sub> containing bilayer of the PM mediates the recruitment of cytosolic signaling proteins and the interaction and fusion of secretory vesicles, including synaptic vesicles, with this membrane. Our results add a new function to a member of the C2 domain-containing protein family, bridging the ER to the PM.

**A calcium-activated RNase regulates ER morphology.**

M. D. Blower<sup>1</sup>, D. Schwarz<sup>1</sup>; <sup>1</sup>Molecular Biology, Massachusetts General Hospital, Boston, MA

Developmental differentiation results in changes to intracellular organization and organelle structure as cells change to fulfill more specific roles. One of the most dramatic intracellular reorganizations in higher eukaryotes occurs at fertilization, when changes in intracellular calcium concentration lead to large-scale changes in the egg to promote formation of an embryo. While calcium signaling is well known to result in changes to the cell cycle state of the egg it is unknown if calcium affects the transcriptome. While studying posttranscriptional RNA regulation at fertilization we discovered an endoribonuclease that is activated by the increase in

calcium concentration at fertilization. We purified this nuclease from *Xenopus* egg extracts and identified the nuclease as EndoU, a ribonuclease previously implicated in snoRNA processing. EndoU is a calcium-activated nuclease in vitro and in vivo with weak sequence preference for poly-U. Interestingly, EndoU copurifies with many ER-resident proteins and localizes to the ER in a variety of cell types. Immunodepletion of EndoU from *Xenopus* egg extracts results in defects in nuclear envelope assembly and dramatic failures in ER-vesicle fusion, suggesting that local degradation of ER-localized transcripts plays a role in controlling ER morphology. We have used RNA-sequencing to identify several hundred transcripts that are degraded at fertilization in an EndoU-dependent manner, which includes many ER-localized transcripts. To determine if EndoU-mediated control of ER morphology is conserved in other cell types we have examined the function of EndoU in human tissue culture cells. Human EndoU is also localized to the ER and RNAi knock-down of hEndoU results in a dramatic change in ER morphology from a balance of ER tubules and sheets to almost exclusively ER-sheets, demonstrating that local control of RNA stability is important for ER morphology in many cell types. Our results identify a novel role for localized transcript destruction in control of organelle structure and may provide a molecular basis for the longstanding observation that calcium signaling is required for nuclear envelope formation and proper ER morphology.

2179

**ER-PM contact sites essential for maintaining both ER morphology and cell signaling pathways.**

A. G. Manford<sup>1</sup>, C. J. Stefan<sup>1</sup>, J. A. MacGurn<sup>1</sup>, S. D. Emr<sup>1</sup>; <sup>1</sup>Weill Institute for Cell & Molecular Biology, Cornell University, Ithaca, NY

Junctions between the peripheral endoplasmic reticulum (ER) and the plasma membrane (PM) are conserved structures with important roles in calcium and phosphoinositide lipid signaling. However, little is known about additional functions for these connections or the structural components that form them. Utilizing quantitative proteomics and electron microscopy experiments in yeast, we demonstrate that the tricalbin proteins (orthologs of the extended synaptotagmins, E-Syt1/2/3, see abstract by Giordano and Saheki), Ist2 (a member of the TMEM16 family of ion channels), and the VAP proteins, Scs2/22, function to tether the cortical ER to the PM. Cells lacking all three families of tethering proteins (a yeast strain deleted for all six genes) display a striking retraction of the cortical ER from the PM, relocating most of the non-nuclear ER into collapsed cytosolic accumulations and long expanded ER sheets. Thus, these conserved ER-PM tethering proteins contribute to an elegant system of regulatory factors (including the reticulons and atlastin) that shape and organize the peripheral ER network. Consistent with previous work (Stefan et al., 2011), phosphoinositide metabolism was severely affected in cells lacking ER-PM tethering proteins, due to the loss of function of the ER-localized phosphoinositide phosphatase Sac1. In addition, the generation of a strain lacking PM-ER junctions allowed us the opportunity to investigate novel functions for these structures. Interestingly, we found that the unfolded protein response (UPR) was constitutively activated in cells lacking ER-PM junctions. Our results provide a molecular mechanism for ER-PM contact site formation and we will present new insights into the function of these organelle junctions in the control of phosphoinositide signaling pathways, as well as other essential cellular stress responses.

Stefan, C.J., Manford, A.G., Baird, D., Yamada-Hanff, J., Mao, Y., and Emr, S.D. (2011). Osh proteins regulate phosphoinositide metabolism at ER-plasma membrane contact sites. *Cell* 144, 389-401.

2180

**Formal evidence using enucleation for the non-genomic effects of STAT5 on endoplasmic reticulum structure.**

J. E. Lee<sup>1</sup>, P. B. Sehgal<sup>2</sup>; <sup>1</sup>Cell Biology and Anatomy, New York Medical College, Valhalla, NY, <sup>2</sup>Cell Biology and Anatomy, and Medicine, New York Medical College, Valhalla, NY

STAT5a/b are classically known as transcription factors that mediate estrogen and prolactin signaling through nuclear transcription. We previously showed that siRNA-mediated knockdown of STAT5a/b in a variety of cell types rapidly led to the development of a dramatic cystic change in the endoplasmic reticulum (ER) characterized by deposition of reticulon-4 and atlastin-3 along cyst membranes and tubule to cyst boundaries, as well as Golgi and mitochondrial fragmentation (Lee et al. 2012). In human pulmonary arterial endothelial cells (HPAECs) the cysts were verified to be dilatation of rough ER by EM identification of ribosomes on their cytoplasmic surface, the presence of CLIMP63 in the lumen and live-cell imaging showing luminal accumulation of KDEL-mCherry. The observation that the cystic ER phenotype developed in response to STAT5a/b siRNAs in the presence of the transcriptional inhibitor, DRB, suggested that the underlying mechanism was independent of the transcription factor function of STAT5a/b i.e. was non-genomic. We have now formally tested the requirement for the nucleus in eliciting the STAT5a/b-siRNA-induced cystic ER phenotype in adherent HPAECs in 35 mm plastic dishes using the cytochalasin B-centrifugation method of enucleation devised by Prescott (1972). In HPAECs, this method routinely yielded 60-80% enucleation as judged by DAPI staining. Enucleated HPAECs displayed normal eNOS localization, ER morphology, and a compact Golgi apparatus. Remarkably, STAT5a/b siRNAs elicited the cystic ER phenotype in the recovered HPAEC cytoplasts demonstrably lacking a nucleus. There was a striking membrane and intracystic accumulation of the ER “spacer” protein CLIMP63 in both nucleated and enucleated cells exposed to STAT5a/b siRNA. Indeed, CLIMP63 siRNA alone led to the development of a cystic ER phenotype; and the combination of STAT5a/b and CLIMP63 siRNAs led to an even further increase in the percentage of HPAECs in a culture exhibiting a cystic ER phenotype (up to 80%). These studies provide (a) formal evidence that the effects of STAT5a/b siRNA in eliciting the cystic ER phenotype are independent of nuclear function and thus are “non-genomic”, and (b) suggest structural and functional involvement of CLIMP63 in the mechanisms underlying development of the cystic ER phenotype. Supported by NIH R01 HL-087176.

**Nitric oxide scavenging induces a tubule to sheet change in endoplasmic reticulum morphology.**

J. E. Lee<sup>1</sup>, P. B. Sehgal<sup>2</sup>; <sup>1</sup>Cell Biology and Anatomy, New York Medical College, Valhalla, NY, <sup>2</sup>Cell Biology and Anatomy, and Medicine, New York Medical College, Valhalla, NY

Emerging studies have identified nitric oxide (NO) as a regulator of organellar structure and dynamics. We have previously shown that Golgi structure was dependent on NO in that exposure of human endothelial cells to an NO scavenger (c-PTIO) or eNOS siRNA led to Golgi fragmentation. This was blocked by prior over-expression of the DN K44A-Dynamin2 (Dyn2) mutant but not wt Dyn2, or prior treatment with dynasore. Lipton and colleagues (2011) identified increased mitochondrial fission resulting from S-nitrosylation of the dynamin-2 related protein-1 (Drp1). We now report the dependence of endoplasmic reticulum (ER) structure in endothelial cells on NO. Human pulmonary arterial endothelial cells (HPAECs) exposed to the

NO scavenger c-PTIO showed a dramatic tubule to sheet change in ER morphology as assayed using live-cell fluorescence (ER tracker, KDEL-mCherry), immunofluorescence (for RTN4 or ATL3), and electron microscopy methods. This ER change co-developed with an increase in fibrillar mitochondria, and the previously reported Golgi fragmentation. Although Golgi fragmentation was blocked by the expression of K44A-Dyn2, the sheet-dominant ER morphology persisted suggesting that NO regulates these organelles via different mechanisms. Furthermore, NO scavenging led to the accumulation of Sec31A ER exit sites adjacent to the dispersed Golgi fragments. The tubule to sheet change upon NO scavenging is likely due to posttranscriptional changes in ER structural proteins, because (a) it was observed in enucleated HPAEC cytoplasts, (b) Western blotting and immunopanning data showed that RTN4b was increasingly ubiquitinated following c-PTIO exposure, and (c) the proteasomal inhibitor MG132 also produced a tubule to sheet change in ER morphology. Thus, at least in endothelial cells, the morphology of the ER is regulated by nitric oxide. Supported by NIH R01 HL-087176.

**Mitotic ER reorganization is coupled to the cell cycle in the early *Drosophila* embryo.**

Z. J. Bergman<sup>1</sup>, J. D. Mclaurin<sup>1</sup>, B. Riggs<sup>1</sup>; <sup>1</sup>Biology, San Francisco State University, San Francisco, CA

Proper alignment and segregation of the genetic material is a fundamental step during cell division. Lesser known is the proper partitioning of the cytoplasm and its organelles during mitosis. Furthermore, regulation of these organelles and their coupling to karyokinesis is poorly understood. The endoplasmic reticulum (ER), an organelle essential for cellular function, exhibits a dramatic reorganization in mitosis and is also necessary for nuclear pore complex and nuclear envelope formation during mitotic exit. The mechanism driving ER reorganization and its coupling to the cell cycle is currently unknown. Here we show that ER reorganization is directly linked to mitotic progression in the early *Drosophila* embryo. Simultaneous double stranded RNA inhibition of all three *Drosophila* mitotic cyclins (A, B, and B3) or injection of cyclohexamide prior to mitotic entry arrests the embryo in interphase and blocks ER reorganization. We also found that, ER organization can be driven into a mitotic morphology by injection of purified cyclin B. Furthermore, inhibition of the anaphase-promoting complex (APC/C) blocked chromosome segregation and arrested ER organization in a mitotic state. Additionally, small molecule disruptions of the cytoskeleton during mitosis show that changes in ER morphology are dependent upon microtubules and independent of actin filaments. Taken together, these results indicate that ER reorganization during mitosis is directly coupled to the cell cycle and is regulated by mitotic cyclins.

**Regulation of de novo phospholipid synthesis and organelle dynamics in the first division of the *C. elegans* embryo.**

S. Bahmanyar<sup>1</sup>, A. Desai<sup>1</sup>, J. Dixon<sup>2</sup>, K. Oegema<sup>1</sup>; <sup>1</sup>Ludwig Institute for Cancer Research, La Jolla, CA, <sup>2</sup>Department of Pharmacology, UCSD, La Jolla, CA

A conserved role for the phosphatidic acid phosphatase Lipin in regulation of nuclear membranes has been proposed, however how Lipin's biochemical function is related to its cell biological role is not clear. Here, we used the *C. elegans* embryo to study how the structural reorganization of the endoplasmic reticulum and nuclear envelope in mitosis is linked to Lipin's role in phospholipid synthesis. In metazoans, the conversion of phosphatidic acid (PA) to diacylglycerol (DAG) by Lipin is required for the formation of phosphatidylcholine (PC) and phosphatidylethanolamine (PE), which are the major phospholipids in ER membranes. Phosphatidic acid itself is converted to phosphatidylinositol (PI) via the CDP-DAG pathway,

which makes up a smaller portion of the total ER phospholipids. While the majority of *de novo* phospholipid synthesis takes place in interphase, the ER network and NE undergo dramatic structural changes during mitosis. Lipin is highly phosphorylated and less active in mitosis, however the Lipin activating phosphatase CTD-NEP1<sup>SCPL-2</sup> when complexed with NEP1R1<sup>SPO-7</sup> dephosphorylates a pool of Lipin. It has been shown that partial inhibition of Lipin inhibits NE breakdown and causes abnormalities in peripheral ER structure. We found that deletion CTD-NEP1<sup>SCPL-2</sup> has specific effects on ER/NE membranes that phenocopy partial Lipin depletions. CTD-NEP1<sup>SCPL-2</sup> is enriched on nuclear membranes and its phosphatase activity is responsible for observed ER/NE phenotypes. Using high resolution quantitative time-lapse microscopy we find that inhibition of CTD-NEP1<sup>SCPL-2</sup> activity causes premature formation of ER clusters in interphase, and delays the scission of membranes between pronuclei and lamin disassembly in mitosis. The partial delay in lamin disassembly in CTD-NEP1<sup>SCPL-2</sup> deletion embryos is enhanced by perturbation of a nuclear pore complex protein (NPP-12<sup>gp210</sup>) that inhibits lamina disassembly without affecting peripheral ER organization. This additive affect on lamina disassembly causes failure in cytokinesis and increased embryonic lethality. Partial inhibition of enzymes downstream of Lipin that convert DAG to PC/PE cause abnormalities in ER structure and inhibition of NE breakdown that resemble partial inhibition of lipin or deletion of CTD-NEP1<sup>SCPL-2</sup>. These data indicate that either a decrease in PC/PE or an increase in the CDP-DAG pathway for PI synthesis contributes to the observed phenotypes. To test this directly, we depleted enzymes in the CDP-DAG pathway for PI synthesis in the CTD-NEP1<sup>SCPL-2</sup> deletion background and found a complete reversal of observed phenotypes to wild type. Furthermore, we show biochemically that CTD-NEP1<sup>SCPL-2</sup> deletion worms have increased PI levels, while PC/PE levels are not significantly changed. Taken together, we propose that activation of a pool of Lipin in mitosis by CTD-NEP1<sup>SCPL-2</sup> is required to promote synthesis of PC/PE and to maintain low levels of phosphatidic acid for incorporation into PI. These data suggest that modulating PI levels during mitosis has significant effects on ER structure and on the timely disassembly of the nuclear lamina.

### **Protrudin/ZFYVE27 acts antagonistically to atlastin GTPases in tubular ER network formation.**

*J. Chang<sup>1</sup>, S. Lee<sup>1</sup>, C. Blackstone<sup>1</sup>; <sup>1</sup>NINDS, National Institutes of Health, Bethesda, MD*

Hereditary spastic paraplegias (HSPs) are inherited neurological disorders characterized by progressive lower limb spasticity and weakness. Though over 50 genetic loci are known (SPG1-52), over half of HSP cases are caused by pathogenic mutations in four genes encoding proteins that function directly in tubular endoplasmic reticulum (ER) network formation: atlastin-1 (SPG3A), spastin (SPG4), reticulon 2 (SPG12), and REEP1 (SPG31). Thus, understanding the cellular mechanism of ER morphogenesis has been postulated to be critical for uncovering the pathogenic mechanisms of HSP. Here we show that the SPG33 protein protrudin/ZFYVE27 interacts with tubular ER proteins through hydrophobic, intramembrane hairpin domains and functions in ER morphogenesis. Recently, lunapark proteins have been shown to alter ER morphology by counterbalancing atlastin-dependent polygon ring closure. Similar to lunapark, protrudin harbors a consensus Zn<sup>2+</sup>-binding site, and protrudin-depleted cells show increases in ER three-way junctions and polygon formation. While N-terminal membrane-binding domains of protrudin are responsible for ER localization, the C-terminus is essential for ER network formation. In contrast to lunapark, protrudin harbors a FYVE domain, and thus may also function in ER contacts with organelles such as endosomes.

**Atlastin-1 mutant P342S, a new mutation causing SPG3A, disrupts the ER network.***P.-P. Zhu<sup>1</sup>, C. Blackstone<sup>1</sup>; <sup>1</sup>CNU, NIH/NINDS, Bethesda, MD*

Hereditary spastic paraplegias (HSPs) comprise a group of inherited neurological disorders characterized by lower extremity weakness and spasticity. SPG3A, whose protein product is atlastin-1, is the most common gene linked to early-onset, autosomal dominant HSP. Atlastins are an evolutionarily-conserved family, with a GTPase motif near the N-terminus and two closely-spaced transmembrane domains near the C-terminus. The transmembrane domains are required for the interactions with ER-shaping proteins such as REEP1 and reticulon-4a. Atlastin GTPase activity is important for maintaining a normal tubular ER network. In addition, a highly-conserved middle domain is important for oligomerization. Here we describe a novel missense mutation (P342S) in a young girl with SPG3A. This residue is highly conserved among species and in all 3 human atlastins. Mutant atlastin-1 P342S has moderately decreased GTPase activity. Upon overexpression of atlastin-1(P342S) in cells, the ER comprises long tubes and loses its polygonal network. This abnormal morphology is the same as upon expression of the atlastin-1 GTPase mutant K80A. Interestingly, normal ER morphology can be restored in atlastin-1 (P342) overexpressing cells by co-overexpression of atlastin-1 or atlastin-2, but not with atlastin-3. In fibroblasts from the patient, atlastin-1 localization is not different from wild-type cells; in both cases it is punctate along the tubules, including at three-way junctions. In conclusion, the middle domain of atlastins is an important region for atlastin function, probably by affecting oligomerization, but also with some effect on GTPase activity. Atlastin family members can at least partially substitute for one another to maintain the ER network. That signs and symptoms of SPG3A are limited to the central nervous system may reflect not only the fact that atlastin-1 is most enriched there, but also that the very low levels of atlastin-2 in brain are inadequate to compensate for atlastin-1 dysfunction.

**ER Sheet Maintenance is coupled to the Actin Cytoskeleton in Mammalian Cells.***M. Joensuu<sup>1</sup>, M. Puhka<sup>1</sup>, I. Belevich<sup>1</sup>, E. Jokitalo<sup>1</sup>; <sup>1</sup>Electron Microscopy Unit, Institute of Biotechnology, University of Helsinki, Helsinki, Finland*

The endoplasmic reticulum (ER) is a large, single-copy, membrane-bound organelle consisting of an elaborate 3D network with diverse structural domains. It is composed of highly curved and tubular regions, ones that are flat and cisternal, and others that are adapted to form contacts with nearly every other organelle in the cell. The ER structure is mainly defined by the integral ER membrane proteins and by the interactions with the cytoskeleton. It is thought that the ER network is spread throughout the cell to accommodate the vast range of ER functions, but it is not known why the organelle is constantly rearranging. The comprehensive picture on how the ER positioning and spreading is maintained and what are different mechanisms employed to accomplish it, remains unclear.

The ER does not move en masse. Instead, the dynamics of ER is accomplished through network remodelling. The studies on the ER dynamics have been concentrating on the tubules and virtually nothing is known about the dynamics and the maintenance of the sheets. To understand the interplay between ER dynamics, morphology and functions, we must first understand more about the factors involved.

We have previously shown that different mammalian cell types show high variation in their sheet and tubule proportions as well as in the morphology of the sheets themselves, which can be large and fenestrated or smaller and intact (Puhka et al., 2012, MBoC, 23:2424). In the present study, we have studied the interactions between the actin cytoskeleton and ER and the dynamic behavior of ER sheets in different mammalian cell lines. We have quantified the general

changes in the ER network induced by actin depolymerisation using a morphometric assay (Puhka et al., 2007, JCB, 179:895). Our results indicate that actin does not seem to have a role on the ER tubules, but rather a maintaining role on the long ER profiles, which correspond to the sheet structures. Our live cell imaging analysis results show that the dynamics of sheets diverges from the tubular dynamics. We also show that the sheets in different mammalian cells lines respond differently to actin cytoskeleton manipulation. The results indicate that the maintenance of the peripheral ER sheets is coupled to the actin cytoskeleton, which affects the sheet persistency and lateral movement of the sheets in some of the mammalian cell types.

**Studies on Golgi biogenesis reveal self-organizing principles of the early secretory pathway.**

*P. Ronchi<sup>1</sup>, R. Pepperkok<sup>1</sup>; <sup>1</sup>Cell Biology and Biophysics, European Molecular Biology Laboratory, Heidelberg, Germany*

More than a century after the first description of the Golgi complex (GC), many aspects of the biology of this key organelle in the secretory pathway are still elusive. How it acquires and maintains its complex structure, as well as its influence in the functionality of other organelles and cellular processes are still open questions. Using laser nanosurgery to remove the GC from living cells, we have previously demonstrated that a functional and structurally normal GC can be *de novo* synthesized in mammalian cells in the absence of a centrosome (Taengemo et al., 2011).

Here, we have observed Golgi biogenesis after laser nanosurgery by high temporal resolution timelapse imaging, providing insights in the process at the light and electron microscopy level. We show that a functional Golgi complex can be *de novo* synthesized with a reproducible sequence of events. In the first phase, for several hours after Golgi removal, despite protein synthesis takes place, the export of secretory cargo from the ER is strongly inhibited. In phase 2, ER-derived carriers are occasionally formed. They move on disorganized microtubule tracks and fuse to each other when they meet. The formation of larger Golgi precursors initiates phase 3. It coincides with the arrangement of a centrally organized microtubule network and with the restoration of the full secretory activity of ER exit sites. As a result of these processes, the Golgi precursors develop into ministacks and cluster in a single perinuclear area (phase 4).

This study reveals a self-organizing nature of the early secretory pathway, and suggests that the GC could play a major role in its spatial and functional organization.

**Identification of GRASP65-interacting proteins and characterization of their roles in Golgi organization.**

*D. Tang<sup>1</sup>, H. Yuan<sup>1</sup>, Y. Wang<sup>1</sup>; <sup>1</sup>MCDB, University of Michigan, Ann Arbor, MI*

The Golgi peripheral protein GRASP65 was identified as a Golgi stacking factor that links adjacent Golgi cisternae by forming mitotically regulated trans-oligomers. Further experiments indicate that GRASP65 function is regulated by proteins in the cytosol. In this study, we have applied biochemical approaches to identify GRASP65-interacting proteins. HeLa cell cytosol was subjected to fractionations using standard biochemical methods followed by affinity chromatography. Proteins that bind to GRASP65 were identified by mass spectrometry and further characterized. Among the identified proteins, clathrin heavy chain, MENA, SHIP2 and Dja1 were confirmed for their interaction with GRASP65 and recruitment to the Golgi membrane. Depletion of these GRASP65 interacting proteins by small interference RNA (siRNA) resulted in Golgi fragmentation in HeLa cells. In both GRASP65-coated bead

aggregation assay and an in vitro Golgi reassembly assay, interphase cytosol which was depleted with GRASP65 interacting proteins had reduced function in GRASP65 oligomerization and Golgi reformation comparing to non-treated interphase cytosol. Our study has identified potential candidates that play essential roles in Golgi stack formation.

### **Understanding the molecular mechanism of Golgi biogenesis in *Trypanosoma brucei*.**

S. Yavuz<sup>1</sup>, G. Warren<sup>1</sup>; <sup>1</sup>Max F. Perutz Laboratories, Vienna, Austria

The Golgi apparatus is the central organelle in the secretory system, which modifies and sorts secretory cargo. Despite its crucial role in secretion, the biogenesis of this organelle is poorly understood. One question that remains unanswered concerns the source of Golgi components during biogenesis; specifically whether the newly forming Golgi uses material provided by the existing Golgi. Initial studies have provided indirect evidence to suggest this; however direct proof is not yet available.

In this project, we aim to provide direct evidence for the involvement of existing Golgi in the formation of new Golgi. The large number of Golgi stacks in mammalian cells makes it difficult to address mechanistic questions about Golgi biogenesis. To circumvent this problem, we have chosen the simple parasite *Trypanosoma brucei* to study Golgi biogenesis in detail. *T. brucei* cells have a single Golgi apparatus which is duplicated and partitioned precisely during cell division. We established stable cell lines in *T. brucei* that express Golgi components fused to optical highlighter fluorescent proteins such as photoactivatable green fluorescent protein (PAGFP). These cell lines will allow us to track Golgi components during Golgi biogenesis by live-cell microscopy. We will then determine the potential contribution of the existing Golgi to new Golgi formation and investigate whether the kinetics of the contribution of this material correlate with the kinetics of new Golgi formation.

Tracking a subpopulation proteins in the cell using photoactivatable fluorescent proteins is an excellent tool to study order of events and kinetics of organelle biogenesis. Using this approach we hope to address questions on the formation of Golgi apparatus.

## **Mitochondria, and Peroxisomes**

2190B1011

### **Investigation of the Ubiquitin Proteasome System in Mitochondrial Dynamics.**

G. O'Mealey<sup>1,2</sup>, S. Plafker<sup>1,2</sup>; <sup>1</sup>Free Radical Biology and Aging Program, Oklahoma Medical Research Foundation, Oklahoma City, OK, <sup>2</sup>Department of Cell Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK

Mitochondria produce the majority of cellular energy but, paradoxically, are also the principal producers of free radicals, which can damage nucleic acids, proteins, and lipids. Mitochondria form a dynamic, reticular network that responds, through fission and fusion events, to the energy needs, redox status, and levels of oxidative stress in cells. This network has the capacity to redistribute throughout the cell on microtubules to fulfill the metabolic needs of particular intracellular structures. Recent efforts to elaborate the molecular mechanisms underlying the dynamic nature of the mitochondrial network have revealed that several mitochondrial proteins are targeted for degradation by the ubiquitin proteasome system (UPS). To further investigate the role(s) of the UPS in maintaining mitochondrial morphology, distribution, and function, we treated immortalized, human retinal pigment epithelial cells (RPE-1) with the proteasome inhibitors, MG132 or epoxomicin. These treatments induced a rapid

collapse of the mitochondrial network into perinuclear clusters. The mitochondrial redistribution was abolished when cells were pre-treated with the microtubule depolymerizing drug nocodazole, consistent with the clustering requiring microtubule-mediated transport. Immunostaining against the centrosomal marker  $\gamma$ -tubulin revealed that MG132-induced mitochondrial clusters were oriented around centrosomes, suggesting that inhibition of the proteasome alters the equilibrium of directional microtubule transport of mitochondria. We additionally tested the hypothesis that proteasome inhibition disrupts the balance between mitochondrial fission and fusion. To determine if fission was required for mitochondrial perinuclear aggregation in response to proteasome inhibition, we used siRNA to knock down the major fission factor, Dynamin-related protein 1 (Drp1). Drp1 depletion, however, did not abolish the perinuclear clustering, indicating that intact fission machinery is not required for the mitochondrial redistribution. Ongoing studies are focused on probing the involvement of the mitochondrial fusion machinery as well as microtubule adaptor proteins. In addition, we are pursuing the observation that proteasome inhibition does not ablate the mitochondrial membrane potential as indicated by the efficient uptake and fluorescence of MitoTracker dye into MG132-treated cells. Together, these data support the intriguing idea that the perinuclear clustering of mitochondria represents a cellular defense mechanism. This defense is designed to preserve cellular ATP production in the face of proteotoxic stress resulting from the inappropriate accumulation of proteasome substrates. Identifying the manner in which cells protect their mitochondrial integrity and function is of clinical interest as impaired proteasome activity and a compromised mitochondrial network are hallmarks of several progressive neurodegenerative disorders. Determining how mitochondria react to mismanaged protein levels is anticipated to provide fresh insights into the etiologies of these debilitating diseases.

2191

### **Mitochondrial Dynamics Regulates Behavioral Plasticity In Response to Oxygen Deprivation in *C. elegans*.**

P. Ghose<sup>1</sup>, E. Park<sup>1</sup>, A. Tabakin<sup>1</sup>, N. Salazar<sup>1</sup>, R. T. Shah<sup>1</sup>, C. Rongo<sup>1</sup>; <sup>1</sup>Department of Genetics, Waksman Institute, Rutgers University, Piscataway, NJ

Mitochondria are especially important for neuronal function and are known to respond dynamically to stress. Here we report that *C. elegans* neuronal mitochondria undergo fission in response to oxygen deprivation, followed by reconstitution following re-oxygenation. We find that the rate and degree of mitochondria reconstitution is modulated by the hypoxia response pathway, as mitochondria in mutants for the proline hydroxylase gene, *egl-9*, show pronounced mitochondrial "hyperfusion" in a HIF-1 dependent manner. This exaggerated mitochondrial reconstitution requires STL-1, a mitochondrial resident and likely homologue of the mammalian stomatin-like protein, SLP-2. Moreover, we find that these changes in neuronal mitochondrial dynamics are accompanied by changes in locomotory behavior of animals following oxygen deprivation and re-oxygenation. Our findings suggest that the behaviors executed by a simple neural circuit can be regulated through changes in mitochondrial dynamics. In addition, we speculate that adaptive mitochondrial dynamic and behavioral responses to oxygen status can be preconditioned for the nematode, perhaps explaining the extraordinary tolerance of *C. elegans* to extreme changes in oxygen supply. The underlying mechanism might provide valuable insights into the resistance or sensitivity of mammalian neurons to oxygen deprivation stress.

2192

**Biochemical characterization of Pcp1p, a mitochondrial rhomboid protease.**A. othan<sup>1</sup>, D. M. Gordon<sup>1</sup>; <sup>1</sup>Biological Sciences, Mississippi State University, Mississippi State, MS

Pcp1p is a mitochondrial rhomboid protease that localizes to the mitochondrial inner membrane in the budding yeast *Saccharomyces cerevisiae*. *PCP1* codes for a 346 amino acid polypeptide having a cleavable N-terminal mitochondrial-targeting signal followed by six transmembrane alpha-helices. The rhomboid-like active site motif containing the catalytic serine and histidine residues are located in transmembrane helices four and six. Haploid yeast cells deleted for *PCP1* are viable, however they have a slow growth phenotype, are unable to grow on non-fermentable carbon, and exhibit abnormal mitochondrial morphology. Two different substrates have been identified for Pcp1p: Ccp1p (cytochrome c peroxidase) and Mgm1p (mitochondrial genome maintenance). Ccp1p localizes to the mitochondrial intermembrane space and functions to remove hydrogen peroxide and other free radicals generated during respiration; Mgm1p, is a dynamin-related GTPase required for mitochondrial fusion. Recent work has shown that in addition to Pcp1p peptidase activity, Mgm1p processing depends on matrix ATP levels and the Tim23-Pam translocation complex. This dependence suggests a functional link between Pcp1p and the inner membrane protein translocation machinery. As an initial attempt to show a physical association between Pcp1p and members of the Tim23 translocon, a co-immunoprecipitation approach was taken. PCR mediated techniques were used to modify genomic copies of *PCP1*, *TIM23*, *TIM21*, and *PAM18* with sequences coding for 13Myc, 3HA and 3FLAG epitope tags. Preliminary western blot analyses suggest that there is a weak interaction between Pcp1p and components of the Tim23 translocon machinery that is sensitive to different detergents. Unfortunately this interaction was not detected by sucrose gradient ultracentrifugation, although we have determined that Pcp1p exists in a higher order protein complex of ~200kD. Future experiments include a cross-linking approach to stabilize what is likely to be a transient interaction between Pcp1p and the translocon machinery as well as identification of the protein components of the ~200kD Pcp1p complex.

2193

**Genetic insight into the function of the *S. cerevisiae* mitochondrial rhomboid protease, Pcp1p.**N. Xiao<sup>1</sup>, C. J. Denison<sup>1</sup>, D. M. Gordon<sup>1</sup>; <sup>1</sup>Biological Sciences, Mississippi State University, Mississippi State, MS

As the central source of energy production in eukaryotic cells, mitochondria are essential for cell viability. One feature that has emerged as a factor impacting mitochondrial activity is organelle morphology. A number of proteins have been identified for their role in controlling mitochondrial dynamics including the mitochondrial rhomboid peptidases, a conserved family of intramembrane serine proteases. The *S. cerevisiae* mitochondrial rhomboid, Pcp1p, localizes to the mitochondrial inner membrane and has been shown to be involved in the proteolytic cleavage of two substrates: Ccp1p and Mgm1p. Ccp1p (cytochrome c peroxidase) is an intermembrane space localized protein involved in the breakdown of reactive oxygen species while Mgm1p (mitochondrial genome maintenance) is critical for mitochondrial fusion-fission based events. Haploid cells deleted for *PCP1* have fragmented mitochondria and are unable to grow when provided with a nonfermentable carbon source. The fact that similar phenotypes have been found for *MGM1* mutants coupled with the finding that Pcp1p cleavage of Mgm1p is required for mitochondrial fusion suggests that Mgm1p processing is the key biological function for Pcp1p. In addition to Pcp1p activity, Mgm1p processing is dependent on mitochondrial ATP

levels and components of the Tim23 translocation machinery. As an initial approach to determine the structural basis of Pcp1p activity and to determine whether Pcp1p function requires an association with additional proteins, we have designed a screen to identify temperature sensitive alleles of *PCP1* generated by hydroxylamine mutagenesis. To date we have screened over 30,000 colonies and have identified four mutants that exhibit a) a temperature sensitive growth profile, b) a respiratory growth defect, c) a defect in Mgm1p and Ccp1p processing, and d) abnormal mitochondrial morphology. Interestingly, the steady state levels of Pcp1p for all four mutants were similar to wild type. All four mutations are a result of single amino acid changes within the fourth and sixth transmembrane domains of Pcp1p, the location of the active site serine and histidine, respectively. Future time-course experiments are designed to better understand the defects associated with these mutants.

2194

**A temperature sensitive screening approach to map amino acids required for Pcp1p activity.**

C. J. Denison<sup>1</sup>, N. Xiao<sup>1</sup>, D. Gordon<sup>1</sup>; <sup>1</sup>Biological Sciences, Mississippi State, Mississippi State, MS

Pcp1p is a mitochondrial serine protease known to be involved in regulating mitochondrial dynamics and apoptosis. In *Saccharomyces cerevisiae*, Pcp1p is required for the proteolytic cleavage of two substrate proteins: Ccp1p and Mgm1p. Ccp1p (cytochrome c peroxidase) localizes to the mitochondrial intermembrane space and is involved in the elimination of reactive oxygen species. One hundred percent of the Ccp1p polypeptide is cleaved by Pcp1p to generate the mature form of this enzyme. Mgm1p (mitochondrial genome maintenance) is responsible for mitochondrial fusion and fission based events that control mitochondrial morphology. Mgm1p is found in two forms, a large and a small isoform. Pcp1p peptidase activity is responsible for converting the long Mgm1p isoform into the short isoform. On average, approximately half of the Mgm1p present in a cell is processed to the short form; the remaining exists as the long isoform. Overall, our aim is to understand the factors that influence this apparent differential processing of substrate proteins by Pcp1p with the goal of identifying and characterizing potential accessory components. As an initial attempt to identify domains outside of the Pcp1p active site required for function, we have designed a screen to isolate both nonfunctional and temperature sensitive alleles of *PCP1*. Plasmid borne *PCP1* was randomly mutagenized with exposure to hydroxylamine and transformed into our *PCP1* shuffle strain. Colonies were then replica printed to plates containing nonfermentable carbon to identify interesting *pcp1* candidates. To date, we have screened ~36,000 colonies and identified five *pcp1* alleles that eliminate Pcp1p activity and four alleles that function as a 'knockdown' of Pcp1p function. The majority of these single amino acid changes map to the fourth and sixth transmembrane helices of Pcp1p, the location of the active site serine and histidine, respectively. Future experiments are designed to determine how these amino acid changes impact Pcp1p activity including changes in Ccp1p and Mgm1p processing and mitochondrial morphology.

2195

### **Mito Tracker labeling in HepG2 Cell Cultures: Influence of different staining techniques on the morphology of mitochondria.**

*R. G. Aktas<sup>1</sup>, S. Karahuseyinoglu<sup>2</sup>, M. Karabork<sup>1</sup>, O. E. Tok<sup>3</sup>, D. Yucel<sup>4</sup>; <sup>1</sup>School of Medicine, Koc University, Istanbul, Turkey, <sup>2</sup>Embryology and Andrology Laboratories, Suleymaniye Research and Training Hospital, Istanbul, Turkey, <sup>3</sup>School of Medicine, Marmara University, Istanbul, Turkey, <sup>4</sup>School of Medicine, Acibadem University, Istanbul, Turkey*

MitoTracker (MT) probes passively diffuse mitochondrial membrane and accumulate in active mitochondria. This dye is useful for the study of morphology and function of mitochondria on live cells. There are different techniques to visualize mitochondria by use of this stain. These techniques are being used at 37 C chambers. Some techniques use carbondioxide incubator, while others use incubators with no carbondioxide. The dye is being diluted in the medium in several techniques, while the others use phosphate buffer saline for dilution. The aim of this study was to analyze if these different techniques effect the morphology of mitochondria.

HepG2 cells, human hepatocellular carcinoma cell line (ATCC), were seeded on glass coverslips. They were grown in Minimum Essential Medium (ATCC) which contain 10% fetal serum bovine. When they became 70% confluent, they were stained with MitoTracker (Invitrogen/Molecular Probes). There were four experimental groups: I. Group: Cells were stained with MT in medium in a carbondioxide incubator. II. Group: Cells were stained with MT in medium in an incubator without carbondioxide. III. Group: Cells were stained with MT in phosphate buffer solution in a carbondioxide incubator. IV. Group: Cells were stained with MT in phosphate buffer solution (PBS) in an incubator without carbondioxide. The cells from each group were analysed by using Zeiss Axioscope fluorescence microscope and Nikon Eclipse 90i confocal microscope.

Our results showed that the cells were containing mitochondria with classical rode shapes when they were incubated in medium in a carbondioxide incubator. When the cells were incubated in an incubator without carbondioxide, the mitochondria became elongated. The mitochondria in the groups which were stained with MT in PBS also showed alterations in the shape.

In conclusion, the different staining techniques with MT on live cells might effect the morphology of the mitochondria. This information is especially important for the studies related with the morphological changes in mitochondria under certain circumstances.

### **Genetic interaction between mitochondrial fission and fusion factors.**

*C. Wang<sup>1</sup>, R. Youle<sup>1</sup>; <sup>1</sup>SNB/NINDS, National Institutes of Health, Bethesda, MD*

Mitochondria dynamics are regulated by constant fission and fusion and play important roles in many biological processes such as apoptosis and autophagy. The essential fission gene Drp1 and fusion gene Opa1 have been extensively studied but understanding the molecular mechanisms underlying their functions have been hampered by the lack of knockout human cell lines. In this study, we used Talen technology to knock out Drp1, Opa1 and other previously reported mitochondrial fission genes in HCT116 cells. As in RNAi studies, both mitochondria and peroxisomes are excessively elongated in Drp1 KO cells. In contrast, mitochondrial morphology and Drp1 recruitment remain normal whereas peroxisomes are elongated in Mff KO, Fis1/Mff DKO and Opa3/Fis1 DKO cells, indicating that: 1) Mff is essential for peroxisome fission but is dispensable for mitochondrial fission; 2) Mff is not the sole receptor for Drp1 recruitment; 3) Fis1 and Opa3 are not redundant to Mff. Opa1 KO cells display fragmented mitochondria but knocking out Drp1 in the Opa1 KO background leads to highly tubular mitochondria, suggesting the existence of Opa1-independent fusion events. Unlike in yeast,

Opa1 deficiency in Drp1 KO cells fails to restore the mitochondrial morphology back to wild type since the Opa1/Drp1 DKO cells exhibit mitochondrial morphology similar to that of Drp1 single KO, indicating that Drp1 is epistatic to Opa1. However, whereas Drp1 KO cells are resistant to apoptosis, Opa1/Drp1 DKO cells are as hypersensitive to ABT-737 treatment as Opa1 KO cells, suggesting that Opa1 is epistatic to Drp1 in controlling cell death and Drp1 inhibits cytochrome c release through Opa1. Whether Drp1 is involved in the disassembly of Opa1 oligomeric complex is under investigation.

#### **Roles for tissue-specific ATP synthase subunits in mitochondrial shaping.**

Y. Hwang<sup>1</sup>, L. Ivey<sup>1</sup>, O. Brown<sup>1</sup>, C. Field<sup>1</sup>, M. Lorenzo<sup>1</sup>, K. Sheaffer<sup>1</sup>, K. G. Hales<sup>1</sup>; <sup>1</sup>Department of Biology, Davidson College, Davidson, NC

During *Drosophila melanogaster* spermatogenesis, mitochondria aggregate and fuse in post-meiotic spermatids to form the Nebenkern, a spherical structure consisting of two interwoven giant mitochondrial derivatives. Males homozygous for *ms(2)1400* are sterile and show defective internal structure of the Nebenkern, which then cannot disentangle and elongate properly. We mapped *ms(2)1400* to a region containing a candidate gene with testis-enriched expression that encodes an unusually large predicted homolog of ATP synthase subunit d. RNAi knockdown of the candidate gene phenocopied *ms(2)1400*. Analysis of the *Drosophila* genome revealed that three other ATP synthase subunits in the peripheral stalk of the complex have predicted paralogs with testis-enriched expression. RNAi knockdown of these genes in the testis gave Nebenkern defects similar to those seen in *ms(2)1400*. In other systems, the peripheral stalk of ATP synthase is known to mediate higher-order dimerization of the complex, in turn influencing inner mitochondrial membrane curvature and cristae structure. Our results demonstrate ATP synthase involvement in Nebenkern shaping that is consistent with what is known about ATP synthase dimerization and cristae formation in these other systems. These novel findings connect tissue-specific mitochondrial shaping with differential expression of ATP synthase subunit paralogs.

#### **Uncoupling Protein 2 Controls Mitochondrial Network Fragmentation and Premature Senescence via Regulating Superoxide-mediated p53 Activation.**

Y. Shimasaki<sup>1</sup>, N. Pan<sup>1</sup>, L. M. Messina<sup>2</sup>, S. M. Shenouda<sup>3</sup>, J. A. Vita<sup>3</sup>, J. F. Keaney, Jr.<sup>1</sup>; <sup>1</sup>Medicine, University of Massachusetts Medical School, Worcester, MA, <sup>2</sup>Surgery, University of Massachusetts Medical School, Worcester, MA, <sup>3</sup>Medicine, Boston University School of Medicine, Boston, MA

**Background** - Mitochondria, although required for cellular ATP production, are also known to have other important functions that may include modulating cellular responses to environmental stimuli. Most mitochondrial actions are linked to the electron transport chain and the resultant mitochondrial membrane potential ( $\Delta\psi_m$ ), which is involved in ATP synthesis and proton leak. Although the latter is largely regulated via uncoupling proteins, the mechanisms whereby uncoupling proteins impact cellular phenotype are not yet clear.

**Methods and Results** - We report here that stimuli for endothelial cell proliferation evoke strong upregulation of mitochondrial uncoupling protein 2 (UCP2) in culture. Analysis *in silico* indicated increased UCP2 expression is common in highly proliferative cell types, including cancer cells. Upregulation of UCP2 was critical for controlling  $\Delta\psi_m$  and superoxide production. In the absence of UCP2, endothelial growth stimulation provoked mitochondrial network fragmentation and premature senescence via a mechanism involving superoxide-mediated p53 activation.

Mitochondrial network fragmentation was both necessary and sufficient for the impact of UCP2 on endothelial cell phenotype. We also examined human endothelial cells from patients with type 2 diabetes—a condition associated with excess mitochondrial superoxide, and found a reduced UCP2 expression and increased mitochondrial fragmentation in the endothelial cells as well as impaired endothelial function of the patients as determined by flow-mediated dilation.

**Conclusions** - We demonstrated that endothelial cell proliferation and angiogenesis require upregulation of UCP2 in order to reduce  $\Delta\psi_m$  and limit mitochondrial superoxide that otherwise promotes p53-dependent mitochondrial fragmentation resulting in premature senescence. Our data also indicate an important role for UCP2 in determining the endothelial cell function of diabetic patients. These findings reveal a new function for UCP2 that has broad implications for processes that involve the function of endothelial cells.

**Asymmetric inheritance of mitochondrial content in aging budding yeast cells.**

*E. A. Martin<sup>1</sup>, M. P. Viana<sup>1</sup>, Y. Zhang<sup>2</sup>, H. Li<sup>2</sup>, L. F. Costa<sup>3</sup>, W. F. Marshall<sup>2</sup>, S. M. Rafelski<sup>1</sup>; <sup>1</sup>Developmental & Cell Biology, UCI, Irvine, CA, <sup>2</sup>Biochemistry and Biophysics, UCSF, San Francisco, CA, <sup>3</sup>Inst. de Física de Sao Carlos, USP, Sao Carlos, Brazil*

Mitochondria must grow with the growing cell to ensure proper physiology and inheritance upon division. But how does mitochondrial content scale with cell size during asymmetric division? Is the same mitochondrial to cell size ratio maintained uniformly in the cell to produce identical mother and daughter cells? Or is there an asymmetry in the inheritance of mitochondrial content? We measured the physical size of mitochondrial networks by computationally skeletonizing the mitochondrial tubules in 3D. We found mitochondrial inheritance to be very asymmetric; newborn daughters inherited a greater mitochondrial to cell volume ratio than their mothers, who lost mitochondrial content during the budding process. By counting bud scars to measure mother generational age, we found that aging mothers progressively lost mitochondrial volume ratio over successive generations. However, newborn daughters continued to inherit the same average volume ratio. This mother-daughter asymmetry could be enhanced or abolished by altering the expression levels of Ypt11p and Mmr1p, representing two independent mitochondrial inheritance pathways. However the final volume ratio inherited by the newborn daughters remained the same as wild-type cells, suggesting that the mitochondrial volume ratio in the bud is actively regulated by the cell. The cell size of newborn daughters and of the population as a whole, however, decreased for mutants with delayed and increased for mutants with enhanced mitochondrial inheritance. Due to the initial delay in redistribution into the bud,  $\Delta ypt11$  mothers inherited a greater volume ratio than wild-type mothers. Over successive generations this resulted in a dramatic decrease of the age-dependent loss of mitochondrial volume ratio in  $\Delta ypt11$  cells. Replicative lifespan analysis of  $\Delta ypt11$  cells revealed two populations, one short lived, absent in wild-type and one with a longer maximal lifespan than wild-type. Because the difference in volume ratio between wild-type and  $\Delta ypt11$  mothers increases with age, the long-lived population represents  $\Delta ypt11$  cells with an increased mitochondrial volume ratio compared to wild-type. We are now investigating whether the short-lived population has a decreased volume ratio compared to longer-lived cells. Our results suggest that “mitochondrial content asymmetry” may contribute to the health and aging of cells.

**Lithocholic acid delays aging and exhibits a potent anti-tumor effect by altering mitochondrial composition, structure, and function.**

A. Beach<sup>1</sup>, M. T. Burstein<sup>1</sup>, V. R. Richard<sup>1</sup>, O. Koupaki<sup>1</sup>, A. Leonov<sup>1</sup>, V. Titorenko<sup>1</sup>; <sup>1</sup>Biology Department, Concordia University, Montreal, QC, Canada

We use the yeast *Saccharomyces cerevisiae* as a model to study the molecular mechanisms by which age-related changes in mitochondrial membrane lipids regulate longevity. We found that an exogenously added bile acid called lithocholic acid (LCA) extends yeast chronological lifespan and accumulates in the inner mitochondrial membrane (IMM). To define the mechanism by which LCA extends yeast longevity, we 1) examined how LCA influences mitochondrial proteome and lipidome; 2) investigated the effect of LCA on the composition and stoichiometry of respiratory complexes and supercomplexes in the IMM; 3) assessed how LCA affects mitochondrial oxygen consumption, membrane potential and reactive oxygen species (ROS); 4) examined how LCA influences mitochondrial morphology and how it affects the chronology of events characteristic of age-related, mitochondria-controlled apoptosis; and 5) investigated the effect of LCA on the lifespans of long- and short-lived mutants lacking individual components of the mitochondrial fission and fusion machines. Our findings imply that LCA delays yeast aging by increasing the level of phosphatidylserine (PS) and decreasing the levels of phosphatidylethanolamine (PE) and cardiolipin in the IMM. By altering the abundance of these lipid species, LCA greatly expands mitochondrial membrane cristae. In addition, LCA enhances the positive effect of PS and weakens the negative effect of PE on membrane protein machines whose activity they modulate – thereby 1) stimulating protein machines driving mitochondrial respiration, the maintenance of mitochondrial membrane potential and ROS homeostasis, and mitochondrial fusion; and 2) inhibiting protein machines promoting mitochondrial fission and mitochondria-controlled apoptosis. We found that LCA also functions as a potent and selective anti-tumor compound in cultured human neuroblastoma, glioma and breast cancer cells by modulating mitochondrial processes playing essential roles in both cancer and aging. The effects of LCA on these processes seen in cancer cell cultures are opposite of those observed in non-cancerous human cells and in chronologically aged, quiescent yeast.

**Amyloid beta-induced structural alterations of subcellular organelles in Alzheimer's disease.**

Y. Huh<sup>1</sup>, S. Jun<sup>1</sup>, M. Kim<sup>1</sup>, K. Choi<sup>1</sup>, S-H. Lee<sup>1</sup>, J. Kim<sup>2</sup>, H-S. Kweon<sup>1</sup>; <sup>1</sup>Division of Electron Microscopic Research, Korea Basic Science Institute, Daejeon, Korea, <sup>2</sup>Section of Genetics, Department of Pediatrics, University of California-Davis Medical Center, Sacramento, CA

Alzheimer's disease (AD) is a progressive neurodegenerative disease and the neuropathologic hallmark of AD is deposition of aggregated amyloid- $\beta$  (A $\beta$ ). The morpho-functional abnormality of subcellular organelles caused by A $\beta$  deposition may play important roles in AD pathogenesis. However, molecular and ultrastructural basis for degenerative process of subcellular organelles and ultimate neuronal death in AD still remains unclear. We have performed immunocytochemical and ultrastructural analyses using fluorescence microscopy, conventional electron microscopy, high voltage electron microscopy, and three-dimensional electron tomography in animal- and cell-model for AD to understand how alteration of subcellular organelles are associated with the progression of AD. In the APP/PSEN1 transgenic mice that express human amyloid precursor protein, the deposition of A $\beta$  plaques and anti-LC3 antibody positive autophagosome were detected in the hippocampus and cortex regions. We also identified the loss of peroxiredoxin 5, an endogenous cytoprotective antioxidant enzyme, and the accumulation of A $\beta$  in the hippocampal mitochondria of transgenic mice with severe

disruption of mitochondrial cristae. In the murine microglial cell line, BV-2, stimulated A $\beta$  1-42 fibrils, which polymerized in *in vitro*, were localized in the periphery of the nucleus as a filamentous structure. In addition, A $\beta$ -positive signals were detected on structurally deteriorated mitochondria and Golgi complex as similar with APP/PSEN1 transgenic mice. Concomitantly, autophagosomes containing fragmented membraneous compartments of mitochondria and Golgi complex were abundant in cytoplasm of BV-2 cell. These results acquired from *in vivo* and *in vitro* studies provide the evidence that the A $\beta$ -induced morpho-functional alterations of subcellular organelles and relative accumulation of autophagosomes are closely associated with the neurodegenerative process in AD.

**p62/SQSTM1 promotes the expression of mitochondrial genes in response to increased autophagy.**

A. Bitto<sup>1</sup>, C. A. Lerner<sup>1</sup>, D. Pulliam<sup>2</sup>, M. Konigsberg<sup>2,3</sup>, H. van Remmen<sup>2</sup>, C. Torres<sup>1</sup>, C. Sell<sup>1</sup>;

<sup>1</sup>Pathology, Drexel University College of Medicine, Philadelphia, PA, <sup>2</sup>University of Texas Health Sciences Center, Barshop Institute for Longevity and Aging Studies, San Antonio, TX,

<sup>3</sup>Universidad Autónoma Metropolitana Iztapalapa, Mexico City, Mexico

Maintaining a pool of functional mitochondria in the cell requires coordinate generation and degradation of these organelles. While several factors have been involved in controlling mitochondrial biogenesis and mitophagy in mammals, little is known about how these two processes are linked together to maintain mitochondrial homeostasis. Using primary human fibroblasts and the autophagy-inducing drug rapamycin, we attempted to define a connection between clearance and renewal of the mitochondrial pool. Stimulating autophagy with rapamycin increased mitochondrial mass and promoted the expression of mitochondrial genes. Chronic exposure to rapamycin also reduced the half-life of the integral mitochondrial protein VDAC, increased mitochondrial membrane potential, and reduced the generation of reactive oxygen species. Furthermore, cells exposed to rapamycin had higher resistance to exogenous stress and delayed the onset of cellular senescence concomitant with a decrease in the p38MAPK stress response pathway activation. These effects appeared to be mediated in part by increased interaction between Keap1 and p62/SQSTM1, a protein involved in the clearance of damaged mitochondria: this increased association promoted nuclear accumulation of the Nuclear Factor Erythroid 2 Like 2 (NFE2L2) in rapamycin treated cells, and increased expression of the Nuclear Respiratory Factor 1 (NRF1) and the mitochondrial Transcription Factor A (TFAM), a protein necessary for mitochondrial genome replication and transcription. Interestingly, p62/SQSTM1 turnover was increased upon exposure to rapamycin, and knockdown of p62/SQSTM1 abrogated the effects of rapamycin on mitochondrial membrane potential and stress resistance, as well as the induction of NFE2L2, NRF1, and TFAM. These results suggest that p62/SQSTM1 coordinates clearance and renewal of mitochondria, and play a key role in maintaining cellular homeostasis.

**Hypertonia-associated mutation impairs Trak1 mitochondrial localization.**

C. A. Lee<sup>1</sup>, L. Li<sup>1</sup>, L-S. Chin<sup>1</sup>; <sup>1</sup>Pharmacology, Emory University, Atlanta, GA

Hypertonia is a pathophysiological condition caused by defects in motor pathways in the central nervous system, resulting in postural abnormalities, jerky movements, and tremor. Hypertonia is associated with a number of neurological disorders, including cerebral palsy, dystonia, Parkinson's disease, stroke, and epilepsy. The molecular mechanisms that trigger the pathogenesis of hypertonia remain poorly understood. The finding that a homozygous

truncation mutation in the trafficking protein, kinesin-binding 1 (Trak1) protein causes a recessively transmitted form of hypertonia in mice highlights the importance of understanding the mechanisms of Trak1 action and the effects of hypertonia-associated Trak1 mutation. We have shown that Trak1 is a ubiquitously expressed protein that localized to both mitochondria and early endosomes. Our subcellular fractionation and immunofluorescence confocal microscopic analyses reveal that the mitochondrial localization of Trak1 is impaired by hypertonia-associated Trak1 mutation. Further characterization of the structural and functional consequences of hypertonia-associated Trak1 mutation will provide new insights into the pathogenic mechanisms of hypertonia.

**MITRAC complexes link mitochondrial protein translocation to respiratory chain assembly and translational regulation.**

*D. U. Mick<sup>1,2</sup>, S. Dennerlein<sup>1</sup>, H. Wiese<sup>3</sup>, B. Warscheid<sup>3</sup>, P. Rehling<sup>1,4</sup>; <sup>1</sup>Dept. of Biochemistry II, University of Goettingen, Goettingen, Germany, <sup>2</sup>Molecular and Cellular Physiology, Stanford University, Stanford, CA, <sup>3</sup>Institute for Biology II, University of Freiburg, Freiburg, Germany, <sup>4</sup>Max-Planck Institute for Biophysical Chemistry, Goettingen, Germany*

The bulk of cellular ATP for most eukaryotic cells is generated by the mitochondrial oxidative phosphorylation system, comprising five transmembrane multi-protein complexes. Defects in function or biogenesis of these key metabolic enzymes have been shown to generate deleterious amounts of reactive oxygen species and are among the most frequent causes for mitochondrial disorders.

The mitochondrial respiratory chain complexes assemble from subunits of dual genetic origin, synthesized both on cytosolic as well as mitochondrial ribosomes. This exceptional situation requires well-balanced and sophisticated regulation of protein expression, transport, and integration of subunits into the inner mitochondrial membrane, where they assemble to form oligomeric complexes. These processes are assisted by a plethora of specific assembly factors, defects of which are the main cause of mitochondrial encephalomyopathies. In yeast, intricate mechanisms are in place to regulate the synthesis of core mitochondrial subunits in response to metabolic needs as well as the assembly status of core subunits themselves. However, due to circumstantial evidence the existence of such mechanisms in mammals has been neglected.

Here, we report a comprehensive dissection of the major human cytochrome c oxidase assembly intermediates by biochemical and mass-spectrometric approaches. Combining native gel electrophoresis with quantitative mass-spectrometry enabled us to define novel intermediates containing newly mitochondria-synthesized and imported respiratory chain subunits, which we term MITRAC complexes. Further biochemical characterization shows that these complexes consist of novel as well as known assembly factors that feedback-regulate mitochondrial translation of central structural subunits, revealing the conservation of this regulating mechanism. Since known constituents of the MITRAC complexes have been implicated in mitochondrial encephalomyopathies, the newly-identified assembly factors are exciting candidates for novel disease genes.

A central yet unresolved question in respiratory chain complex assembly is by which mechanism imported subunits are delivered to assembly-intermediates containing mitochondria-encoded subunits. We find that MITRAC20 is an integral component of the inner membrane presequence translocase. MITRAC20 is dispensable for protein import, but required for assembly of early-assembling presequence-containing subunits into MITRAC complexes. These findings establish an unexpected molecular link between the TIM23 transport machinery and assembling respiratory chain complexes that regulate mitochondrial protein synthesis in response to their assembly-state.

**Mitochondrial mistargeting causes autosomal dominant renal Fanconi syndrome.**

*E. D. Klootwijk<sup>1</sup>, M. Reichold<sup>2</sup>, A. Helip-Wooley<sup>3</sup>, H. Stanescu<sup>1</sup>, D. Bockenbauer<sup>1</sup>, W. Gahl<sup>3</sup>, R. Warth<sup>2</sup>, R. Kleta<sup>1</sup>; <sup>1</sup>UCL Centre for Nephrology, LEG, London, United Kingdom, <sup>2</sup>University of Regensburg, Regensburg, Germany, <sup>3</sup>NHGRI, Bethesda, MD*

Patients with renal Fanconi syndromes show a generalized renal proximal tubular functional defect leading to glucosuria, aminoaciduria, phosphaturia, metabolic acidosis, and small molecular weight proteinuria.

For this study the causative genetic factor as well as the underlying molecular pathology was unraveled in an large family with autosomal dominantly inherited renal Fanconi syndrome without kidney failure. To this end whole genome multipoint parametric linkage analysis was performed resulting in a significant LOD score (3.6) for a single locus. All genes in the linked area were sequenced resulting in the identification of a heterozygous mutation (p.E3K) in a gene, which we called Fanconin. This mutation results in a de-novo formation of a mitochondrial targeting motif as it was predicted with Protein Prowler 1.2. This mutation was not found in ethnically matched controls. To assess the functional impact of the mutation stable permanently transfected cell lines were generated expressing either the mutant or wild type Fanconin protein. These cell lines were obtained from the human cell line TSA201 (HEK cell derivative) and the pig cell line LLC-PK1, the latter which is a renal proximal tubular cell model. Immunohistochemical analysis using these cells showed appropriate intracellular localization for the wild type human Fanconin and mistargeting for human mutant Fanconin to the mitochondria. Immunohistochemical analysis was performed for mouse and human kidneys to investigate the expression of Fanconin. Our results indicated that Fanconin is expressed in renal proximal tubules which coincides with the proximal tubular dysfunction in patients with renal Fanconi syndrome.

Knockout mice for Fanconin, as expected, did not show a proximal tubular transport defect as assessed by aminoacid analysis using GC-MS. We therefore hypothesized that the renal Fanconi phenotype in our family is not caused by haploinsufficiency.

Since mutant Fanconin is localized to mitochondria the impact of this mutation on mitochondrial function was investigated. Respirometric analysis using a high-resolution respirometer showed an impaired oxidative phosphorylation in the mutant Fanconin expressing cells. Transport studies documented abrogated transepithelial transport of water.

**Atypical mitochondrial fission upon Listeria infection.**

*F. Stavru<sup>1</sup>, P. Cossart<sup>1</sup>; <sup>1</sup>UIBC, Institut Pasteur, Paris, France*

The bacterial pathogen *Listeria monocytogenes* causes fragmentation of the mitochondrial network through the secreted pore-forming toxin listeriolysin O (LLO) early during infection and the efficiency infection is affected in host cells with perturbed mitochondrial dynamics (Stavru, PNAS (2011) 108:3612-7). Here, we examine mechanistic aspects of LLO-induced mitochondrial fragmentation and find that, surprisingly, it does not depend on key mitochondrial dynamics factors, such as Drp1 and Opa1. LLO-induced mitochondrial fragmentation differs drastically from uncoupler-induced mitochondrial fragmentation and therefore seems atypical. Furthermore, Drp1 appears to dissociate from mitochondria upon LLO-induced fragmentation due to degradation of its recently described receptor Mff. Collectively, our data shows a new mode of regulation for the mitochondrial fission protein Drp1.

**Standardized mitochondrial analysis gives new insights into mitochondrial dynamics and OPA1 function.**

A. Chevrollier<sup>1</sup>, J. Cassereau<sup>2</sup>, M. Ferre<sup>1</sup>, J. Alban<sup>1</sup>, V. Desquiret-Dumas<sup>1</sup>, N. Gueguen<sup>1</sup>, P. Amati-Bonneau<sup>1</sup>, V. Procaccio<sup>1</sup>, D. Bonneau<sup>1</sup>, P. Reynier<sup>1</sup>; <sup>1</sup>Biochemistry Genetic University Hospital Angers, Umr Cnrs 6214 – Inserm 1083, Angers, France, <sup>2</sup>Neurology, Umr Cnrs 6214 – Inserm 1083, Angers, France

Mitochondria are dynamic organelles that adapt to cellular requirements by changing their shape through processes of fission and fusion to form tubular networks. Defective mitochondrial metabolism is associated with a wide range of human diseases covering most medical subspecialties. The increasing importance of defective mitochondrial dynamics in several diseases including common neurodegenerative disorders calls for the development of reference imaging tools for medical investigation and drug screening. Current approaches to study mitochondrial morphology are limited by low data sampling coupled with manual identification and classification of complex morphological phenotypes. We have therefore normalized the quantification of mitochondrial dynamics by means of micropatterned (from CYTOO SA) designed to standardize the size and shape of cultured fibroblasts. In addition, we present a novel method of imaging mitochondrial networks and nucleoid distribution in 3D, in models of live or fixed cells. Our approach was validated by using fibroblasts with mutations in the OPA1 and MFN2 genes, known to be involved in mitochondrial fusion, as well as with drugs inducing mitochondrial uncoupling which elicited structural mitochondrial defects such as changes in total mitochondrial volume, connectivity of the network, number of mitochondrial branch points, and mitochondrial organization in general. Our results showed that mitochondria emerging from the microtubule organizing centre may be crucial to mitochondrial biogenesis since it appeared to be protected against mitochondrial fragmentation induced by OPA1 mutations. This imaging investigation of mitochondrial dynamics opens new perspectives for establishing the relationship between the description of mitochondrial subcellular distribution and specific experimental and pathological conditions.

2208

**Functional characterization of the role of Pex19p in peroxisome biogenesis in *Pichia pastoris*.**

G. Agrawal<sup>1</sup>, H. H. Shang<sup>1</sup>, S. Subramani<sup>1</sup>; <sup>1</sup>Section of Molecular Biology, University of California San Diego, La Jolla, CA

One aspect of the study of peroxisome biogenesis seeks to understand the underlying processes involved in the initial formation, maturation, and proliferation of peroxisomes. Two peroxins, Pex3p and Pex19p, have essential functions in peroxisome biogenesis; cells lacking Pex3p or Pex19p have no detectable peroxisomes. Pex19p has an N-terminal Pex3p-binding domain and a C-terminal domain known to interact with the membrane peroxisomal targeting signal (mPTS) of other peroxisomal membrane proteins (PMPs). Previous studies have implicated Pex19p in the post-translational insertion of PMPs in the peroxisomal membrane. It was hypothesized that Pex19p is involved in binding and stabilizing newly synthesized mPTS-containing PMPs in the cytoplasm, transporting them to the peroxisomal membrane, where Pex19p docks by its interaction with Pex3p. The interaction between Pex3p and Pex19p is therefore crucial for peroxisome formation. However, recent studies have highlighted the importance of the endoplasmic reticulum (ER) in the *de novo* synthesis of peroxisomes, which proposes a focused assembly of PMPs in a specialized domain of the ER, referred to as the pre-peroxisomal ER. It was shown that PMP-containing pre-peroxisomal vesicles bud from this

domain in a Pex19p-dependent manner and mature by importing matrix proteins sequentially from the cytosol, in a process requiring Pex3p. Nevertheless, the mechanism by which Pex19p promotes the budding process is currently unknown. In support of this novel model of Pex19p function, we have characterized several Pex19p N and C-terminal deletions to determine the minimal structural requirement of the peroxin that supports proper PMP and peroxisome assembly from the ER. As expected, deletions in the N-terminal Pex3p binding site disrupted Pex19p's interactions with Pex3p but preserved interactions with Pex12p, a mPTS-containing PMP known to bind the C-terminal end of Pex19p. In contrast, deletions in the C-terminal mPTS-binding domain of Pex19p disrupted the interaction between Pex19p and Pex12p, while leaving Pex19p-Pex3p interactions intact. However, to our surprise, import competent peroxisomes were still formed in both sets of deletions. Finally with a sequential deletion analysis, we determined a stretch of 61 amino acids as the minimum structural requirement for peroxisome biogenesis. Interestingly, these amino acids of Pex19p lack the classical Pex3p and mPTS binding sites. In conclusion, physical segregation of the Pex3p and PMP binding domains of Pex19p has provided novel insights into the role of a new domain of Pex19p in peroxisome biogenesis.

### **Comparison of two expression systems using COS7 cells and yeast cells for expression of heart/muscle-type carnitine palmitoyltransferase 1**

T. Hada<sup>1,2</sup>, Y. Kato<sup>1,2</sup>, E. Obana<sup>1,2</sup>, N. Yamazaki<sup>2</sup>, T. Yamamoto<sup>1</sup>, Y. Shinohara<sup>1,2</sup>;

<sup>1</sup>Institute for Genome Research, University of Tokushima, Tokushima, Japan, <sup>2</sup>Faculty of Pharmaceutical Science, University of Tokushima, Tokushima, Japan

Carnitine palmitoyltransferase 1 (CPT1), catalyzing the transfer of the acyl group from acyl-CoA to carnitine to form acylcarnitine, is located at the outer mitochondrial membrane. Because it is easily inactivated by solubilization, expression systems using living cells are essential for its functional characterization. COS7 cells or yeast cells are often utilized for this purpose; however, the advantages/disadvantages of the use of these cells or the question as to how the CPT1 enzyme expressed by these cells differs are still uncertain. In this study, we characterized the heart/muscle-type isozyme of rat CPT1 (CPT1b) expressed by these two cellular expression systems. The mitochondrial fraction prepared from yeast cells expressing CPT1b showed 25% higher CPT1 activity than that obtained from COS7 cells. However, the expression level of CPT1b in the former was 3.8 times lower than that in the latter; and thus, under the present experimental conditions, the specific activity of CPT1b expressed in yeast cells was estimated to be approximately five times higher than that expressed in COS7 cells. Possible reasons for this difference are discussed.

## **Endocytic Trafficking III**

### **ADAM17 is the central modulator of A1 adenosine receptor-mediated EGFR transactivation and apical exocytosis in bladder umbrella cells.**

H. S. prakasam<sup>1</sup>, G. Apodaca<sup>1</sup>; <sup>1</sup>Medicine, University of Pittsburgh, Pittsburgh, PA

When exposed to stretch, umbrella cells undergo two sequential bouts of apical exocytosis: the first, is rapid and independent of protein synthesis, whereas the second "late phase" is slower to initiate, requires protein synthesis, and is triggered by transactivation of the epidermal growth factor receptor (EGFR). In this process, a proteinase cleaves the EGFR ligand HB-EGF,

stimulating EGFR activation and mitogen-activated protein kinase (MAPK)-dependent protein synthesis. The steps that lead to EGFR transactivation, and evidence for other stimuli that trigger the late phase exocytic response are unknown or unavailable. Here, we report that activation of apically localized A1 adenosine receptors (A1ar) using the agonist CCPA also stimulated exocytosis at the apical surface of umbrella cells, akin to the “late phase” stretch response. The HB-EGF specific inhibitor CRM-197, the EGFR inhibitor AG1478, the MAPK inhibitor U0126, and the protein synthesis inhibitor cycloheximide inhibited this effect. Furthermore, AG1478 blocked CCPA-stimulated phosphorylation of the EGFR tyrosine residue 1173 (Y-1173), indicating that they acted upstream of EGFR activation. Thus we report a bona fide EGFR transactivation pathway triggered by A1ar. Interestingly, we found that activation of PKC by PMA stimulated a similar exocytic response in these cells. A known effector of PKC and a critical mediator of EGFR transactivation in other cells types is A Disintegrin and a Metalloproteinase 17 (ADAM17). We observed this proteinase to be expressed in vesicles at the apical domain of umbrella cells and upon activation by PMA ADAM17 redistributed to the apical surface. A broad-spectrum metalloproteinase inhibitor GM6001 and an ADAM17 selective inhibitor Tapi-2 blocked CCPA-mediated exocytosis. Finally, using an exogenously expressed human growth hormone (hGH) assay system, we found that hGH is released from the apical surface upon treatment with CCPA and remarkably silencing the expression of ADAM17 using adenoviral-based in situ shRNAs completely blocked CCPA-induced hGH release. We propose a model whereby activation of Gi-protein coupled A1ar triggers PLC-mediated generation of IP<sub>3</sub>, which increases intracellular calcium and leads to PKC-mediated activation of ADAM17. In turn, activated ADAM17 cleaves HB-EGF and triggers EGFR activation leading to MAPK-mediated protein synthesis and apical exocytosis.

2211

**A directed RNAi screen for *C. elegans* TGF- $\beta$ -related DBL-1 trafficking components reveals non-synaptic vesicle machineries in neurons.**

K. K. Beifuss<sup>1</sup>, R. D. Schultz<sup>1</sup>, S. Bageshwar<sup>1</sup>, E. E. Bennett<sup>1</sup>, T. L. Gumienny<sup>1</sup>; <sup>1</sup>Molecular and Cellular Medicine, Texas A&M Health Science Center, College Station, TX

Transforming Growth Factor- $\beta$  (TGF- $\beta$ ) superfamily members are secreted morphogens that require precise regulation for normal development. Here we report results from a directed RNA inhibition (RNAi) screen we performed to identify gene products required for normal localization of green fluorescent protein (GFP)-tagged *Caenorhabditis elegans* TGF- $\beta$  member DBL-1. We generated a *C. elegans* screening strain expressing functional, GFP-tagged DBL-1 that is sensitized to the effects of RNAi by an *rrf-3* mutation, which removes endogenous RRF-3/RNA-directed RNA polymerase (RdRP) from the animal. Because our screening strategy is designed to eliminate potential embryonic lethality upon RNAi inhibition of gene function, we were able to identify late roles in TGF- $\beta$  localization for genes for which early lethal phenotypes were previously identified. We then used this strain to screen an RNAi library for genes required for proper DBL-1 localization *in vivo*.

We discovered that DBL-1 localization is punctate within the nerve cord neurons that secrete DBL-1, and these punctae are not synaptic vesicles. We found that mouse BMP4, another TGF- $\beta$  superfamily member, has the same function and localization pattern as DBL-1 in *C. elegans*. This localization depends on other TGF- $\beta$  pathway members in the receiving cell and extracellular matrix constituents. Specific cellular machinery components involved in ubiquitination, sumoylation, and progression of endosomes to lysosomes, specifically Endosomal Sorting Complex Required for Transport (ESCRT) machinery, the adaptor protein (AP) 3 complex, and specific Rab GTPases, are also required for tight localization of GFP-tagged DBL-1. Furthermore, Wnt pathway members affect the localization of GFP-tagged DBL-

1. Reduction of these screen isolates' function by RNAi resulted in spreading of GFP-DBL-1-positive punctae away from neurons. These results provide insights into the cellular mechanisms regulating TGF- $\beta$  localization and regulation in a living organism.

**Formin-driven actin polymerization is involved in regulation of early endosome dynamics.**

*N. Flores-Rodriguez<sup>1</sup>, A. Mogilner<sup>2</sup>, A. Bershadsky<sup>1,3</sup>; <sup>1</sup>Mechanobiology Institute, National University of Singapore, Singapore, Singapore, <sup>2</sup>Department of Mathematics and Department of Neurobiology, Physiology and Behavior, University of California, Davis, Davis, CA, <sup>3</sup>Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel*

Microtubule- and actin-dependent transport are central to many aspects of cellular homeostasis. Recent work has proposed that formins modulate the dynamics of both the actin and microtubule (MT) cytoskeletons, but their effect on MT-dependent organelle movement remains relatively unexplored. Here, we chose endocytic organelles as a model cargo, defined by the presence of the fluorescently tagged GTPase Rab5. To date, there are some studies that have provided insight into how formins (known to be potent activators of actin polymerization) might regulate endosome dynamics, however, these works have obtained information at low temporal resolution or in fixed cells. We have used computer-based automated particle tracking, with high temporal resolution (33 frames/sec) and a systematic analysis to describe the involvement of formin proteins, specifically the Diaphanus-related formin, mDia1 and its activator GTPase RhoA, in GFP-Rab5 labeled endosome dynamics. By using low levels of GFP-Rab5 expression and low levels of light we avoided perturbation of endosome function. The motility analysis of typically 2000 endosome tracks per imaged cell revealed that endosomal transport, specifically average speed, run length and duration, was profoundly reduced upon activation of mDia1 (mDia1 $\Delta$ N3) or RhoA (RhoA-V14) and in cells treated with the small molecule inhibitor of formin homology 2 domains (SMIFH2). The SMIFH2 effects could be reversed after washout of the drug. These results indicate the need for intact mDia1 to allow endosomal movement. All the effects caused by activation of the RhoA-mDia1 pathway in endosome transport were reversibly abolished by treating the cells with Latrunculin A, indicating that the effect of mDia1 on MT organelle movement depends on formin-driven actin polymerization. RhoA-V14 and mDia1 $\Delta$ N3 induced perturbation of endosomal transport are independent of the downstream RhoA effector ROCK, since treatment with the ROCK inhibitor Y-27632 did not rescue endosome motility. mDia1 RNAi knock-down caused milder inhibitions. A mean-square displacement analysis revealed that endosome motion in formin disrupted cells was subdiffusive compared to control cells that showed a combination of both subdiffusive and superdiffusive motion. The dominance of a subdiffusive regime suggests that endosomes in formin disrupted cells tended to be either effectively trapped or stalled by cytoskeletal barriers. Altogether these data suggest that the RhoA-mDia1 pathway can regulate endocytosis via its effect on MT-based endosome movement.

**Visualizing the dynamic architecture of the endocytic machinery by high resolution tracking of fluorescent proteins in yeast cells.**

*A. Picco<sup>1</sup>, F. Nédélec<sup>1</sup>, M. Kaksonen<sup>1</sup>; <sup>1</sup>Cell Biology and Biophysics Unit, European Molecular Biology Laboratory, Heidelberg, Germany*

Budding of clathrin-coated endocytic vesicles is driven by a highly dynamic and complex machinery consisting of over 50 different proteins. Although individual proteins have been studied extensively, their function as parts of the endocytic machinery is not well understood.

Especially, it is not known how most of the protein components are organized *in situ* during vesicle budding.

We have developed a live-cell particle tracking approach that measures average positions of fluorescently tagged endocytic proteins in relation to each other during the vesicle budding process with high spatial and temporal resolution. To reconstruct the dynamic organization of the endocytic machinery we combine this tracking data with estimates of numbers of molecules, and with available structural and correlative light and electron microscopy data.

We first investigated coat-associated proteins Sla2 and Sla1. The clathrin coat is structurally well studied but the organization of other coat-associated proteins is poorly understood. Our results suggested that the elongated rod-shaped Sla2 protein is located at the central part of the endocytic coat. By using N- and C-terminal GFP tagging we were able to resolve that Sla2 is oriented perpendicular to the plasma membrane so that its lipid binding domain is at the membrane and the actin binding domain projects away into the cytoplasm. Sla1, in contrast to Sla2, is likely located in the peripheral part of the coat. Next we tracked actin and several actin binding proteins to study the polymerization dynamics of the endocytic actin network. Two opposite models have been proposed about the direction of actin polymerization in relation to the forming vesicle. Our tracking of actin cytoskeletal proteins combined with FRAP experiments supported a model where actin filaments polymerize at the base of the invagination, not at the vesicle surface. Finally, we analyzed the dynamics of a BAR domain protein Rvs161/167 that binds to the membrane at the neck of the invagination to regulate vesicle scission. Our results suggested that Rvs161/167 starts assembling just below the coated tip of the invagination and then extends toward the base as the invagination elongates, eventually covering most of the tubular part of the invagination. The Rvs161/167 assembly ends with a catastrophic disassembly that coincides with vesicle scission. In summary, our results reveal several new insights into the mechanisms of endocytosis and demonstrate that live-cell imaging can provide detailed information about the dynamic molecular architecture of the endocytic machinery.

2214

#### **Retromer's Role in Insulin-Stimulated GLUT4 Trafficking in Adipocytes.**

*K. H. Lee<sup>1</sup>, Y. Zhe<sup>1</sup>, A. Bugarcic<sup>1</sup>, B. Collins<sup>1</sup>, R. D. Teasdale<sup>1</sup>; <sup>1</sup>Institute for Molecular Bioscience, The University of Queensland, Brisbane, Australia*

The Vps35-Vps29-Vps26 trimeric protein complex, termed Retromer, controls the endocytic sorting of various cargo molecules. Although proteomic studies have revealed that Retromer is present on Glut4 storage vesicle (GSVs) together with transmembrane protein Sortilin (Jedrychowski et al (2010), J. Biol. Chem., 285:104-114), the role of Retromer in cell differentiation and insulin-stimulated Glut4 trafficking remains unknown. We have used the 3T3-L1 cell model to investigate changes in Retromer subunits during differentiation. Interestingly, Vps26B protein levels increased by 50 fold after differentiation, while Vps26A protein levels remains unchanged. Using shRNA knockdown approach, we depleted the Retromer protein levels during the differentiation of 3T3-L1 fibroblasts to adipocytes. Within the cytoplasm, of Vps35 and Vps26A depleted adipocytes we observed a change in lipid droplet morphology with a higher population of small lipid droplets observed. Differentiated adipocytes with depleted Retromer levels have impaired Glut4 trafficking, including translocation to the plasma membrane in response to insulin stimulation.

**Regulated Antagonism between Endocytosis and the Cytoskeleton Controls *Drosophila* Blastoderm Development.***D. M. Lee*<sup>1</sup>, *T. J. Harris*<sup>1</sup>; <sup>1</sup>*Cell and Systems Biology, University of Toronto, Toronto, ON, Canada*

Actin networks push and pull the plasma membrane for the control of cell structure and behavior. Membrane trafficking also regulates the plasma membrane, suggesting it could impact the membrane cytoskeleton and vice versa. We discovered mutual antagonism between endocytosis and actomyosin networks and its impact on plasma membrane furrow ingression during cellularization of the *Drosophila* embryo. Steppke, a cytohesin Arf-GEF, acts at the tips of ingressing furrows to promote localized endocytosis and restrain actomyosin networks during early furrow ingression. Without Steppke, Amphiphysin-positive endocytic tubules (Amph tubules) no longer form, and the actomyosin networks and associated plasma membrane abnormally expand, disrupting furrow structure and expelling nuclei from the forming epithelium. Overexpressing Steppke induced ectopic Amph tubule formation, reduced furrow F-actin, and shortened furrow length, effects dependent on its Arf-GEF activity. Arguing that the Steppke phenotypes were ultimately due to actin mis-regulation, the overall Steppke loss-of-function phenotype was by suppressed by reducing levels of Rho1, a positive actomyosin regulator. The suppression with Rho1 also restored normal Amph tubules, suggesting that actomyosin overactivity inhibits endocytosis. To independently test whether actomyosin networks inhibits endocytosis, we stabilized actin in embryos using Jasplakinolide, which forced expansion of actomyosin networks and reduced Amph tubule formation. The Steppke phenotypes also suggested that endocytosis inhibits actomyosin networks. To independently test this idea, we examined the effect of chemical inhibitors of actin (Cytochalasin D) and clathrin (Chlorpromazine). Embryos treated with a low dose of Cytochalasin D displayed furrow loss, and remarkably, Chlorpromazine nullified the effect of Cytochalasin D, showing that reducing endocytosis can stabilize actomyosin networks. Overall, these results argue that endocytosis normally inhibits the actin cytoskeleton at cellularization furrows, and elevated actomyosin activity can also act reciprocally to inhibit the endocytosis. We propose that during early furrow ingression Steppke-dependent endocytosis keeps actomyosin cytoskeleton in check, but as cellularization proceeds, the actomyosin cytoskeleton gains strength, blocks the endocytic inhibition, and finally closes off the base of each cell to form the blastoderm.

2216

**Lipid composition as a modulator of liposome uptake in a human astrocytoma cell line.***E. Suesca*<sup>1</sup>, *N. Bolanos*<sup>2</sup>, *C. Leidy*<sup>1</sup>, *J. M. Gonzalez*<sup>2</sup>; <sup>1</sup>*Department of Physics, Universidad de los Andes, Bogota, Colombia,* <sup>2</sup>*Facultad de Medicina, Universidad de los Andes, Bogota, Colombia*

Astrocytes are the most abundant cells in the central nervous system (CNS). In the CNS, astrocytes form part of the blood brain barrier, supply neurons and oligodendrocytes with substrates for energy metabolism, control homeostasis, regulate neurotransmitter release and modulate the immune response. Glioblastoma multiforme is the most common and severe glioma variant in adults, and is originated primarily from astrocytes. Tumor development induces apoptosis of the surrounding glia cells, neurons, and oligodendrocytes. This implies that the GBM may be exposed to lipid debris generated from the myelin sheath. In previous work, we have shown that lipids found in the myelin sheath upregulate the uptake of liposomes by an astrocytoma cell line. This motivated us to study how lipid composition can be used to enhance liposome uptake in this tumor cell line, as a mechanism for targeted drug delivery. Experiments were carried out using a Human astrocytoma cell line, which was cultured in the presence of

small unilamellar vesicles (SUVs) of varying compositions labelled with NBD-PE. The results show that sulfocerebrosides increase significantly liposome uptake compared to phosphocholine enriched liposomes, without reducing cell viability or enhancing the production of inflammatory response molecules such MHC molecules expression, and pro-inflammatory chemokines secretion. Liposomes are observed through time-lapse fluorescence microscopy to accumulate near the nucleus, indicating that uptake takes place through endocytotic routes. Endocytic inhibitors were evaluated to determine the endocytic route used by liposomes. Cytochalasin D was used to inhibit the macropynocytosis route, by blocking the actin polymerization. Chlorpromazine was used to inhibit the clathrin dependant route, and Nystatin was used to inhibit caveolae mediated endocytosis by diminish cholesterol in the plasma membrane. This information is integrated to propose a model for lipid dependent endocytosis in the astrocytoma cell line.

**Selective transport of pinosomal contents based on the molecular sizes.**

C. Chen<sup>1</sup>, H. Li<sup>2,3</sup>, S. Duan<sup>1</sup>; <sup>1</sup>*School of Medicine, Zhejiang University, Hangzhou, China,* <sup>2</sup>*Institute of Neuroscience, Chinese Academy of Sciences, Shanghai, China,* <sup>3</sup>*Institute of Neuroscience, Chinese Academy of Sciences, Shanghai, China*

Pinocytosis is a major way immune cells use to capture antigens, thus is fundamental in antigen presentation. However, the mechanisms underlying the processing and trafficking of the engulfed antigens are still mysteries. Here we report a size-based selection of pinosomal contents in which small molecules were sorted out, whereas larger ones were still retained inside pinosomes. Further results suggested that the size-based selection was mediated by kiss-and-run fusion events. Interestingly, disturbance of the selection of pinosomal contents significantly impaired antigen presentation, but had no impact on antigen uptake or T cell survival. Our results indicate that kiss-and-run fusion between vesicles leads to selective transport of pinosomal contents based on their molecular sizes, contributing to efficient antigen presentation.

**Recycling of integral membrane proteins to the cell surface is regulated by their deubiquitination.**

C. MacDonald<sup>1</sup>, R. Piper<sup>1</sup>; <sup>1</sup>*Molecular Physiology & Biophysics, University of Iowa, Iowa City, IA*

The regulation of protein levels at the cell surface is critical for proper function of a variety of cellular processes. Integral membrane proteins, such as nutrient transporters or receptors that recognize extracellular ligands can be maintained at the cell surface where they function, circulate between endosomes and the plasma membrane (PM), or be sent to the lysosome for degradation. Conjugation of ubiquitin by E3 ubiquitin ligases onto cargo membrane proteins serves as a signal for trafficking into the multivesicular body (MVB) pathway and into lysosomes for degradation. Deubiquitinating peptidases (DUBs) can counteract this regulation by removing the ubiquitin sorting signal. We propose that deubiquitination throughout the endocytic pathway is a regulated mechanism to recycle proteins back to the cell surface, and that many yeast proteins have the capacity to recycle membrane proteins back to the cell surface by default. To test this we have taken advantage of the class E *vps* mutants of *Saccharomyces cerevisiae* that block MVB biogenesis and accumulate ubiquitinated cargo membrane proteins in enlarged endosomes known as Class E compartments. We developed a technique to chemically induce hetero-dimerization of a DUB enzyme onto cargo proteins otherwise trapped on class-E compartment endosomes. This technique quickly and acutely deubiquitinates cargo and

prevents further ubiquitination. We find this approach triggered recycling of membrane proteins such as Ste3 (a GPCR) and nutrient transporters back to the plasma membrane thus revealing the capacity to recycle in the absence of a ubiquitin sorting signal. Currently, pathway analysis indicates that the recycling route taken by “un-ubiquitinated” proteins relies on the Skp1/Rcy1 complex and is distinct from the Retromer-dependent pathway. Future experiments will identify relevant DUBs and protein machinery that facilitate recycling through this “default” pathway.

#### Antigen-stimulated exocytosis in RBL mast cells.

*J. D. Wilson<sup>1</sup>, D. Holowka<sup>1</sup>, B. Baird<sup>1</sup>; <sup>1</sup>Chemistry and Chemical Biology, Cornell University, Ithaca, NY*

Stimulated exocytosis events are a hallmark of the mast cell allergic response. These processes are triggered by multivalent antigen-mediated crosslinking of IgE bound to its high affinity Fc receptor, FcεRI, on the mast cell surface. We previously showed that in RBL-2H3 mast cells, internalized cholera toxin B (CTXB) bound to ganglioside GM<sub>1</sub> traffics to the plasma membrane in response to antigen stimulation (Naal et al., *Traffic* 4, 190-200, 2003). This result indicated that in addition to secretory granule exocytosis (degranulation), CTXB-labeled recycling endosome (RE)-derived membranes also fuse with the plasma membrane in response to antigen. Here we use the v-SNAREs VAMP2, VAMP3, VAMP7, and VAMP8, C-terminally fused to the pH-sensitive variant of GFP known as super-ecliptic pHluorin, to monitor antigen-stimulated exocytosis. VAMP2, VAMP3, and VAMP8 colocalize at REs, whereas VAMP7 is mostly found in secretory granules. Using these tagged v-SNAREs, we monitor stimulated exocytosis by fluorimetry and visualize individual exocytic events with TIRF microscopy. Similar to constitutive RE trafficking, we find that stimulated RE-derived vesicle exocytosis, as monitored by VAMP2, VAMP3, and VAMP8, is attenuated by expression of dominant negative (S25N) Rab11. Surprisingly, stimulated VAMP7 exocytosis is also reduced in the presence of dominant negative Rab11, suggesting that expression of this mutant broadly impacts the endolysosomal system. We find that stimulated VAMP3 exocytosis is almost completely inhibited in the C1 cell line, a mutant variant of the RBL-2H3 cell line known to have defects in ganglioside expression and antigen-stimulated calcium mobilization necessary for granule exocytosis. In contrast, stimulated exocytosis of antibody-labeled transferrin receptors, which localize to endocytic compartments distinct from the RE, is less affected. Together, our results suggest the existence of multiple, distinct endosome-derived vesicle populations that exocytose in response to antigen.

2220

#### Functional characterisation of the Fam21-interacting proteins and their role in regulating WASH complex function.

*C. L. Freeman<sup>1</sup>, M. N. Seaman<sup>1</sup>; <sup>1</sup>Clinical Biochemistry, University of Cambridge, Cambridge, United Kingdom*

The WASH complex is a multimeric protein complex that is recruited to endosomal membranes by retromer. This association is mediated by the interaction of VPS35 with the unstructured tail domain of WASH complex member Fam21, which also binds a number of other proteins. Depletion of the WASH complex members strumpellin, SWIP or Wash1 results in an increased prevalence of endosomal tubules positive for the retromer components Snx1 and VPS26, and the WASH complex is therefore implicated in the regulation of endosomal membrane dynamics. We aimed to elucidate further the role of the WASH complex in these processes. Here we identify and characterise a novel interactor of the Fam21 tail domain. We show that depletion of

this protein causes a profound increase in the presence of retromer-positive endosomal tubules. These tubules are abolished by microtubule depolymerization, but not by inhibition of the V-ATPase using bafilomycin. We show that this tubulation phenotype is not the result of destabilisation of the retromer or WASH complexes. Through the transient expression of truncated forms, we have identified regions in both proteins that are necessary for the interaction to be maintained. Finally, we have extended our investigation of this phenotype to other WASH complex members and known retromer cargoes. The identification of a further WASH complex interactor with roles in endosomal tubulation highlights the importance of this complex in the tight regulation of membrane dynamics, and may provide a means of explaining the mechanism by which depletion of WASH complex members upregulates tubule formation.

**Molecular mechanism of cargo capture and vesicle formation by the ESCRT-III polymer.**

N. J. Buchkovich<sup>1</sup>, W. M. Henne<sup>1</sup>, S. D. Emr<sup>1</sup>; <sup>1</sup>Weill Institute for Cell and Molecular Biology, Cornell University, Ithaca, NY

The endosomal sorting complex required for transport (ESCRT) proteins constitute a highly conserved set of proteins involved in MVB formation. ESCRT-III is composed of four subunits (Vps20, Snf7, Vps24 and Vps2) and is the minimal machinery necessary to generate vesicles within MVBs<sup>1</sup>. However, the structure and mechanism of ESCRT-III-mediated membrane remodeling remain unresolved. Here, we directly visualize ESCRT-III and propose how it mediates vesicle formation. Mutations promoting Snf7 activation generate long ~9nm protofilaments composed of two ~4nm Snf7 sub-filaments running in parallel<sup>2</sup>. These protofilaments form vast 2-D spiral arrays when assembled on lipid monolayers, which are converted to rings that are ~65 nm in diameter upon addition of ESCRT-II and Vps20<sup>2</sup>. It is currently not understood how this polymer interacts with membrane. Understanding how the ESCRT-III subunits, and the assembled ESCRT-III complex, bind and/or deform membrane is critical for understanding the process of membrane scission and intraluminal vesicle formation. Using the structure of hVps24 as a model, we performed a structural-based mutagenesis screen of Snf7 to identify potential membrane-interacting regions. We have identified two regions important for membrane binding: 1) positively-charged interface on the core region and 2) N-terminal hydrophobic residues. Mutating the positively-charged membrane binding interface affects both membrane localization and function. Mutation of the N-terminal hydrophobic residues affects Snf7's ability to bind membrane *in vitro*, but not to localize to the membrane fraction *in vivo*. Accordingly, mutating the N-terminus affects Snf7's ability to create ILV's and sort cargo, but not to sequester cargo, suggesting it has a key role in vesicle formation. We will present data on the role of the domains in membrane deformation and scission during intraluminal vesicle formation.

**An Ubiquitin-independent Lysosomal Sorting Pathway: AP-3 and ALIX Coordinate Sorting of PAR1 into Multivesicular Endosomes.**

M. R. Dores<sup>1</sup>, J. Trejo<sup>1</sup>; <sup>1</sup>Pharmacology, University of California San Diego, La Jolla, CA

The sorting of signaling receptors to lysosomes is an essential regulatory process. Many receptors are modified with ubiquitin and sorted by ESCRT-0, -I, -II and -III complexes into

intraluminal vesicles (ILVs) of multivesicular bodies (MVBs) prior to degradation. However, it remains unclear whether a single universal mechanism mediates MVB sorting of all receptors. The protease-activated receptor-1 (PAR1), a G protein-coupled receptor (GPCR) for thrombin, is sorted to lysosomes independent of ubiquitination and the ubiquitin-binding ESCRTs, Hrs and Tsg101. Here we report that PAR1 sorts to ILVs of MVBs through an AP-3- and ALIX-dependent pathway that occurs independent of ubiquitination. AP-3 and ALIX function sequentially to sort PAR1 from early endosomes to late endosomes/MVBs, coupling PAR1 to the ESCRT-III complex prior to entry into ILVs. Depletion of AP-3 inhibits PAR1 degradation and disrupts interaction between PAR1 and ALIX. AP-3 binds to a YXX $\Phi$  motif within the PAR1 C-tail, which precedes PAR1 interaction with ALIX. Mutation of the PAR1 YXX $\Phi$  motif causes PAR1 to localize to microdomains within the limiting membrane of late endosomes, blocking entry into ILVs of MVBs. ALIX then interacts with PAR1, mediating entry into ILVs by coupling PAR1 to the ESCRT-III complex subunit CHMP4. Depletion of ALIX or mutation of the ALIX Bro-1 domain inhibits PAR1 degradation by blocking PAR1 interaction with CHMP4. The ALIX V-domain binds directly to a YPX<sub>n</sub>L motif within the intracellular loop 2 of PAR1. In addition, disruption of ALIX binding by mutation of the PAR1 YPX<sub>n</sub>L motif inhibits PAR1 entry into the lumen of MVBs. Interestingly, multiple GPCRs contain YPX<sub>n</sub>L motifs within intracellular loop 2, suggesting that ALIX may mediate ubiquitin-independent lysosomal sorting of a wide range of signaling receptors. This study reveals a novel MVB/lysosomal sorting pathway for signaling receptors that bypasses the requirement for ubiquitination and ubiquitin-binding ESCRTs that utilizes AP-3, ALIX and the ESCRT-III complex to facilitate degradation of PAR1.

#### **An ARF6 / Rab35 GTPase cascade for endocytic recycling and successful cytokinesis.**

*L. Chesneau<sup>1</sup>, D. Dambournet<sup>1</sup>, M. Machicoane<sup>1</sup>, I. Kouranti<sup>1</sup>, M. Fukuda<sup>2</sup>, B. Goud<sup>3</sup>, A. Echard<sup>1</sup>; <sup>1</sup>Membrane Traffic and Cell Division lab, Institut Pasteur, Paris, France, <sup>2</sup>Department of Developmental Biology and Neurosciences, Tohoku University, Sendai, Japan, <sup>3</sup>Molecular mechanisms of intracellular transport lab, Institut Curie, Paris, France*

Cytokinesis bridge instability leads to the formation of binucleated, tetraploid cells that can be a starting point for tumorigenesis in vivo. Membrane trafficking is crucial for animal cell cytokinesis, and several endocytic pathways regulated by distinct GTPases (Rab11, Rab21, Rab35, ARF6, RalA/B) contribute to the post-furrowing steps of cytokinesis. However, little is known about how these pathways are coordinated for successful cytokinesis.

We previously reported that the Rab35 GTPase controls a fast recycling endocytic pathway and must be activated for SEPTIN cytoskeleton localization at the intercellular bridge and thus for completion of cytokinesis [1-2].

We will present evidence showing that the ARF6 GTPase negatively regulates Rab35 activation and hence the Rab35 pathway. Human cells expressing a constitutively activated, GTP-bound ARF6 mutant display identical endocytic recycling and cytokinesis defects as those observed upon overexpression of the inactivated, GDP-bound Rab35 mutant. This includes defects in Transferrin Receptor fast-recycling back to the plasma membrane, SEPTIN2, MHC-I and PI(4,5)P2 accumulation on abnormal intracellular vacuoles, and post-furrowing cytokinesis failure associated with SEPTIN2 delocalization from early bridges. As a molecular mechanism, we identified the Rab35GAP EPI64B as an effector of ARF6 in negatively regulating Rab35 activation. Unexpectedly, this regulation takes place at clathrin coated pits, and activated ARF6 reduces Rab35 loading into the endocytic pathway. Thus an effector of an ARF protein is a GAP for a downstream Rab protein, and we propose that this hierarchical ARF/Rab GTPase cascade controls the proper activation of a common endocytic pathway essential for cytokinesis [3].

**GRAF1 and MICAL-L1 co-operate in tubular recycling endosome biogenesis.**

*B. Cai<sup>1</sup>, S. Caplan<sup>1</sup>, N. Naslavsky<sup>1</sup>; <sup>1</sup>Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE*

The protein GTPase Regulator Associated with Focal Adhesion Kinase-1 (GRAF1) plays a role in the endocytosis of clathrin-independent carriers. It is found enriched at podosome-like adhesions and implicated in cell spreading. GRAF1 is comprised of: N-terminal BAR domain, PH domain, RhoGAP domain and C-terminal SH3 domain. GRAF1 binds to tubular membranes via its BAR and PH domains. Our group has been studying MICAL-L1, a regulator of endocytic recycling and a component of tubular recycling endosomes, and we hypothesized that GRAF1 and MICAL-L1 might physically and/or functionally interact on these tubular membranes. Indeed, we show that GRAF1 interacts with MICAL-L1 by co-immunoprecipitation. Interestingly, high exogenous expression of GRAF1 displaces MICAL-L1 from tubules, while weakly expressed GRAF1 co-localizes with MICAL-L1 on tubular endosomes. In addition, the depletion of GRAF1 by siRNA induces hyper-tubulation of MICAL-L1- and Rab11-containing endosomes, and leading to delayed recycling of  $\alpha$ 1 integrin. However, upon MICAL-L1-depletion, the tubular localization of GRAF1 remains unchanged, suggesting that it localizes to recycling endosomes independently of MICAL-L1. Accordingly, we propose that GRAF1 regulates recycling by controlling the localization of MICAL-L1 to tubular recycling endosomes.

2225

**Exchange and activation of the Nedd4-family adaptor Hua1 is controlled by ubiquitination and ubiquitin-peptidases.**

*C. A. Williams<sup>1</sup>, S. B. Shields<sup>1</sup>, S. C. Winistorfer<sup>1</sup>, R. C. Piper<sup>1</sup>; <sup>1</sup>Molecular Physiology and Biophysics, University of Iowa, Iowa City, IA*

The sorting of cell surface proteins to the lysosome is triggered by their ubiquitination. The major ubiquitin ligase in yeast responsible for protein sorting to the lysosome/vacuole is Rsp5, a Nedd4-family ligase distinguished by a catalytic HECT domain and 3 central WW domains that bind PPxY motifs in target proteins. Many substrates of Rsp5 do not bind directly, but instead rely on adaptor proteins, which have PPxY motifs and bridge the interaction with Rsp5. Recent studies indicate that these adaptors may be more active in their ubiquitinated state, but it is not clear how ubiquitination “activates” them and whether this step is regulated. Here, we describe a mechanism for how Nedd4-like ubiquitin ligase adaptors are activated. Our studies focused on Hua1, an Rsp5 adaptor that brings Rsp5 to ESCRT-0 to promote sorting of membrane proteins into multivesiculated bodies. Hua1 is also ubiquitinated. When overexpressed, Hua1 inhibits Rsp5 by competing away interactions with other Rsp5 adaptors. A ubiquitin-Hua1 fusion protein, which mimics a constitutively ubiquitinated form of Hua1, is a dramatically more potent inhibitor, while Hua1 lacking its Rsp5 binding motifs or ubiquitinatable lysines lacks the ability to inhibit Rsp5. We also found that Ub-Hua1 binds much tighter to Rsp5 than WT Hua1. Rsp5, like Nedd4, has a binding site within the C-lobe of the HECT domain that mediates non-covalent binding to ubiquitin. Eliminating this ubiquitin-binding domain reduced the potency of inhibition displayed by the Ub-Hua1 fusion protein. Rsp5 also associates with the deubiquitinating enzyme Ubp2. Eliminating Ubp2 increased the inhibitory activity of Hua1 overexpression. These data support a model whereby adaptors become ubiquitinated and bind tighter to Rsp5 via both WW domains and the Rsp5 ubiquitin-binding domain. This tight association allows the adaptor to stay bound to Rsp5 thus directing Rsp5 to a subset of targets. Ubp2 deubiquitinates

adaptors, allowing them to disengage Rsp5 and allow for cycling of adaptors. Loss of Ubp2 results in depriving the full complement of adaptors onto Rsp5, resulting in dysfunction of Rsp5.

2226

**Cargo sorting and endosome-to-Golgi retrograde transport pathways.**

*P. Z. Chia<sup>1</sup>, F. J. Houghton<sup>1</sup>, D. M. Hatters<sup>1</sup>, P. A. Gleeson<sup>1</sup>; <sup>1</sup>Biochemistry and Molecular Biology and Bio21 Molecular Science and Biotechnology Institute, University of Melbourne, Melbourne, Australia*

Transport pathways from the endosomal system to the trans-Golgi network (TGN) (retrograde transport) are critical for the recycling of membrane proteins which regulate a range of cellular and development functions. Recent advances have identified multiple retrograde transport pathways each regulated by a distinct set of molecular machinery. For example, the cargoes TGN38 and Shiga toxin are transported by distinct routes to the TGN which are defined by specific machinery which regulate these pathways. Furin is an essential proprotein convertase whose trafficking itinerary also involves cycling between the endosomes and the TGN, presumably allowing it to cleave a variety of substrates as it passes through the different cellular compartments.

*Objective:* The goal of this study was to compare the retrograde trafficking pathway of furin and TGN38, to define the cargo signals for intracellular transport and to develop high throughput flow cytometry analyses to monitor and quantitate protein localisation changes, eg trafficking, in cells.

*Results:* Using internalisation assays, we show that furin transits the early and late endosomes en route to the TGN. The late-endosome-localized GTPase Rab9 and the TGN golgin tether GCC185 were both required for TGN-retrieval of furin. In contrast TGN38, which circumvents the late endosome, is Rab9 and GCC185-independent. To identify the sorting signals for the early endosome-to-TGN pathway, the trafficking of furin/TGN38 chimeras were investigated. The diversion of furin from the Rab9-dependent late endosome-to-TGN pathway to the retromer-dependent early endosome-to-TGN pathway required both the transmembrane domain and cytoplasmic tail of TGN38. We present evidence to suggest that the length of the transmembrane domain is a contributing factor in endosomal sorting.

Standard approaches for detecting the intracellular location of cargo involve microscopy-based methods that are highly limited in their throughput capacity, speed of acquisition and quantitation. The development of fast, sensitive and quantitative approaches to detect intracellular localisation and trafficking would represent a significant advance in the field. We have developed a pulse shape analysis (PulSA) to monitor protein localization changes in cells by flow cytometry (Ramdzan et al *Nature Methods*, 2012;9:467-70). We demonstrate that PulSA can be used successfully to monitor the PM to Golgi retrograde transport of cargo in cell populations.

*Conclusions:* These data show that furin uses the Rab9-dependent pathway from late endosomes and that retrograde transport directly from early endosomes is dependent on both the transmembrane domain and the cytoplasmic tail. The possible underlying mechanisms for this sorting event will be discussed. In addition, with flow cytometry flow rates of >10,000 cells per sec, PulSA provides a major advance in quantitative analysis of retrograde cargo trafficking.

## Rab GTPases

### A novel endogenous Rab library.

S. Dunst<sup>1</sup>, M. Brankatschk<sup>1</sup>, A. Sagner<sup>1</sup>, T. Kazimiers<sup>1</sup>, H. Jambor<sup>1</sup>, P. Tomancak<sup>1</sup>, S. Eaton<sup>1</sup>;  
<sup>1</sup>Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

Rab GTPases and their effectors are essential coordinators of the intracellular membrane and protein transport machinery. In humans, more than 60 Rab proteins have been identified, and the disruption of Rab-mediated transport has been implicated in several inherited human disorders. While most of the data on intracellular trafficking has come from tissue culture experiments, a model system for studying the role of Rab-mediated intracellular transport in the development and function of tissues is still lacking.

The *Drosophila melanogaster* genome encodes 23 conserved Rab proteins with clear vertebrate homologues. We used homologous recombination to generate a novel Rab library in the fly that includes *rab* genes fused to a fluorophore or a proteolytic cleavage site, as well as precise loss-of-function (LOF) alleles. This new resource will allow us to identify the *in vivo* function and localization of each individual Rab protein at endogenous levels. Moreover, we introduced a CATMAID-based online platform that enables collaborative data collection and annotation towards the decryption of the “Rab code” in *Drosophila* tissues.

We used our novel Rab library to systematically profile and annotate the localization and expression of all conserved Rab proteins in the larval salivary gland, wing disc, fat body, CNS and adult ovary/testis. We found that many Rab proteins show cell type-specific expression, subcellular localization and compartment morphology. Additionally, we observed quantitative differences in protein levels between tissues and developmental stages.

Rab profiling in fat body cells revealed a unique cortical localization of Rab35. We reasoned that this localization could be important for the trafficking of Lipid transfer particle (LTP), which also localizes to the cellular cortex in the fat body. LTP controls the lipidation status of Lipophorin (Lpp) that is required for lipid transport within the organism (Palm *et al.*, 2012). Indeed, when we generated a specific knockdown of our fluorescently tagged Rab35 in fat body cells, we observed a loss of LTP from the cortex. Other markers, including Discs large, F-actin, Lpp, Lava lamp and KDEL, were unchanged, suggesting that general cortical transport, actin bundling, protein secretion and intracellular membrane compartments (i.e., Golgi and endoplasmic reticulum) were unaffected. Furthermore, the knockdown of Rab35-EYFP in the fat body caused an accumulation of lipids in the midgut, resembling the characteristic LTP mutant phenotype. This proves that established genetic knockdown tools directed against the introduced Rab protein tag are suitable to induce specific phenotypes.

The combination of our novel genetic resource and online data management platform comprises a valuable new *in vivo* approach for Rab protein profiling and functional analysis that facilitates new insights into the intracellular trafficking machinery.

**The actin nucleation factor WHAMM cooperates with the small GTPase Rab1 to drive membrane tubulation and procollagen transport.**

*K. G. Campellone<sup>1</sup>, A. J. Russo<sup>1</sup>, N. Wong Meng La<sup>2</sup>, M. D. Welch<sup>2</sup>; <sup>1</sup>Molecular and Cell Biology, University of Connecticut, Storrs, CT, <sup>2</sup>Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA*

The actin cytoskeleton provides mechanical support and generates protrusive forces during plasma membrane dynamics, yet comparably little is known about how actin shapes secretory organelles. In mammalian cells, actin filament networks are assembled and organized by the WASP (Wiskott-Aldrich Syndrome Protein) family of actin nucleation factors, and several of these proteins are recruited to the plasma membrane by small GTPases like Cdc42 or Rac1 to drive endocytosis or cell migration. Another one of the nucleation factors, WHAMM (WASP Homologue associated with Actin, Membranes, and Microtubules), promotes membrane tubulation and ER-to-Golgi transport, but its mechanism of membrane recruitment and its endogenous functions in trafficking have not been well characterized. We therefore tested whether ER- or Golgi-associated GTPases are involved in WHAMM-mediated membrane dynamics and anterograde transport. We found that Rab1 stimulates the formation and elongation of WHAMM-associated membrane tubules, as well as the secretion of collagen, the primary protein component of connective tissue. A portion of WHAMM called the WMD (WHAMM Membrane-interaction Domain) binds directly to a prenylated form of Rab1 in vitro, and active Rab1 recruits WHAMM to membranes in cells. Interestingly, WHAMM and Rab1 co-localize along tubular structures that contain procollagen and require both actin and microtubules for their movement. Finally, depletion or inactivation of WHAMM or Rab1 causes large amounts of procollagen to accumulate within fibroblasts. These results highlight a previously unrecognized ability of Rab1 to signal to the cytoskeleton, and demonstrate that this GTPase cooperates with WHAMM to promote membrane remodeling and procollagen transport.

2229

**Phospho-regulation of ezrin-ACAP4 interaction serves as a switch in polarized membrane trafficking.**

*X. Ding<sup>1</sup>, W. Yao<sup>2</sup>, D. Wang<sup>3</sup>, F. Wang<sup>2</sup>, T. Ward<sup>2</sup>, J. Li<sup>1</sup>, X. Yao<sup>2</sup>; <sup>1</sup>BUCM-MSM Joint Research Group for Cellular Dynamics & Plasticity, Beijing University of Chinese Medicine, Beijing, China, <sup>2</sup>Physiology, Morehouse School of Medicine, Atlanta, GA, <sup>3</sup>Cellular Dynamics, University of Science & Technology of China, Hefei, China*

The ezrin-radixin-moesin proteins provide a regulated linkage between membrane proteins and the cortical cytoskeleton and also participate in signal transduction pathways. Our recent biochemical characterization demonstrates that ezrin cooperates with ACAP4, ARF6GTPase activating protein, in spatial control of apical membrane trafficking (J. Biol. Chem. 2010. 285, 18769-80). ACAP4 locates in the cytoplasmic membrane in resting parietal cells but translocates and recruits v-SNAREs to the apical plasma membrane upon histamine stimulation in an ezrin phosphorylation-dependent manner. In these parietal cells, secretagogue stimulation produced a striking apical membrane expansion associated with HCl secretion and the secretory phenotype. Given the fact that phosphorylation of ACAP4 at Tyr733 elicits its interaction with Grb2 (J. Biol. Chem. 2011. 286, 43735-46), we probed for the functional relevance of phospho-Tyr733 of ACAP4 in polarized membrane trafficking by introducing the phospho-mimicking ACAP4 into culture parietal cells. Surprisingly, Y733E mutant ACAP4 was more typically localized to the basolateral membrane associated with Grb2-rich projections. Moreover, H,K-ATPase and v-SNAREs were recruited to the Y733E ACAP4-enriched basolateral domains with non-secretory phenotype. The large basolateral expansion is predicted

to recruit membranes from sources not normally targeted to that surface. We reason that phosphorylation of ACAP4 provide a switch in polarized vesicular trafficking in epithelial cells. Currently, we are investigating how phosphorylation of ACAP4 orchestrates epithelia cell plasticity changes in response to extracellular cues.

**Selective activation of Rab5 by distinct endocytic pathways.**

*I. Jozic<sup>1</sup>, S. C. Saliba<sup>1</sup>, M. Rodriguez Silva<sup>1</sup>, M. A. Barbieri<sup>1</sup>; <sup>1</sup>Biological Sciences, Florida International University, Miami, FL*

The process of endocytosis is a complex pattern of membrane vesicle trafficking, which permits the continuous flow of membrane between cell surface and various intracellular compartments, via fusion and fission events, with Rab5 mediating the fusion events of early endosomes. Since it has been well established that varying concentrations of Epidermal Growth Factor (EGF) during the endocytosis of EGF-Receptor can elicit uptake via numerous endocytic routes, we were interested in analyzing which of these endocytic pathways is/are responsible for activation of Rab5. We've discovered activation of Rab5 is dependent on temperature, time of uptake as well as the concentration of ligand available at the cell surface. Furthermore, by utilizing specific inhibitors against key regulators of endocytosis (i.e., chlorpromazine, dynasore or filipin) and by varying the concentration of EGF stimulation, we have provided first evidence for the existence of at least three distinct pathways of Rab5-dependent internalization of EGF-receptors. Overexpression of either Rin1 or Rabex-5 is able to rescue Rab5 activity even in absence of EGF and/or in the presence of any of the employed inhibitors. Taken together, these results constitute evidence for the first time showing differential activation of Rab5 with respect to the different routes of uptake of EGF.

**Rab35 is a novel ciliary protein.**

*C. Seixas<sup>1</sup>, J. Ramalho<sup>1</sup>, D. Barral<sup>1</sup>; <sup>1</sup>CEDOC- Faculdade Ciências Médicas, Lisboa, Portugal*

Primary cilia are microtubule-based mechanosensory organelles that protrude from the cell surface and are essential for several signaling pathways. Cilia proteomic and comparative sequence studies have identified more than a thousand of putative ciliary proteins, including small GTPases, such as Ran, Rab and Arf/ Arf-like (Arl) family members. It is well established that small GTPases regulate different steps of vesicle trafficking, including vesicle budding, transport, tethering, docking and finally fusion with acceptor membranes. Several models have been proposed to explain how ciliary cargo reaches the base of cilia, from where proteins can be transported to the ciliary tip by intraflagellar transport. The most accepted model postulates a trafficking route based on polarized exocytosis, in which the ciliary components are carried into vesicles from intracellular compartments towards the base of the cilium and then, by fusion delivered to the ciliary membrane. It has been shown that the trans-Golgi network can be the source of vesicular carriers destined for the cilium. Alternatively, it was hypothesized that other intracellular compartments, such as the endosome recycling compartment (ERC), can also serve as a source of vesicles that carry ciliary cargo.

We have investigated the localization of Rab proteins known to be involved in endocytic recycling trafficking that could also be involved in ciliary trafficking. We found that Rab35 localizes at the base of primary cilia and along the ciliary axoneme of murine inner medullary collecting duct (IMCD3) cells and NIH-3T3 fibroblasts. Rab35 was previously shown to regulate the endocytic recycling pathway and control the docking of vesicles from the ERC to the plasma membrane. Furthermore, we analyzed the ciliogenesis capacity and the trafficking of ciliary

cargo when Rab35 levels were affected. Taken together, our results suggest that Rab35 is a novel ciliary protein and modulates ciliogenesis.

2232

**EHD1 shapes developing primary cilia and influences transport from the ciliary pocket.**

Q. Lu<sup>1</sup>, J. Rahajeng<sup>2</sup>, C. Ott<sup>3</sup>, J. Lipincott-Schwartz<sup>3</sup>, S. Caplan<sup>2</sup>, P. Jackson<sup>4</sup>, C. Westlake<sup>1</sup>;  
<sup>1</sup>NCI-Frederick, Frederick, MD, <sup>2</sup>University of Nebraska, Omaha, NE, <sup>3</sup>NIH-NICHD, Bethesda, MD, <sup>4</sup>Genentech, South San Francisco, CA

The primary cilium is a sensory structure important in development and disease pathways. Ciliogenesis involves coordinated assembly of a microtubule-based axoneme from the mother centriole and vesicular membrane transport and fusion forming a ciliary membrane around the developing axoneme. Previously, we demonstrated that a Rab11-Rab8 cascade functions in ciliogenesis. The Rab8 GEF, Rabin8, binds to Rab11 and is transported to the centrosome to activate Rab8 and initiate ciliary membrane assembly. Although it is well established that Rab11 and Rab8 define the ciliary-destined vesicles, it is still unclear how the proteins recruited by these Rab proteins influence cilia formation and maintenance. Here we show the preciliary vesicles carry Rab11/Rab8 associated cargo required for ciliary membrane assembly. Specifically, we find that EHD1 is present on both the preciliary and ciliary membranes via binding to Rab11 and Rab8 effector proteins, all of which are required for ciliogenesis. Live imaging studies show EHD1 is localized to the developing primary cilium membrane prior to Rab8 recruitment, which leads to ciliary membrane extension. This result, along with the known membrane deformation ability of EHD proteins, suggests that EHD1 functions in ciliary vesicle to ciliary membrane sheath transition. Interestingly, in mature cilia EHD1 was detected near the proximal end of the primary cilium. Correlative light-electron microscopy (CLEM) demonstrated that EHD1 is absent from the ciliary membrane that has emerged from the cell surface and is restricted to a region containing the ciliary pocket, an invaginated membrane between the plasma membrane and primary cilium membrane. Using structured illumination microscopy (SIM) and total internal reflection fluorescence microscopy (TIRF) EHD1, unlike Rab8, was often restricted to the pocket membrane and/or the adjacent submerged ciliary membrane. EHD1 displayed dynamic trafficking to the ciliary pocket and was found on membrane tubules forming from the pocket. These tubules also contained proteins that appeared to have exited the primary cilium. The role of EHD1 in primary cilium signal transduction from this poorly understood membrane domain is further described as well as its importance in pocket structure formation and maintenance.

**Rab8 Regulates Invagination of the Furrow Canal During *Drosophila* Development.**

L. M. Mavor<sup>1</sup>, J. T. Blankenship<sup>1</sup>; <sup>1</sup>Biological Sciences, University of Denver, Denver, CO

Epithelial sheets create a boundary between the exterior and interior environments of organisms. The maintenance of adhesion within these sheets is critical to the function of the tissue and loss of this maintenance drives the metastasis of many epithelial cancers. In *Drosophila*, the epithelium is created via a process known as cellularization. Cellularization requires the coordinated invagination of plasma membrane to create an epithelial sheet 30µm tall. In the presented work, we show that vesicular trafficking is necessary for this invagination process to occur. Using fixed and live-imaging *in vivo*, we have shown that Rab8, a late exocytic vesicle marker, localizes both to future sites of furrow ingression and to the Furrow Canal (FC) during cellularization. Prior to the onset of cellularization, Rab8 forms tube-like projections, which mark future ingression furrows and precede F-actin, a cytoskeletal element known to play

a vital role during this process. During cellularization, these same tubules follow the length of the Furrow Canal (FC) and lead the basal-most portion of the FC. Knockdown of Rab8 via RNAi leads to a failure in formation of the FC and thus failure to initiate cellularization. We propose that polarized vesicular trafficking via late exocytic pathways is required for providing the membrane components necessary to drive the invagination of the FC and thus form the epithelial sheet of the *Drosophila* embryo.

**The interplay between the Rab27A effectors Slp4 a and MyRIP controls hormone-evoked Weibel-Palade body exocytosis.**

R. Bierings<sup>1,2</sup>, N. Hellen<sup>1</sup>, N. Kiskin<sup>1</sup>, L. Knipe<sup>1</sup>, V. Fonseca<sup>1</sup>, M. Hannah<sup>1</sup>, T. Carter<sup>1</sup>; <sup>1</sup>Physical Biochemistry, MRC National Institute for Medical Research, London, United Kingdom, <sup>2</sup>Plasma Proteins, Sanquin Research and Landsteiner Laboratory AMC, Amsterdam, Netherlands

Hormone-evoked Von Willebrand factor (VWF) secretion from endothelial cells (ECs) is mediated by exocytosis of specialized secretory granules called Weibel-Palade bodies (WPBs). This allows the endothelium to rapidly respond to vascular trauma or stress through the release of a pre-synthesized cocktail of hemostatic, inflammatory and angiogenic proteins. The identities of the cellular components that regulate hormone-evoked WPB exocytosis remain unclear. Here we identify new endogenous components of the WPB: Rab3B, Rab3D and the Rab27A/Rab3 effector Slp4-a (granuphilin), and determine their role in WPB exocytosis. We show that Rab3B, Rab3D and Rab27A contribute to Slp4-a localization to WPBs. siRNA knockdown of Slp4 a, MyRIP, Rab3B, Rab3D, Rab27A or Rab3B/Rab27A, or overexpression of EGFP-Slp4 a or EGFP-MyRIP showed that Slp4-a is a positive and MyRIP a negative regulator of WPB exocytosis and that Rab27A alone mediates these effects. We found that ECs maintain a constant amount of cellular Rab27A irrespective of the WPB pool size, and that Rab27A (and Rab3s) cycle between WPBs and a cytosolic pool. The dynamic redistribution of Rab proteins markedly decreased the Rab27A concentration on individual WPBs with increasing WPB number per cell. Despite this, the probability of WPB release was independent of WPB pool size showing that WPB exocytosis is not determined simply by the absolute amount of Rab27A and its effectors on WPBs. Instead we propose that the probability of release is determined by the fractional occupancy of WPB-Rab27A by Slp4-a and MyRIP, with the balance favoring exocytosis.

**A Role of Ypt1 in Preautophagosomal Structure Formation.**

J. Kim<sup>1</sup>, Z. Lipatova<sup>2</sup>, D. Taussig<sup>1</sup>, N. Segev<sup>2</sup>; <sup>1</sup>Biological Sciences, University of Illinois at Chicago, Chicago, IL, <sup>2</sup>Biochemistry and Molecular Genetics, University of Illinois at Chicago, Chicago, IL

In the autophagic pathway, cellular material is shuttled via a double-membrane organelle termed autophagosome to the lysosome/vacuole for degradation. The first step of the pathway is the formation of the preautophagosomal structure, PAS, which requires the assembly of several autophagy-specific proteins (Atgs) on Atg9-containing membranes. While there are multiple Atg9-containing membranes, there is only one PAS in each cell. Ypt/Rab GTPases regulate all intracellular pathways by recruiting their downstream effectors to membranes. One class of Ypt/Rab effectors is coiled-coil tethering factors, which serve as the first specific linkers in membrane fusion. The established role of Ypt1 and its human homolog Rab1 is in the regulation of ER-to-Golgi transport. Recent studies have shown that Ypt1, with its upstream autophagy-specific regulator Trs85, play a role in autophagy. However, the mechanism by

which Ypt1 regulates autophagy is not known. We found that Ypt1 regulates autophagy via an autophagy-specific downstream effector, Atg11. Atg11 contains four coiled-coil (CC) domains and therefore might act as a tethering factor. We have shown that the CC2 and CC3 domains of Atg11 are necessary for the interaction with Ypt1. The Ypt1-1 mutant protein, which contains a mutation in the effector-binding domain, does not interact with Atg11, as shown by yeast-2-hybrid and recombinant-protein pull-down. In *ypt1-1* mutant cells, PAS components do not localize properly and PAS is not formed. The Trs85 upstream regulator, Ypt1, and the downstream effector Atg11 function together as a module to regulate autophagy. Whereas Trs85 and Ypt1 alone interact on multiple Atg9-containing membranes, all three proteins, Trs85, Ypt1 and Atg11, interact only on PAS. Based on our results, we propose that Trs85 first activates Ypt1 on the Atg9-containing membranes and then Ypt1 interaction with Atg11 initiates fusion of these membranes to form PAS.

2236

#### **Trs20/Sedlin is Required for TRAPP Conversion.**

*D. Taussig<sup>1</sup>, X. Zhang<sup>2</sup>, Z. Lipatova<sup>2</sup>, N. Segev<sup>2</sup>; <sup>1</sup>Biological Sciences, University of Illinois at Chicago, Chicago, IL, <sup>2</sup>Biochemistry and Molecular Genetics, University of Illinois at Chicago, Chicago, IL*

Trs20 is one of ten subunits of the modular TRAPP complexes in yeast, which act as nucleotide exchangers on Ypt1 and Ypt31/32, the Rab-family GTPases governing protein transport at the cis and trans Golgi, respectively. Mutations in the mammalian ortholog of Trs20, Sedlin, cause the cartilage-specific disorder SEDT. However, the molecular basis of this disease, as well as the role of Trs20 in the TRAPP complexes, remain unclear. Although Trs20 is currently classified as a subunit of TRAPP I, a complex activating Ypt1, we show that Trs20 is required for the assembly and function of TRAPP II, a larger complex activating Ypt31/32. Trs20 interacts directly with TRAPP II-specific subunit Trs120, and is required for the conversion of TRAPP I to TRAPP II. Furthermore, a mutation analogous to one causing SEDT in humans, D46Y, abolishes interaction between Trs20 and Trs120, but not between Trs20 and the TRAPP I complex. These results indicate that Trs20 is crucial for TRAPP II assembly, and implicate a loss of Trs20-Trs120 interaction as the molecular basis for SEDT.

2237

#### **Regulation of the Golgi-to-cell surface transport of $\alpha$ 2-adrenergic receptors by Rab26.**

*C. Li<sup>1</sup>, Y. Fan<sup>1</sup>, T-H. Lan<sup>1</sup>, N. A. Lambert<sup>1</sup>, G. Wu<sup>1</sup>; <sup>1</sup>Pharmacology and Toxicology, Georgia Health Sciences University, Augusta, GA*

The molecular mechanisms underlying the transport from the Golgi to the cell surface of G protein-coupled receptors (GPCRs) remain poorly elucidated. Here we determined the role of Rab26, a Ras-like small GTPase involved in vesicle-mediated secretion, in the cell-surface export of  $\alpha$ 2-adrenergic receptors ( $\alpha$ 2-ARs). We found that transient expression of Rab26 mutants and siRNA-mediated depletion of Rab26 significantly attenuated the cell-surface numbers of  $\alpha$ 2A-AR and  $\alpha$ 2B-AR as well as ERK1/2 activation by the receptors. Furthermore, the receptors were extensively arrested in the Golgi by Rab26 mutants and siRNA. Moreover, Rab26 directly and activation-dependently interacted with  $\alpha$ 2B-AR, specifically the third intracellular loop. These data demonstrate that the small GTPase Rab26 regulates the Golgi-to-cell surface traffic of  $\alpha$ 2-ARs, likely through a physical interaction. These data also provide the first evidence implicating an important function of Rab26 in coordinating plasma membrane protein transport.

2238

### Unique Regulatory Mechanism of Tbc1d1 RabGAP in GLUT4 Trafficking Revealed by Single Molecule Imaging of GLUT4 Behavior.

H. Hatakeyama<sup>1</sup>, M. Kanzaki<sup>1</sup>; <sup>1</sup>Grad. Sch. Biomed. Eng., Tohoku University, Sendai, Japan

The glucose transporter GLUT4 mediates both insulin- and exercise-responsive facilitation of glucose uptake via its translocation from intracellular storage compartments to the plasma membrane. TBC1 domain family RabGAPs AS160/Tbc1d4 and Tbc1d1 are considered to be key regulators of GLUT4 trafficking in responses to the two stimuli, but precise functional roles remain uncertain due to technical limitations. We previously developed a novel method for quantifying intracellular GLUT4 behavior based on single molecule imaging and revealed that “static GLUT4 retention” and its “insulin-responsive liberation” are critical properties of insulin-responsive GLUT4 trafficking systems. We also found that AS160/Tbc1d4 mediates the latter process. Here, we analyzed functional roles of another key RabGAP Tbc1d1 with this approach. We first found that, in contrast to AS160/Tbc1d4, insulin failed to liberate static GLUT4 in the presence of Tbc1d1. Instead, an AMPK activator AICAR successfully liberated static GLUT4, which occurred concomitantly with increased phosphorylation of Ser237, an AMPK consensus site, but not with that of Thr596, an Akt consensus site, indicating that Tbc1d1 can facilitate GLUT4 liberation similarly to AS160/Tbc1d4, though their proximal regulatory signals differ. Intriguingly, we found that insulin did trigger GLUT4 liberation when the cells had previously been treated with AICAR. Insulin-induced Thr596 phosphorylation was essential for the insulin-responsive liberation since T596A mutant showed no such liberation, but the mutant was fully functional in terms of introductory AICAR-induced liberation. In contrast, S237A mutant completely lost GLUT4 liberation activity with any stimuli, indicating phosphorylation of Ser237 to be crucial for both AICAR-induced GLUT4 liberation and temporal acquisition of insulin responsiveness. Finally, we revealed that the functional PTB domain of Tbc1d1 is essential for the temporal acquisition of insulin responsiveness, since a point mutation in the putative PTB sequence showed no acquired ability to liberate GLUT4 in response to sequential insulin stimulation. A natural mutation of Tbc1d1 which relates to severe obesity and locates in the same PTB domain also showed no acquired insulin responsiveness. In conclusion, we identified a unique regulatory mechanism responsible for temporal acquisition of Tbc1d1 insulin responsiveness that relies on its PTB domain. This regulatory mode shift might be a key to the beneficial effects of exercise on muscle insulin potency.

### Motor Protein Effectors Are Crucial to Rab6 Regulation of Golgi Apparatus Homeostasis and Trafficking.

W. Majeed<sup>1</sup>, S. Liu<sup>1</sup>, B. Storrie<sup>1</sup>; <sup>1</sup>Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR

Rab6 is the most abundant Golgi associated Rab GTPase and is implicated in regulation of Golgi trafficking and homeostasis. Genetically, Rab6 acts upstream of the retrograde Golgi tether proteins Zeste white 10 (ZW10)/ RINT1 or conserved oligomeric Golgi complex protein 3 (COG3). Knockdown of either tether protein results in Golgi fragmentation. However in epistatic, double knockdown experiments, Rab6 depletion inhibited Golgi ribbon disruption and accumulation of Golgi-derived vesicles induced by ZW10 and COG3 knockdown (Sun et al., 2007, MBoC). In single protein depletion experiments, Rab6 knockdown resulted in the accumulation of Golgi proximal coated vesicles and a concomitant proliferation of Golgi cisternae (Storrie et al., 2012, Traffic). Considering the importance of motor proteins as Rab6 effectors, these results suggest a working hypothesis: proteins affecting vesicle transport could be the immediate Rab6 effector(s) whose depletion produces the observed epistatic

suppression and whose activity is a key regulator of normal Golgi organization and homeostasis.

The goal here was to determine which of the biological cocktail of Rab6 effectors was most crucial to Golgi organization and vesicle transport. Hence, we used our epistatic, double knockdown approach as a screen for candidate effector protein(s) that could mimic the upstream Golgi phenotype effects produced by Rab6 depletion. The Rab6 effectors tested included: Kif1C, Kif5B, Kif20A motors, BicD1, BicD2 dynein regulators, MyosinIIA, Golgin-97 and OCRL. Epistatic knockdown of BicD1, BicD2 and Myosin IIA selectively suppressed ZW10- and COG3-depletion induced Golgi ribbon fragmentation. Depletion of other motor protein effectors, either singly or in the case of Kif1C and Kif5B together, had no suppressive effect. Similarly, neither Golgin-97 nor OCRL depletion was epistatically suppressive. Among the positive candidates, depletion of Myosin IIA alone did not mimic the Rab6 depletion phenotype of Golgi proximal accumulation of coated vesicles and Golgi cisternae proliferation (Storrie et al. 2012, Traffic). Experiments are in progress to test whether knockdown of BicD1/2 mimics the Golgi proximal accumulation of coated vesicles and concomitant proliferation of Golgi cisternae observed with Rab6 knockdown. Based upon the experimental outcomes to date, we speculate that dynein, a motor protein regulated by BicD1/2, is crucial to Golgi cisternal homeostasis and Golgi-derived coated vesicle transport.

Supported in part by the NIH grant GM092960.

### **Novel functions of Myosin Vc in melanosome biogenesis through interactions with Rab proteins.**

J. J. Bultema<sup>1</sup>, P. Malenke<sup>1</sup>, R. E. Cheney<sup>2</sup>, S. M. Di Pietro<sup>1</sup>;

<sup>1</sup>Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, <sup>2</sup>Cell and Molecular Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Rab GTPases are well established as coordinators and markers of intracellular protein trafficking pathways. Rab GTPases function as molecular switches and regulate trafficking through interactions with various effector proteins. In melanocyte cells, the biogenesis and transport of melanosomes is highly dependent on the function of several Rabs. Previous work has established the role of Rab32 and Rab38 in the trafficking of protein cargoes from early endosomes to maturing melanosomes. However, relatively little is known about how Rab32 and Rab38 function with other proteins to facilitate this trafficking.

Here, we report the novel interactions of Rab32 and Rab38 with a class V myosin, Myosin Vc, which was not previously known to function in this pathway. Using the yeast two-hybrid system, the interaction of Myosin Vc with Rab32 and Rab38 has been mapped to partially overlapping regions in the tail of Myosin Vc. This binding is dependent on the GTP-bound state of Rab32 and Rab38 as they bind to Myosin Vc only with constitutively-active, GTP-locked mutations, and is specific to Myosin Vc as Rab32 and Rab38 do not bind to Myosin Vb. Additionally, the binding of Rab32 and Rab38 to Myosin Vc has been mapped to specific amino acid residues on the surface of Rab32 and Rab38 that can be disrupted by mutation of individual residues. Live-cell microscopy experiments demonstrate that Myosin Vc has a polarized distribution within melanocytes and localizes to both small and large structures, likely corresponding to vesicles and melanosomes respectively. Depletion of Myosin Vc from melanocytes causes a phenotype in overall pigmentation and in the trafficking of melanosome protein cargoes. Interestingly, it appears that this Myosin may have dual roles in melanosome biogenesis and transport that future experiments will serve to clarify.

**Rab11-FIP2 Interaction with MYO5B Regulates Movement of Rab11a-Containing Recycling Vesicles.**

J. C. Schafer<sup>1</sup>, N. Baetz<sup>1</sup>, L. A. Lapierre<sup>1</sup>, R. E. McRae<sup>1,2</sup>, J. T. Roland<sup>1</sup>, J. R. Goldenring<sup>1,2,3,4</sup>;  
<sup>1</sup>Surgical Sciences and the Epithelial Biology Center, Vanderbilt University, Nashville, TN, <sup>2</sup>Cell and Developmental Biology, Vanderbilt University, Nashville, TN, <sup>3</sup>Nashville VAMC, Vanderbilt University, Nashville, TN, <sup>4</sup>Vanderbilt-Ingram Cancer Center, Vanderbilt University, Nashville, TN

Previous investigations have demonstrated that a tripartite association of Rab11a with both Rab11-FIP2 and MYO5B regulates recycling endosome trafficking. We have now sought to define the intermolecular interactions that are required for interaction of Rab11-FIP2 with MYO5B. Using a random mutagenesis strategy to generate mutants of the minimal MYO5B binding region of Rab11-FIP2 (amino acids 129 to 356), we performed yeast 2-hybrid screening to identify point mutants with loss of interaction with MYO5B. Point mutations at S229P or G233E caused a loss of interaction with MYO5B in yeast 2-hybrid assays as well as a loss of interaction of Rab11-FIP2(129-356) with MYO5B tail when expressed in HeLa cells. Single mutations or the double S229P/G233E mutation failed to alter the association of full-length Rab11-FIP2 with MYO5B tail in HeLa cells. However, when the Rab11-binding domain was inactivated with an I481N mutation, the S229P and G233E mutations in Rab11-FIP2 again caused a loss of localization with MYO5B. While EGFP-Rab11-FIP2 wild type co-localized with endogenous MYO5B staining, EGFP-Rab11-FIP2(S229P/G233E) showed a significant decrease in localization with endogenous MYO5B. Analysis of Rab11a-containing vesicle movement in live HeLa cells demonstrated that, compared with cells expressing wild type Venus-Rab11-FIP2, cells expressing Venus-Rab11-FIP2(S229P/G233E) showed patterns of faster vesicle movement that traversed significantly longer paths, all consistent with a decrease in tethering of vesicles to the cytoskeleton. Furthermore, knockdown of Rab11-FIP2 in HeLa cells led to significant increases in vesicle speed, track length, and track displacement which were rescued with full-length Venus-Rab11-FIP2, but not with Venus-Rab11-FIP(S229P/G233E). These results support a critical role for the interaction of MYO5B with Rab11-FIP2 in stabilizing the functional complex with Rab11a, which regulates dynamic movements of membrane recycling vesicles.

**Molecular characterization of melanin transfer from donor melanocytes to recipient keratinocytes.**

M. S. Correia<sup>1,2</sup>, A. K. Tarafder<sup>1,3</sup>, F. J. Pereira<sup>1,2</sup>, G. Bolasco<sup>3</sup>, D. Barral<sup>1</sup>, M. C. Seabra<sup>1,2,3</sup>;  
<sup>1</sup>Biomedical and Translational Research, Centro de Estudos de Doenças Crônicas, Oeiras, Portugal, <sup>2</sup>Membrane Traffic, Instituto Gulbenkian de Ciência, Oeiras, Portugal, <sup>3</sup>Molecular Medicine Section, NHLI, Imperial College, London, England

The “Epidermal-Melanin Unit” comprises the functional complex in which melanocytes and keratinocytes co-operate in a synergistic fashion to maintain skin pigmentation. The transfer of specialized lysosome-related organelles, called melanosomes, from donor melanocytes to recipient keratinocytes and subsequent redistribution to the supra-nuclear area is a critical process in skin pigmentation and photo-protection against ultra-violet damage. However, the molecular mechanism underlying inter-cellular transfer of melanin remains controversial and the molecular machinery involved in the ultimate fate of melanin within keratinocytes is still poorly characterized.

Using co-cultures of melanocytes with keratinocytes we found that keratinocytes stimulate melanin release and transfer, and that depletion of the small GTPase Rab11b leads to a

decrease in melanin exocytosis. Rab11 is involved in the endocytic recycling pathway and in regulated exocytosis. Interestingly, Rab11 has been shown to be essential for the remodeling of the lytic granules in cytotoxic T-cells, prior to the exocytosis of these lysosome-related organelles. To further investigate the melanin transfer process, we used keratinocytes fed with melanosomes or melanocores, which lack the limiting membrane, isolated from melanocytes. We found that melanin is taken up by keratinocytes and accumulates in lysosome-like structures that resemble the physiological supra-nuclear cap observed in human skin.

Taken together, our observations suggest that the predominant mechanism of melanin transfer is keratinocyte-induced exocytosis, through a Rab11b-dependent remodeling of the melanosome, followed by subsequent endocytosis by keratinocytes. We are currently developing a high-throughput image-based siRNA screen to find novel players involved in keratinocyte-induced melanin uptake and the microtubule-dependent movement towards the perinuclear region of the cell.

### **Lipid Droplet Breakdown is Dependent on a Novel Dyn2-Rab10 Interaction.**

*B. Schroeder<sup>1</sup>, Z. Li<sup>1</sup>, R. Schulze<sup>1</sup>, S. Weller<sup>1</sup>, C. Casey<sup>2</sup>, M. McNiven<sup>1</sup>; <sup>1</sup>Mayo Clinic, Rochester, MN, <sup>2</sup>University of Nebraska Medical Center, Omaha, NE*

Lipid droplets (LDs) are dynamic lipid-storage organelles that respond to the metabolic requirements of the cell by alterations in both size and number. During periods of nutritional deficit, LDs are metabolized by mechanisms that are currently poorly defined. However, a substantial number of cytoskeletal and membrane trafficking proteins have been shown to associate with LDs and may participate in the breakdown of these organelles. We postulated that the large GTPase Dynamin-2 (Dyn2), well known to support membrane deformation and cellular protein trafficking events throughout the cell, might also participate in the breakdown of LDs in hepatocytes and provide a central “scaffold” for this process. Importantly, we have found that inhibition of Dyn2 function leads to an accumulation of LDs in hepatocytes. HuH-7 hepatocellular carcinoma cells incubated with 150 $\mu$ M oleic acid for 16 hours and starved for 65 hours in low-serum media normally undergo lipolysis, leading to a near-complete loss of LDs. A targeted knockdown of Dyn2 by siRNA resulted in 10 times the number of LDs retained compared to cells treated with a non-targeting siRNA. A substantial attenuation of LD breakdown was also observed in HuH-7 and Hep3B cells treated throughout the starvation period with 80 $\mu$ M Dynasore, a widely-used pharmacological dynamin inhibitor. As a third approach toward disrupting Dyn2 function, Dyn2 conditional knockout mouse fibroblasts (courtesy of Ferguson and De Camilli, Yale), treated with tamoxifen to induce KO of Dyn2 and loaded with oleic acid, exhibited a 2.4-fold increase in the number of LDs. Importantly, the transient expression of a Dyn2 mutant lacking residues 300-521 of the middle domain (Dyn2<sup>mid</sup>) significantly attenuates LD breakdown, suggesting that this domain may be critical to its role in lipolysis. Subsequently, we performed a screen using GST-tagged Dyn2<sup>mid</sup> to identify binding partners from rat brain homogenates. A prominent association was observed with Rab10, a small GTPase that mediates vesicle traffic and has been identified previously by proteomic screens to reside on lipid droplets. Specific interaction between Dyn2 and Rab10 was confirmed by co-immunoprecipitation from hepatocyte homogenates. GST-pulldowns using purified proteins in vitro identified a specific 10aa Dyn2-interactive region within the Rab10 effector domain. Subsequent super-resolution immunofluorescence imaging of lipid-loaded HuH-7 cells reveals that both Dyn2 and Rab10 co-localize to the LD surface in prominent “crescent” shaped structures. This localization, and the biochemical interaction, is markedly altered in cells exposed to starvation conditions in which LDs are metabolized. Finally, siRNA knock down of either Dyn2 or Rab10 results in a loss of LD-associated crescents and a corresponding effect on LD metabolism. Together, these findings demonstrate an

important role for a novel Dyn2-Rab10 interaction in LD disassembly. Supported by NIH R01 AA020735 to CAC and MAM.

## ER and Golgi Transport

2244

### Modulation of the sizes of COPII/KLHL12-coated vesicles.

S-D. Kim<sup>1</sup>, S. A. Boyadjiev<sup>1</sup>, R. Schekman<sup>2</sup>, H-S. Kweon<sup>3</sup>, J. Kim<sup>1</sup>; <sup>1</sup>Department of Pediatrics, University of California Davis Medical Center, Sacramento, CA, <sup>2</sup>Department of Molecular and Cell Biology, University of California Berkeley, Berkeley, CA, <sup>3</sup>Division of Electron Microscopic Research, Korea Basic Science Institute, Daejeon, Korea

COPII proteins (SAR1, SEC23/24, and SEC13/31) carve the ER membrane into transport vesicles that are typically about 60-80 nm in diameter and package cargos into newly forming vesicles. Procollagen forms about a 300-nm-long rigid fibril in the ER and requires COPII proteins for export from the ER. Thus, COPII proteins should generate larger carriers to accommodate procollagen. It has been recently shown that monoubiquitylation of SEC31 by CUL3-KLHL12 is essential for ER export of procollagen. Overexpression of KLHL12 drives the assembly of COPII/KLHL12-coated megavesicles and expedites secretion of procollagen. However, how COPII proteins generate such vesicles remains unanswered. Cranio-lenticulo-sutural-dysplasia (CLSD), an autosomal recessive syndrome, with skeletal features thought to be due to defective deposition of collagen. We identified homozygous *F382L SEC23A* mutation in the original consanguineous family by positional cloning. Recently, we described a new CLSD case with a heterozygous *M702V SEC23A* mutation that was inherited from clinically normal father. Expression of *M702V SEC23A* partially attenuates ER export of procollagen. Purified recombinant *M702V SEC23A*, however, interacts normally with other COPII components and efficiently packages the smaller cargo molecules that we have tested. Interestingly, *M702V SEC23A* accelerates SAR1B GTP hydrolysis when SEC31 is present. Because accelerated SAR1 GTP hydrolysis leads to premature release of COPII proteins from the membrane, premature release of COPII proteins from the membrane may lead to formation of smaller COPII vesicles and exclusion of procollagen from nascent vesicles. Remarkably, when we overexpressed KLHL12, the sizes of KLHL12-coated vesicles became smaller in the *M702V* patient's fibroblasts than in control fibroblasts. We, therefore, hypothesize that the rate of SAR1 GTP hydrolysis or the availability of COPII controls the sizes of COPII/KLHL12-coated megavesicles.

### Human Sar1 paralogs differ biochemically in the assembly of the COPII coat.

S. Studer<sup>1</sup>, D. B. Melville<sup>1</sup>, R. Schekman<sup>1</sup>; <sup>1</sup>Department of Molecular and Cell Biology and Howard Hughes Medical Institute, University of California, Berkeley, Berkeley, CA

COPII coated vesicles are the primary mediators of ER-to-Golgi trafficking. Sar1, one of the five core COPII components, is a highly conserved small GTPase, which, upon GTP binding, recruits the other COPII proteins to the ER membrane. Mammals have two paralogs of Sar1, SAR1A and SAR1B, which share 90% sequence identity and can both promote vesicle budding *in vitro*. It has been found that mutations in SAR1B, but not SAR1A, are associated with Chylomicron retention disease (CMRD) in humans, suggesting that, despite their strong sequence similarity, they have distinct physiological roles. We have previously identified a functional difference between the paralogs, namely that when combined with a disease-

associated allele of SEC23A (F382L), SAR1A is more efficient than SAR1B at recruiting the Sec13-Sec31 complex that comprises the COPII outer coat. Because the primary defect of the F382L-SEC23A allele appears to be a diminished capacity to recruit Sec31, we therefore hypothesized that the differences observed between the Sar1 paralogs may be due to their specific interactions with Sec31. Using membrane budding assays in semi-intact cells, we have identified three amino acid residues sufficient to restore the efficiency of Sar1b to that of Sar1a in the presence of F382L-SEC23A. Through a photo-crosslinking assay we have found that these amino acids bind the proline rich active fragment of Sec31, and that this active fragment stimulates Sar1 GTPase activity. These data illuminate the relationship between Sar1 paralogs and the COPII outer coat, and suggest a possible mechanism for the paralog specific defects seen in CMRD.

2246

**The COG complex coordinates vesicular trafficking via SNARE interactions.**

*R. A. Willett<sup>1</sup>, T. Kudlyk<sup>1</sup>, I. Pokrovskaya<sup>1</sup>, D. Unga<sup>2</sup>, R. Duden<sup>3</sup>, V. Lupashin<sup>1</sup>; <sup>1</sup>University of Arkansas for Medical Sciences, Little Rock, AR, <sup>2</sup>Biology (Area 9), University of York, Heslington, United Kingdom, <sup>3</sup>Medical Institute of Biology, University of Luebeck, Luebeck, Germany*

Membrane trafficking within the eukaryotic cell is a highly organized process that utilizes a set of regulatory components including SNARE's, Rab's, and tethers. The conserved oligomeric Golgi (COG) complex, a multi-subunit peripheral protein complex, has been implicated in the tethering of retrograde intra-Golgi vesicles. The COG complex consists of 8 subunits, grouped into two subcomplexes: COG 1–4 (Lobe A) and COG 5–8 (Lobe B). Two of the eight COG subunits have been shown to interact with SNARE proteins. In this study, we have extended our initial observation of COG-SNARE interactions to include all COG subunits with 15 Golgi localized SNARE proteins. We have found that COGs 4, 6, and 8 are capable of interacting with the SNAREs STX5, STX6, STX16, GS27, and SNAP29 as determined by yeast two hybrid and native Co-immunoprecipitation assays. Further analysis of the COG4-STX5 and the COG8-STX16 interactions by a COG mitochondrial re-localization assay reveals that COG4 and COG8 proteins are re-routing two classes of Golgi trafficking intermediates to the mitochondria vicinity. These results suggest that the COG subunits and/or sub-complexes can initiate the formation of two different tethering platforms for the proper delivery of two populations of Golgi vesicular carriers.

2247

**Sedlin controls the ER export of procollagen by regulating Sar1 cycle.**

*R. Venditti<sup>1</sup>, M. Santoro<sup>1</sup>, V. Malhotra<sup>2</sup>, B. Verte<sup>3</sup>, C. Wilson<sup>1</sup>, M. De Matteis<sup>1</sup>; <sup>1</sup>Telethon Institute of Genetics and Medicine, Naples, Italy, <sup>2</sup>Department of Cell and Developmental Biology, Centre de Regulacio Genomica, Barcelona, Spain, <sup>3</sup>Department of Cell Biology and Anatomy, Rosalind Franklin University of Medicine and Science, Chicago, IL*

Genetics defects occurring in the Sedlin gene, a conserved component of TRAPP complex, cause the Spondyloepiphyseal Dysplasia Tarda (SED), a rare progressive condition characterised by impaired chondrogenesis resulting in short stature, flattening of vertebrae and premature osteoarthritis. The role of Sedlin in the pathogenesis of SEDT disease is still unknown. Prompted by the consideration that Sedlin mutations cause cartilaginous-restricted dysfunctions, we analysed the role of Sedlin in membrane trafficking generally but in particular in the transport of chondrocyte-specific cargoes, such as procollagen type II. We found that

Sedlin is selectively required for PCII to exit the ER, while it is not essential for ER exit of small soluble and membrane-associated cargoes.

Neosynthesized proteins exit the endoplasmic reticulum (ER) via COPII vesicles. Procollagen (PC), however, forms rigid 300 nm prefibrils that are too large to fit into standard 60-90 nm COPII vesicles and thus needs megacarriers.

TANGO1 binds PC and COPII and assists PC packing, but how it promotes the growth of megacarriers is not known. We show that TANGO1 recruits Sedlin and that Sedlin binds and promotes the inactivation of Sar1, a GTPase that in its active form can constrict membranes, and thus allows nascent carriers to grow and to incorporate PC prefibrils.

Sedlin depletion and/or mutation in SEDT patients slow-down the Sar1 cycle and prolongs the membrane association of Sar1-GTP at the ER exit sites, inducing constriction and premature fission of nascent carriers which fail to incorporate the large PC protofibrils but are still competent for smaller cargoes. All together these findings provide new insights not only into understanding the role of Sedlin but also shed new light on the molecular mechanisms underlying SEDT.

2248

**Scyl1 functions as a scaffold for multiple components of the COPI machinery.**

J. N. Hamlin<sup>1</sup>, H. Dokainish<sup>1</sup>, M. Fotouhi<sup>1</sup>, P. Melançon<sup>2</sup>, P. S. McPherson<sup>1</sup>; <sup>1</sup>Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, QC, Canada, <sup>2</sup>Department of Cell Biology, University of Alberta, Edmonton, AB, Canada

COPI-coated vesicles mediate retrograde trafficking from the Golgi apparatus and the endoplasmic reticulum-Golgi intermediate compartment (ERGIC) to the ER in the early secretory pathway. We recently demonstrated that Scyl1-like 1 (Scyl1), a member of the Scyl1-like family of catalytically inactive protein kinases binds COPI coat proteins and that loss of Scyl1 disrupts COPI trafficking. We now demonstrate that Scyl1 interacts with class II Arfs, most notably Arf4, but does not bind class I Arfs. Moreover, Scyl1 co-localizes with Arf4 at the ERGIC. Scyl1 interacts with membranes through a C-terminal helical domain that is distinct from its non-overlapping binding sites for COPI and Arf4, suggesting that Scyl1 couples Arf4 to COPI on ERGIC membranes. Additionally, gel filtration chromatography reveals that Scyl1 undergoes trimerization mediated by HEAT repeats found in the central region of the protein. HEAT-repeat assemblies generate binding sites for proteins and remarkably, through the HEAT repeats Scyl1 also binds to GBF1, a guanine-nucleotide exchange factor for class II Arfs. Thus, Scyl1 appears to be a scaffold for multiple components of COPI vesicle formation and consistently, over expression of Scyl1, which will disrupt the scaffold function leads to tubulation of the ERGIC. Our data reveal Scyl1 as the first known protein to interact specifically with class II Arfs and place Scyl1 as a key organizer of the COPI protein machinery.

**The structure of Sec12 implicates potassium ion coordination in Sar1 activation.**

C. McMahon<sup>1</sup>, S. M. Studer<sup>2</sup>, C. Clendinen<sup>1</sup>, G. P. Dann<sup>1</sup>, P. D. Jeffrey<sup>1</sup>, F. M. Hughson<sup>1</sup>; <sup>1</sup>Department of Molecular Biology, Princeton University, Princeton, NJ, <sup>2</sup>Department of Chemical Physiology, The Scripps Research Institute, La Jolla, CA

COPII-coated vesicles traffic proteins and lipids from the endoplasmic reticulum to the Golgi. Crucial for the initiation of COPII coat assembly is Sec12, a guanine nucleotide exchange factor responsible for activating the small G protein Sar1. Once activated, Sar1-GTP binds tightly to ER membranes and recruits COPII coat components (Sec23/24 and Sec13/31). Here, we report the 1.35-Å resolution crystal structure of the catalytically active, 38-kDa cytoplasmic portion of

*Saccharomyces cerevisiae* Sec12. Sec12 adopts a  $\beta$  propeller fold, as previously predicted. Conserved residues cluster around a loop we term the “K loop”. Structure-guided site-directed mutagenesis, in conjunction with in vitro and in vivo functional studies, reveal that this region of Sec12 is catalytically essential, presumably because it makes direct contact with Sar1. Strikingly, the crystal structure also reveals that the K loop coordinates a potassium ion; bound potassium is, moreover, essential for optimum guanine nucleotide exchange activity in vitro. Thus, our results reveal a novel role for a potassium binding loop in catalyzing guanine nucleotide exchange, while at the same time deepening our understanding of the initiation of COPII vesicle budding.

### **Luminal Calcium Regulates ER-to-Golgi Transport Efficiency Through ALG-2/Sec31 Interactions.**

J. R. Helm<sup>1</sup>, M. Bentley<sup>1</sup>, K. Thorsen<sup>1</sup>, J. Klumperman<sup>2</sup>, J. C. Hay<sup>1</sup>; <sup>1</sup>Division of Biological Sciences, The University of Montana, Missoula, MT, <sup>2</sup>Department of Cell Biology, University of Utrecht, Utrecht, Netherlands

Luminal calcium released from secretory organelles has been suggested to play a regulatory role in vesicle transport early in the secretory pathway. In ER-to-Golgi transport, specific depletion of luminal calcium leads to unidentified enlarged clusters of intermediate compartment markers (IC) at ER exit sites. In vitro, blocking luminal calcium egress leads to release of residual (post-budding) COPII subunit sec31 and unregulated COPII vesicle fusion, suggesting a role for residual COPII coat retention in the regulation of ER-to-Golgi transport. The calcium sensor apoptosis-linked gene 2 (ALG-2) stabilizes residual sec31 on COPII vesicles in response to calcium and restricts fusion, suggesting that it may be part of a signaling cascade by which luminal calcium exerts effects on ER-to-Golgi transport (Bentley, et al., 2010, *Mol. Biol. Cell* 21:1033). Here we demonstrate using an intact-cell morphological transport assay that specific luminal calcium depletion leads to a significant decrease in ER-to-Golgi transport rates for transmembrane cargo proteins. Furthermore, ultrastructural analysis revealed that luminal calcium depletion is accompanied by increased accumulation of IC proteins in COPII buds and clusters of unfused COPII vesicles at ER exit sites--no enlarged fusion structures were observed. Finally, in over-expression studies, we demonstrate that disruption of interactions between ALG-2 and the sec31 proline rich region (PRR) loop cause severe defects in ER-to-Golgi transport, and that these interactions regulate sec31 function on the membrane rather than initial targeting to ERES. Though ALG-2/sec31 interactions may regulate sec31 interactions with its other binding partners, their most rate-limiting consequence does not appear to be regulation of sec31A GAP-stimulating activity toward Sar1. This work identifies for the first time a functional requirement for luminal calcium at a demonstrably post-protein-folding step in ER-to-Golgi transport in intact cells. The kinetic and ultrastructural analyses combined indicate that luminal calcium may be involved in promoting efficient budding and/or post-ER sorting of transmembrane cargo between anterograde and retrograde directions of movement. For the first time, ALG-2 interactions with sec31 are shown to possess a functionally critical role in anterograde transport, indicating that ALG-2 is at least one of the calcium sensors that effect luminal calcium's regulatory role in vesicle trafficking.

2251

**Roles of GOLPH3 and GOLPH3L in Establishing Golgi Organization**

*S. J. Field<sup>1</sup>, M. M. Ng<sup>1</sup>, H. C. Dippold<sup>1</sup>, M. C. Peterman<sup>1</sup>, S. E. Farber-Katz<sup>1</sup>, M. D. Buschman<sup>1</sup>, M. Xing<sup>1</sup>, C. J. Noakes<sup>1</sup>, J. Rahajeng<sup>1</sup>, D. M. Cowan<sup>1</sup>; <sup>1</sup>Medicine, University of California, San Diego, La Jolla, CA*

We have shown that GOLPH3 homologs from yeast (Vps74p) to humans function as PI4P effectors (Dippold, et al., Cell 2009). GOLPH3 localizes to the trans-Golgi via its interaction with PI4P. GOLPH3 also interacts with MYO18A, linking the Golgi to the actin cytoskeleton, and imparting a tensile force that participates in vesicle budding and in establishing the Golgi's characteristic extended ribbon morphology. Unexpectedly, GOLPH3 is also an oncogene commonly amplified in human cancers and capable of enhancing growth factor signaling. Among vertebrates there exists an additional gene in the GOLPH3 family, GOLPH3L, which has been minimally characterized previously. Interestingly, although we find that GOLPH3 is ubiquitously expressed at high levels in all tissues and cell types, we find that GOLPH3L expression levels are low and restricted to secretory cells and tissues. We find that GOLPH3L shares some features of GOLPH3. GOLPH3L binds tightly and specifically to PI4P and localizes to the Golgi. However, we also find surprising differences between GOLPH3 and GOLPH3L with important implications for understanding the role of PI4P in organizing the Golgi.

2252

**The role of CK2 in Sec31 phosphorylation and membrane trafficking.**

*M. Koreishi<sup>1</sup>, Y. Honjo<sup>1</sup>, A. Satoh<sup>1</sup>; <sup>1</sup>Okayama University, Okayama, Japan*

Protein export from the endoplasmic reticulum (ER) is an initial and rate-limiting step of molecular trafficking and secretion. This is mediated by coat protein II (COPII)-coated vesicles, whose formation requires small GTPase Sar1 and 6 Sec proteins including Sec31 and Sec23. Sar1 initiates and promotes COPII vesicle formation, but the mechanism that regulates coat assembly is largely unknown. The outer layer component of COPII coat Sec31 has been identified as a phosphoprotein. Here, we show that Sec31 phosphorylation regulates COPII vesicle formation. Sec31 phosphorylation reduced its membrane association whereas its non-phosphorylatable mutant remained at ER exit sites for longer. We identified the phosphorylation sites in the middle linker region of Sec31. Sec31 is phosphorylated by CK2, and thus, Sec31 phosphorylation is reduced by CK2 depletion and enhanced by CK2 expression. CK2 knockdown increased affinity of Sec31 for Sec23 and decreased ER-to-Golgi trafficking. These results suggest that Sec31 phosphorylation by CK2 controls the duration of COPII vesicle formation to regulate ER-to-Golgi trafficking.

2253

**Molecular analysis of trafficking of collagen in the early secretory pathway.**

*K. Bajaj Pahuja<sup>1</sup>, L. Jin<sup>1</sup>, A. Gorur<sup>1</sup>, K. Wickliffe<sup>1</sup>, M. Rape<sup>1</sup>, R. Schekman<sup>1</sup>; <sup>1</sup>MCB, UC Berkeley, Berkeley, CA*

The early secretory pathway is highly conserved among all the metazoans and is considered crucial for several cellular processes including development and function of the immune, neuronal, endocrine and skeletal systems. This pathway is tightly regulated and contributes to the trafficking of a considerable fraction of the whole proteome in and around the urbane environment of a cell. It involves designated export machinery, consisting of COPII coat proteins involved in sorting of the cargoes in membrane bound vesicles emanating from the endoplasmic reticulum (ER). The flexibility of the coat machinery to accommodate diverse size and shaped cargoes in order to meet the sophisticated demands of the cell is long-debated and is still under

consideration. Some post-translational modifications or protein-protein interactions of the coat proteins are speculated to contribute to the coat conformational changes resulting in different size transport vesicles, but the mechanism involved in lugging large cargo, e.g. collagen remains to be determined. Collagen fibrils are the principal source of tensile strength in metazoans and define the shape and form of tissues in which they occur. Type I collagen is the major component of fibrils in tendon, bone and skin. There are numerous human skeletal and connective tissue disorders associated with the defects in the early secretory pathway which involve aberrations in COPII protein subunits or accessory proteins, which in turn perturbs the ability of collagen to sort correctly in trafficking machinery. Some of the pathological conditions associated with these diseases results from collagen deposition defect. The work described here resulted in the novel identification of ubiquitination in regulating ER-Golgi trafficking of collagen. This study would provide framework to advance our basic understanding of the early secretory pathway involved in collagen transport and its emerging connection with human skeletal diseases.

2254

#### **Dissecting the Role of the Novel Interactor Ssp120 in the Emp46/Emp47 Complex.**

*B. D. Bean<sup>1</sup>, M. Davey<sup>1</sup>, E. Conibear<sup>1</sup>; <sup>1</sup>Center for Molecular Medicine and Therapeutics, Vancouver, BC, Canada*

Correct localization is crucial for the function of proteins. It is achieved by conserved, membrane-associated, trafficking machinery that recognizes cargo and facilitates movement between compartments. Recently, a genome-wide proteomics project in *Saccharomyces cerevisiae* (Babu, M. *et al* in press) successfully identified many novel components of membrane-associated complexes by performing affinity purification in the presence of detergents followed by mass spectrometry. We investigated one such interaction, that of Ssp120, a protein of unknown function, with Emp46/Emp47, a complex that traffics glycosylated proteins from the ER to the Golgi. The inclusion of Ssp120 in the established Emp46/Emp47 complex was validated by both microscopy and co-immunoprecipitation. Ssp120 was found to localize to the Golgi, similar to Emp46/Emp47, in an Emp47-dependent manner. Homology searches revealed that Ssp120 resembles human MCFD2, a binding partner of the human homolog of Emp46/Emp47, LMAN1. In humans MCFD2 acts as a cargo-specific adaptor for LMAN1 that is necessary for the trafficking of a subset of glycosylated proteins from the ER to the Golgi. Mutations in MCFD2 often prevent secretion of coagulation factors V and VIII, resulting in hemophilia. While the calcium binding EF hands of MCFD2 mediate the LMAN1-MCFD2 interaction, we found that the C-terminal domain of Ssp120 mediates the Emp47-Ssp120 interaction. However, the calcium-binding EF hands may be important as *ssp120* strains have an equally strong calcium sensitivity phenotype as *emp47* strains. While we have yet to identify cargo for Ssp120, our work supports the model that Ssp120 acts as a cargo-specific adaptor for Emp46/Emp47.

2255

#### **Modulation of membrane rigidity by human and yeast homologs of the vesicle trafficking protein Sar1.**

*A. F. Loftus<sup>1</sup>, V. Hsieh<sup>1</sup>, R. Parthasarathy<sup>2</sup>; <sup>1</sup>Department of Chemistry, University of Oregon, Eugene, OR, <sup>2</sup>Department of Physics, University of Oregon, Eugene, OR*

Understanding how proteins manipulate the shape and form of membranes is crucial to intracellular cargo trafficking, yet the mechanical activities of trafficking proteins remain poorly understood. Using an optical-trap based assay involving dynamic membrane deformations and

fluorescence recovery after photobleaching (FRAP) to measure protein mobility on *in vitro* endoplasmic reticulum mimic membranes, we examined the behavior of the two human paralogs of Sar1, a key component of the COPII family of vesicle coat proteins. Like their yeast (*S. cerevisiae*) counterpart, the human Sar1 proteins can lower the mechanical rigidity of the membranes to which they bind. Unlike the yeast Sar1, the rigidity is not a monotonically decreasing function of concentration. At high concentrations, we find increased bending rigidity and decreased protein mobility. These features imply a model in which protein clustering influences membrane mechanical properties.

2256

**Membrane rigidity, vesicle formation and the ER quality control checkpoint.**

A. Copic<sup>1</sup>, C. Latham<sup>1</sup>, J. D'Arcangelo<sup>1</sup>, M. Horlbeck<sup>1</sup>, E. A. Miller<sup>1</sup>; <sup>1</sup>Biological Sciences, Columbia University, New York, NY

Eukaryotic secretory proteins exit the endoplasmic reticulum (ER) via transport vesicles generated by the essential COPII coat proteins. This step represents a critical quality control checkpoint in that misfolded proteins are generally excluded from COPII vesicles. In a search for yeast mutants that have defective ER retention of misfolded proteins, we identified several bypass-of-sec-thirteen (bst) mutants, where the otherwise essential COPII protein, Sec13, becomes dispensable. A genome-wide screen for the full complement of bst mutants identified nine "core" proteins that generally contribute to the packaging of asymmetrically distributed cargo proteins, including the particularly abundant GPI-anchored proteins. Our genetic and biochemical analyses suggest that within the outer coat scaffold formed by Sec13 and Sec31, Sec13 acts to rigidify the COPII cage, increasing its membrane-bending capacity. This structural integrity is not required when a bst mutation renders the membrane more amenable to deformation by depleting cargoes. We propose that the lapse in ER quality control that occurs in bst mutants reflects the altered biophysical properties of the membrane and coat itself to create structures that are more permissive to the inclusion of aberrant proteins. Restoring rigidity to the outer coat layer reverses the quality control breakdown of bst mutants, linking vesicle architecture to ER quality control.

2257

**Functional characterisation of the golgin GMAP-210.**

K. Sato<sup>1</sup>, M. Lowe<sup>2</sup>; <sup>1</sup>Tokyo Medical and Dental University, Tokyo, Japan, <sup>2</sup>University of Manchester, Manchester, UK

Golgins are coiled-coil proteins localised to the cytoplasmic face of the Golgi apparatus. Members of the golgin family are thought to be involved in the long-range attachment or tethering of membranes that in some cases are required for Golgi structure and/or protein trafficking. GMAP-210 is a golgin localised to the cis-Golgi. GMAP-210 has two membrane-interacting domains, namely a curvature-sensitive amphipathic lipid-packing sensor (ALPS) motif at the N terminus and a GRIP-related Arf binding (GRAB) domain at the C terminus that interacts with the small GTPase Arf1. A truncated GMAP-210 comprising the ALSP motif, GRAB domain, and a short (one-third of original protein) middle region that is mainly comprised of coiled-coil domains between these two regions was shown to asymmetrically tether curved and flat lipid membranes *in vitro*; however its cellular function is poorly understood. To investigate the *in vivo* role of GMAP-210, we have carried out a functional study of GMAP-210 using HeLa cells. Surprisingly, when GMAP-210 is depleted by RNA interference (RNAi), the Golgi becomes compact. This phenotype is observed using four different siRNA oligos and is rescued by the exogenous expression of Myc-tagged GMAP-210, indicating that this morphological alteration is

specific. Electron microscopy revealed that the Golgi ultrastructure is also disturbed. Yeast two hybrid and pull down experiments revealed that GMAP-210 specifically binds to Rab2 GTPase in a nucleotide dependent manner, and RNAi rescue experiments with truncated GMAP-210 constructs indicated that not only the ALPS motif but also interaction with Rab2 is important for the function of GMAP-210 in vivo. Moreover, the transport of VSV-G protein from the endoplasmic reticulum to the Golgi is delayed by the knockdown of GMAP-210. These results indicate that GMAP-210 has key roles both in the maintenance of Golgi structure and in the secretory trafficking.

### **Deciphering protein sorting itineraries at the trans-Golgi network of polarized epithelial cells.**

A. Treyer<sup>1</sup>, F. Lazaro-Dieiguez<sup>1</sup>, D. Cohen<sup>1</sup>, A. Müsch<sup>1</sup>; <sup>1</sup>*Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY*

The trans-Golgi network (TGN) is thought of as the diverging point for the sorting of apical and basolateral proteins into their subsequent itineraries through the rest of the secretory pathway. However, how the membrane structure or lipid and protein composition of the TGN provides for the specific sorting of such itineraries remains unclear. Our preliminary studies, which rely on analysis of fluorescently labeled, cargo protein-enriched, fractionated TGN membranes show that much of the apical and basolateral cargo mass is independent of either the enzymatic trans-Golgi cisternae (sialyltransferase) or the cycling TGN (TGN38) markers, indicating that most of the cargo that accumulates in the TGN delineates an independent functional compartment that is essentially devoid of known compartmental markers. Furthermore, our studies show that ~70% of apical DPPIV and basolateral VSVG cargo proteins are present in distinct TGN-entities after a cargo accumulation step at 20°C. This indicates that a significant segregation of apical and basolateral proteins has occurred within the 20°C compartment, but additional protein sorting step(s) must occur to result in the release of distinct apical and basolateral carriers in MDCK cells. Currently, we are attempting to elucidate the mechanisms and the stringencies of the “coarse” and “fine” sorting events for the different cargo types in the TGN.

### **Substrate driven regulation of GBF1 recruitment to cis-Golgi membranes.**

D. M. Quilty<sup>1</sup>, F. Gray<sup>1</sup>, N. Summerfeldt<sup>1</sup>, P. Melançon<sup>1</sup>; <sup>1</sup>*Department of Cell Biology, University of Alberta, Edmonton, AB, Canada*

Guanilyl nucleotide exchange factors (GEFs) catalyze the activation of small GTPases such as ADP-ribosylation factors (Arfs) by facilitating the exchange of bound GDP for GTP. Arf activation allows recruitment and/or activation of several effectors critical for membrane trafficking at the Golgi. At *cis*-Golgi membranes, Golgi-specific BFA resistance factor 1 (GBF1) is the primary GEF responsible for Arf activation. Recruitment of cytosolic GBF1 to Golgi membranes represents a critical step, since activation can only occur at the membrane surface following association of both GBF1 and inactive Arf•GDP. Recently, we have elucidated a novel mechanism for regulation of recruitment of active GBF1 onto *cis*-Golgi membranes. Several laboratories previously reported that treatment with Brefeldin A (BFA) causes rapid accumulation of GBF1 on Golgi membranes, an effect attributed to formation of an Arf•BFA•GBF1 membrane-bound complex. We have now demonstrated that several manipulations that result in increased cellular Arf•GDP, including Exo1 treatment and ArfGAP1 over-expression, also caused accumulation of endogenous GBF1 onto Golgi membranes.

These results are consistent with our previous report that trapping of Arf in a ternary Arf•BFA•GBF1 complex is not detected in vivo, and suggest instead that accumulation of Arf•GDP substrate promotes recruitment of GBF1. The possibility that substrate Arf•GDP positively regulates GBF1 association with membranes was tested using inactive Arf T31N mutants. We observe that expression of low levels of several Arf T31N isoforms caused dramatic accumulation of GBF1 onto membranes. This Arf•GDP dependent enrichment of GBF1 occurred specifically on *cis*-Golgi membranes. Moreover, accumulated GBF1 resulted in increased Arf•GTP production and was therefore active. These results provide the first clear function for “inactive” Arf•GDP. Accumulation of GBF1 onto Golgi membranes occurred independently of PtdIns4P levels and required association of Arf•GDP with membranes through its myristoylated N-terminal helix. This result indicates that Arf•GDP likely regulates a membrane-associated factor found specifically on *cis*-Golgi membranes, potentially a GBF1 receptor. Together, our results suggest a novel mechanism in which Arf•GDP regulates recruitment of GBF1 to *cis*-Golgi membranes to facilitate maintenance of homeostatic levels of Arf•GTP.

### **Plasmolipin is associated with targeting membranes and proteins to the apical and myelin membranes.**

Y. Yaffe<sup>1</sup>, I. Nevo-Yassaf<sup>1</sup>, J. Shepshelovich<sup>1</sup>, A. Yeheskel<sup>2</sup>, M. Pasmanik-Chor<sup>2</sup>, M. Simons<sup>3,4</sup>, K. Hirschberg<sup>1</sup>; <sup>1</sup>Department of Pathology, Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel, <sup>2</sup>Bioinformatics Unit, G.S.W. Faculty of Life Sciences, Tel Aviv University, Tel Aviv, Israel, <sup>3</sup>Max-Planck-Institute of Experimental Medicine, Göttingen, Germany, <sup>4</sup>Department of Neurology, University of Göttingen, Göttingen, Germany

The myelin and epithelial apical membranes are involved in forming barriers. While the myelin sheath insulates axonal microenvironment to allow fast signal propagation, the apical membrane faces and controls harsh extracellular environments. Myelin and apical epithelial membranes have a similar composition of liquid ordered phase-promoting lipids such as cholesterol and sphingolipids. The protein content of both membranes shows significant resemblance as well. Among these is plasmolipin (PLLP), an 18kDa protein comprised of the MARVEL four trans-membrane spanning domain. The function of PLLP in both localizations is unknown. Sequence analysis of human PLLP revealed a 29% identity to MAL, an apical targeting machinery protein previously shown by us to facilitate membrane domains formation. PLLP shares the same intramembrane dimerization WVMF motif ( $\phi XX\phi$ ) and contains another three intramembrane helix-helix interaction motifs.

Fluorescent protein tagged-PLLP localized to the PM, TGN and an unidentified tubular membrane compartment in non-polarized COS7 or MDCK cells. In the Golgi, PLLP was segregated from the Golgi marker GalT but co-localized with GPI-anchored fluorescent protein (FP). Golgi to PM transport of the VSVG membrane cargo protein was blocked by overexpression of PLLP in COS7 cells. Elongation of the VSVG trans-membrane domain by 4 amino acids eliminated this effect while the shortened VSVG mutant ( $\Delta 7$ -aa's) reached the PM rather in a significantly decreased transport rate. These data demonstrate there is an association of the TMD length of cargo proteins, which correspond to PLLP's TMD and the membrane lipids environment, and transport rate. This leads to a suggested trafficking and sorting capacity of PLLP and its effect on the transport machinery of cargo proteins. The hypothesis is that through hydrophobic mismatch interactions, PLLP serves as a “gate keeper”, blocking unmatched cargo proteins from passing through the Golgi.

Acceptor photobleaching demonstrated a substantial fluorescence resonance energy transfer (FRET) between cerulean- and YFP-tagged PLLP, demonstrating that PLLP forms oligomers when in the TGN and PM.

Together, our data support the premise that PLLP interacts with its membrane lipid environment and is part of the machinery that forms and maintains the unique composition of the apical and myelin membranes.

**Division of the intermediate compartment at the onset of mitosis provides a mechanism for Golgi inheritance.**

*M. Marie<sup>1</sup>, H. A. Dale<sup>1</sup>, N. Kouprina<sup>1</sup>, J. Saraste<sup>1</sup>; <sup>1</sup>Department of Biomedicine, University of Bergen, Bergen, Norway*

As mammalian cells prepare for mitosis the Golgi ribbon is first unlinked into its constituent stacks and then transformed into spindle-associated, pleiomorphic membrane clusters in a process that remains enigmatic. Also, whether Golgi inheritance involves the incorporation of Golgi enzymes into a pool of coat protein I (COPI) vesicles, or their COPI-independent transfer to the endoplasmic reticulum (ER) remains unclear. Based on the observation that the intermediate compartment (IC) at the ER-Golgi boundary is connected to the centrosome, we examined its mitotic fate and possible role in Golgi breakdown. The use of multiple imaging techniques and markers revealed that the IC elements persist during the M phase, maintain their compositional and structural properties and remain associated with the mitotic spindle, forming circular arrays at the spindle poles. At G2/M transition, the movement of the pericentrosomal domain of the IC (pclC) to the cell center and its expansion coincide with the unlinking of the Golgi ribbon. At prophase, coupled to centrosome separation, the pclC divides together with recycling endosomes, providing novel landmarks for mitotic entry. We provide evidence that the permanent IC elements function as way stations during the COPI-dependent dispersal of Golgi components at prometa- and metaphase, indicating that they correspond to the previously described Golgi clusters. In addition, they continue to communicate with the vesicular "Golgi haze" and thus are likely to provide templates for Golgi reassembly. These results implicate the IC in mitotic Golgi inheritance, resulting in a model that integrates key features of the two previously proposed pathways.

**Rab1 and its GAP TBC1D20 are recruited to Lipid droplets by the Hepatitis C Virus Nonstructural Protein 5A.**

*I. Nevo-Yassaf<sup>1</sup>, Y. Yaffe<sup>1</sup>, M. Lovelle<sup>1</sup>, K. Hirschberg<sup>1</sup>, E. Sklan<sup>2</sup>; <sup>1</sup>Pathology, Tel Aviv University, Tel Aviv, Israel, <sup>2</sup>Virology, Tel Aviv University, Tel Aviv, Israel*

Replication and assembly of Hepatitis C virus (HCV) depends on the host's secretory and lipid-biosynthetic machinery. Viral replication occurs on endoplasmic reticulum (ER)-derived modified membranes while viral assembly is thought to occur on lipid droplets (LDs). The ER and LD-binding non-structural protein 5A (NS5A) is a candidate for interfacing with the host membrane as well as secretory and lipid synthesis machineries. The interaction of GFP-tagged NS5A with host cell membranes and binding partners was characterized in living cells. The binding of NS5A to LDs is apparently irreversible, both in HCV-infected cells and when ectopically expressed. In HCV-infected cells, NS5A fluorescence was observed around the LDs and in perinuclear structures that were incorporated into a highly immobile platform superimposed over the ER membrane. The GTPase activating protein (GAP) TBC1D20 and its cognate GTPase Rab1 are recruited by NS5A to LDs. The NS5A-TBC1D20 interaction was previously shown to be essential for the viral life cycle. In cells, expression of the Rab1 dominant negative (Rab1DN) GTPase mutant abolished steady state LDs. In infected cells, Rab1DN induced the elimination of NS5A from viral replication sites. Currently, we are mapping the interaction between NS5A

and TBC1D20 using NS5A mutagenesis. We hypothesize that TBC1D20, via its GAP activity dissociates Rab1 from secretory membranes thereby facilitating its recruitment to LD membranes to promote LD biogenesis. Thus, we speculate that the HCV NS5A diverts lipid droplet metabolism to sustain the viral life cycle via activation of TBC1D20.

### Identification of novel Wnt signaling-associated protein kinases.

*E. C. Park<sup>1</sup>, E-Y. Shin<sup>1</sup>, Y. Hong<sup>1</sup>, G-H. Kim<sup>1</sup>; <sup>1</sup>Division of Life Science, Korea Basic Science Institute, Daejeon, Korea*

The Wnt pathway is an evolutionarily conserved signaling network that is critical for mammalian development and adult tissue maintenance. In addition, aberrant activation of the Wnt signaling is implicated in driving the formation of various human cancers, particularly those of the digestive tract. Inhibition of aberrant Wnt pathway activity in cancer cell lines efficiently blocks their growth, highlighting the great potential of therapeutics designed to achieve this in cancer patients. In this study, we try to identify novel protein kinases that are associated with canonical Wnt signaling pathway by using TOPflash reporter assay system and human protein kinase (~600 genes) library. As the result, we identified numbers of protein kinases that positively regulate Wnt signaling pathway. The novel protein kinases would be possible and valuable target for regulating Wnt pathway in cancer and mammalian development.

2264

### Role of conserved NDR kinase Orb6 in the control of polarized cell growth.

*D. J. Wiley<sup>1</sup>, I. Suarez<sup>1</sup>, M. Das<sup>1</sup>, F. Verde<sup>1</sup>; <sup>1</sup>University Of Miami School of Medicine, Miami, FL*

The conserved NDR kinase Orb6 controls cell morphogenesis in different organisms, ranging from yeast to neuronal cells. We previously found that Orb6 kinase regulates cell polarity by spatial control of Cdc42 GTPase. (Das et al, Curr Biol, 2009) Here we report that Orb6 kinase has a genetically separable function in the control of cell growth that is mediated by the RNA-binding protein Sts5.

We found that Sts5 is a cytoplasmic protein that rapidly localizes to the P-bodies, sites of RNA storage and degradation, following nutritional stress. In addition, a synthetic genetic array screen (SGA) revealed genetic interactions between Orb6 and several signaling pathways involved in nutritional response. Consistent with our finding that Sts5 is a substrate of Orb6 kinase, loss of Orb6 kinase activity leads to localization of Sts5 to the P-bodies.

We have identified several mRNAs that associate with Sts5 by microarray and q-PCR analysis. These mRNAs encode for conserved signaling proteins involved in morphology and bipolar growth activation, as well as cargos with a role in cell wall formation. The cellular levels of Sts5-associated mRNAs increase in *sts5* deletion mutants, suggesting that Sts5 may promote mRNA degradation, and decrease upon Orb6-kinase inhibition.

Our findings suggest that Orb6 kinase promotes polarized cell growth by preventing Sts5 localization to the P-bodies and consequent mRNA degradation and indicate that the Orb6 kinase function plays a role in modulating cellular responses to nutritional stress.

**Angiomotin family proteins are both targets and regulators of the Hippo pathway kinase Lats2.**

*P. Murugam<sup>1</sup>, S. Mana-Capelli<sup>1</sup>, S. Dutta<sup>1</sup>, D. McCollum<sup>1</sup>; <sup>1</sup>University of Massachusetts Medical School, Worcester, MA*

Angiomotin (AMOT) proteins were originally identified as regulators of angiogenesis, cell polarity, and cell migration. More recently AMOT-family proteins (AMOT, AMOTL1, and AMOTL2) were shown to also regulate cell growth and proliferation through the Hippo tumor suppressor pathway. We previously showed that a conserved N-terminal region of the AMOT proteins promotes the activity of the Hippo pathway kinase Lats2. The N-terminus of the AMOT proteins also localizes to actin stress fibers and promotes their assembly. Our experiments suggest that the AMOT N-terminus may act as a scaffold for Hippo signaling since it binds the three core Hippo components Mst2, Lats2, and YAP. Several studies have shown that the Hippo pathway is regulated by the actin cytoskeleton, but the mechanism is not known. To determine how AMOT proteins activate the Hippo pathway and whether the effects of actin on the Hippo pathway (and vice versa) are mediated by AMOT, we have begun a structure/function approach to analyze the conserved AMOT N-terminus. Data identifying binding sites for Hippo pathway components and regions required for actin localization and bundling will be presented. Although we showed that AMOT proteins can activate the Lats2 kinase, we find that the actin bundling activity of AMOT proteins may in turn be regulated by Lats2. We have identified a single conserved phosphorylation site (S175) in AMOT (130 kDa isoform) that is directly phosphorylated by Lats2. Phosphorylated AMOT130 is unable to bundle actin, and instead localizes to large vesicles. We propose that the Hippo pathway is not only activated by AMOT proteins, but also affects their ability to promote cell migration, cell polarity, and angiogenesis.

**Formation of GPCR Docking Site on GRK2: Role of the Extreme Amino Terminus and Active Site Tether.**

*R. Sterne-Marr<sup>1</sup>, K. Michalski<sup>2</sup>, A. Beautrait<sup>3</sup>, T. Lopež<sup>2</sup>, K. Mannix<sup>2</sup>, D. McDonald<sup>2</sup>, A. Cutter<sup>2</sup>, C. Medina<sup>2</sup>, C. Francis<sup>1</sup>, M. Bouvier<sup>3</sup>, J. Tesmer<sup>4,5</sup>; <sup>1</sup>Biology, Siena College, Loudonville, NY, <sup>2</sup>Chemistry and Biochemistry, Siena College, Loudonville, NY, <sup>3</sup>Institute for Research in Immunology and Cancer, University of Montreal, Montreal, QC, Canada, <sup>4</sup>Pharmacology, University of Michigan, Ann Arbor, MI, <sup>5</sup>Life Science Institute, University of Michigan, Ann Arbor, MI*

G protein-coupled receptor (GPCR) kinases (GRKs) were identified by their ability to specifically phosphorylate agonist-activated GPCRs leading to their desensitization. The seven GRKs are members of the AGC kinase superfamily, but their mechanism of activation is poorly defined. Agonist-activated receptors dramatically stimulate the catalytic activity of GRKs; thus, we sought to identify GRK2 residues located outside the active site that play a role in interactions with their substrate receptors. In a previous study, we showed that kinase carboxyl-tail (C-tail) residues are required for GRK activation. Genetic and antibody inhibition studies suggested that the amino terminus plays a role in receptor phosphorylation by GRK2 and GRK1, respectively. A crystal structure of GRK6 in a closed conformation and biochemical crosslinking of GRK1 suggest that N-terminal helix and the kinase C-tail interaction is important for GRK activation. In this study we carried out systematic mutagenesis of residues 3-18 and more exhaustive mutagenesis of a sub-region of the kinase C-tail, the active site tether (AST), of GRK2. Of the N-terminal mutants, Tyr<sup>13</sup> has the most dramatic effect on receptor phosphorylation, but many residues appear to make contributions. N-terminal and AST mutants exhibited parallel

deficiencies in receptor-mediated activation in vitro and  $\beta_2$ -adrenergic receptor phosphorylation in intact cells. Many, but not all, of the N-terminal and AST phosphorylation-defective mutants harbor defects in the agonist-induced recruitment to an activated  $\alpha_2$ -adrenergic receptor, measured by a cellular BRET-based assay. These results suggest that the N-terminus and AST, both intrinsically disordered in the inactive kinase, play important roles in formation of the docking site for activated receptors.

**RGS domain-mediated dimerization regulates GRK5 plasma membrane localization and function.**

H. Xu<sup>1</sup>, X. Jiang<sup>1</sup>, P. B. Wedegaertner<sup>1</sup>; <sup>1</sup>Thomas Jefferson University, Philadelphia, PA

G protein-coupled receptor (GPCR) kinases (GRKs) phosphorylate activated GPCRs at the plasma membrane (PM) to both terminate further activation of G proteins and promote G protein-independent signaling. Our goal is to elucidate the mechanisms of PM targeting of GRKs. Despite high sequence similarity, GRK5 and GRK6 constitutively localize at the PM whereas expressed GRK4 is predominantly cytoplasmic. GRK5/GRK4 chimeras and point mutations in GRK5 identified a short sequence within the Regulator of G protein Signaling (RGS) domain in GRK5 that is critical for GRK5 PM localization. Interestingly, this region of the RGS domain of GRK5 coincided with a region of GRK6 shown to form a hydrophobic dimeric interface (HDI) in the published GRK6 crystal structure. Co-immunoprecipitation (co-IP) and bimolecular fluorescence complementation (BiFC) assays suggested that expressed GRK5 wt, self-associated in cells, whereas GRK5-M165E/F166E (GRK5-EE), containing hydrophilic mutations in this RGS region, showed greatly decreased co-IP and BiFC interactions. Moreover, forced dimerization of GRK5-EE, via fusion to leucine zipper motifs, or appending an extra C-terminal membrane binding region to GRK5-EE (GRK5-EE-CT) recovered PM localization. In addition, we showed that GRK5-EE displayed a decreased ability to inhibit Par-1-induced calcium release compared with GRK5 wt. In contrast, PM-localized GRK5-EE-Caax or GRK5-EE-CT showed a comparable ability to GRK5 wt to block Par-1-induced calcium release. The results in this study suggest a novel model in which GRK5 dimerization is important for its plasma membrane localization and function.

Supported by NIH R01 GM56444.

**Protease-activated receptor 2 performs the protein secretion through the phosphorylation of CAMK II in rat parotid gland acinar cells.**

T. Saino<sup>1</sup>, E. L. Watson<sup>2</sup>, Y-I. Satoh<sup>1</sup>; <sup>1</sup>Anatomy, Iwate Medical University, Yahaba, Japan, <sup>2</sup>Oral Health Sciences, University of Washington, Seattle, WA

Protease-activated receptors (PARs) represent a novel class seven transmembrane domain G-protein coupled receptors. Recent studies have reported that PARs are present in a variety of cells and have been implicated in the regulation of a number of vital functions. The issue of whether the stimulation of PARs induces responses in parotid glands was examined; with special reference to intracellular  $\text{Ca}^{2+}$  ( $[\text{Ca}^{2+}]_i$ ) dynamics during PARs stimulation. In the present study, PAR2 mRNA was expressed strongly in the parotid glands. Following vascular perfusion with HR buffer containing PAR2-activating peptide (PAR2-AP:SLIGRL-NH<sub>2</sub>), the parotid acini showed a wide lumen and massive compound exocytosis in electron microscopy. In parotid acinar cells, PAR2-AP induced an increase in  $[\text{Ca}^{2+}]_i$ . Both removing of extracellular  $\text{Ca}^{2+}$  and using of  $\text{Ca}^{2+}$  channel blockers did not inhibit the PAR2-AP-induced  $[\text{Ca}^{2+}]_i$  increase. The response to PAR2 activation was mainly caused by  $\text{Ca}^{2+}$  mobilization from intracellular  $\text{Ca}^{2+}$

stores. This peptide induced  $\text{Ca}^{2+}$  release and entry were partially inhibited by the nitric oxide (NO) synthase inhibitor, L-NAME. The NO donor, GEA 3162, but not 8-bromo-cGMP, mimicked the effects of PAR2 in activating non capacitative calcium entry (NCCE). Both KN93 and W7 completely blocked a  $\text{Ca}^{2+}$  release from intracellular  $\text{Ca}^{2+}$  store and a  $\text{Ca}^{2+}$  influx from extracellular spaces. And when the cells were preincubated with KN93 and then were stimulated with PAR2-AP, the KN93 completely inhibited the PAR2-induced release of amylase. These results indicate that PAR2-AP activates a  $\text{Ca}^{2+}$  release from intracellular  $\text{Ca}^{2+}$  stores and following a NCCE pathway. And we proposed that an effect of PAR2 is dependent on CAMKII and CaMKII lies upstream of PAR2-induced  $\text{Ca}^{2+}$  release from intracellular stores in parotid gland.

2269

### **Effects of protease-activated receptors (PARs) on intracellular calcium dynamics of acinar cells in rat lacrimal glands.**

*M. Oikawa<sup>1,2</sup>, T. Saino<sup>1</sup>, K. Kimura<sup>2</sup>, D. Kurosaka<sup>2</sup>, Y-I. Satoh<sup>1</sup>; <sup>1</sup>Anatomy, Iwate Medical University, Yahaba, Japan, <sup>2</sup>ophthalmology, Iwate Medical University, Morioka, Japan*

The lacrimal gland is responsible for secretion of the aqueous portion of the tear film. The functional unit of the lacrimal gland is the acinus structure, which consists of polarized cells connected around a central lumen via tight junctions.

Protease-activated receptors (PARs) represent a novel class seven transmembrane domain G-protein coupled receptors, which are activated by proteolytic cleavage. To date, four members of this class of receptors have been identified. The mechanism by which PARs are activated involves the proteolytic unmasking of an N-terminal sequence that acts as a tethered ligand. Recent studies have reported that PARs are present in a variety of cells and have been prominently implicated in the regulation of a number of vital functions. The issue of whether the stimulation of PARs induces responses in lacrimal glands was examined; with special reference to intracellular  $\text{Ca}^{2+}$  ( $[\text{Ca}^{2+}]_i$ ) dynamics during PARs stimulation.

In the present study, mRNAs for all known PAR subtypes were checked by a reversetranscriptase polymerase chain reaction. PAR2 mRNA was only detected in the lacrimal glands. In lacrimal gland acinar cells, both trypsin and PAR2-activating peptide(PAR2-AP), SLIGRL-NH<sub>2</sub>, induced an increase in  $[\text{Ca}^{2+}]_i$ . Both removing of extracellular  $\text{Ca}^{2+}$  and using of  $\text{Ca}^{2+}$  channel blockers, did not inhibit the PAR2-AP-induced  $[\text{Ca}^{2+}]_i$  increase. U73122 and Xestospongin C failed to inhibit PAR2-induced increases in  $[\text{Ca}^{2+}]_i$ . And we checked the origin of the calcium influx after  $\text{Ca}^{2+}$  release from intracellular  $\text{Ca}^{2+}$  stores. The NO donor, GEA 3162 mimicked the effects of PAR2 in activating non capacitative calcium entry (NCCE). Both low concentration of  $\text{Gd}^{3+}$  (5 $\mu\text{M}$ ) and calyculin A, did not completely block PAR2-AP-induced  $[\text{Ca}^{2+}]_i$  increase.

These results indicate that the response to PAR2 activation was mainly caused by  $\text{Ca}^{2+}$  mobilization from intracellular  $\text{Ca}^{2+}$  stores and PAR2-AP activates both NCCE and CCE pathways. PAR-2 may function as a key molecule, under pathophysiological conditions such as tissue injury or inflammation.

2270

**The mechanism study of spironolactone-induced  $\text{Ca}^{2+}$  increases in rat testicular arteriole smooth muscle cells.**

Y. Tamagawa<sup>1</sup>, T. Saino<sup>1</sup>, M. Matsuura<sup>2</sup>, Y-I. Satoh<sup>1</sup>; <sup>1</sup>Anatomy, Iwate Medical University, Yahaba, Japan, <sup>2</sup>Advanced Pharmaceutics, school of pharmacy, Iwate Medical University, Yahaba, Japan

Arterioles play pivotal roles in controlling blood supply in various tissues. We have previously reported that spironolactone (SP) induced intracellular  $\text{Ca}^{2+}$  concentration ( $[\text{Ca}^{2+}]_i$ ) increase in rat testicular arteriole smooth muscle cells. SP-induced dynamics of  $[\text{Ca}^{2+}]_i$  can be caused by either a  $\text{Ca}^{2+}$  influx from extracellular fluid or  $\text{Ca}^{2+}$  mobilization from internal  $\text{Ca}^{2+}$  store, with the former being dominant. However, this  $[\text{Ca}^{2+}]_i$  increasing mechanism is not so clear. This time we have investigated the alteration of  $[\text{Ca}^{2+}]_i$  in testicular arterioles with respect to SP and some other drugs using a real-time confocal laser scanning microscope.

We isolated arterioles from testis of rats and soaked in Hepes-buffered Ringer's Solution (HR)(pH7.4). Connective tissues were digested by purified collagenase (100 units/ml) for 2 hours, then the specimens were loaded by Indo-1/AM (5  $\mu\text{M}$ ) for 1 hour at room temperature. They were placed on cover slides in chambers which were coated with Cell-Tak® and continuously perfused with HR containing some drugs. We used a real-time confocal microscope (Nikon RCM/Ab).

When SP (300  $\mu\text{M}$ ) was used as a stimulus, an increase of  $[\text{Ca}^{2+}]_i$  in the smooth muscle cells was observed. The response was considerably inhibited under either extracellular  $\text{Ca}^{2+}$ -free conditions, the presence of  $\text{Gd}^{3+}$ , or with a treatment of diltiazem. U73122 failed to inhibit SP-induced increases in  $[\text{Ca}^{2+}]_i$ . 2-APB (a potent IP3 receptor antagonist) showed almost same as above. The protein kinase A inhibitor, H89, partially inhibited this increase, whereas, it had no effect using PKC inhibitor, GF109203X. In the presence of either suramin (a G protein antagonist) or NF449 (a  $\text{G}\alpha$  inhibitor), SP-induced increases in  $[\text{Ca}^{2+}]_i$  is partially blocked. When we used mifepristone, a glucocorticoid receptor antagonist, SP-induced  $\text{Ca}^{2+}$  increase was partially blocked.

In present study, we propose that the SP-induced dynamics of  $[\text{Ca}^{2+}]_i$  can be caused by both a  $\text{Ca}^{2+}$  influx from extracellular fluid and  $\text{Ca}^{2+}$  mobilization from internal  $\text{Ca}^{2+}$  store, with the former being dominant. We suggested that there is some possibilities that SP is interact with both extracellular (i.e.a G protein-coupled type) and intracellular (i.e. glucocorticoid receptors, etc) receptors, and then rises in intracellular  $\text{Ca}^{2+}$  and causes the smooth muscle contraction in rat testicular arterioles.

2271

**Calcineurin regulates  $\text{Ca}_v3.2$  T-type  $\text{Ca}^{2+}$  channel by NFAT-like direct interaction.**

C-H. Huang<sup>1,2</sup>, Y-C. Chen<sup>1</sup>, C-C. Chen<sup>1,2</sup>; <sup>1</sup>Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan, <sup>2</sup>Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan

Re-expressed  $\text{Ca}_v3.2$  T-type  $\text{Ca}^{2+}$  channel is required for the pressure overload-induced cardiac hypertrophy and is involved in the activation of calcineurin/NFAT pathway in heart. In this study, we investigated the interaction between  $\text{Ca}_v3.2$  and calcineurin and the functional consequences of their interaction. We showed that calcineurin interact with  $\text{Ca}_v3.2$  through two conserved motifs, PCISVE and LTVP, on the C-terminal region of  $\text{Ca}_v3.2$ . The interaction between  $\text{Ca}_v3.2$  and calcineurin were both calmodulin and  $\text{Ca}^{2+}$  dependent. Interestingly, the dose response curve of  $\text{Ca}^{2+}$  dependence of  $\text{Ca}_v3.2$ /calcineurin interaction is similar to that of calcineurin phosphatase activity. This indicates that the binding of  $\text{Ca}_v3.2$  may affect calcineurin phosphatase activity. Indeed,  $\text{Ca}_v3.2$  bound calcineurin had a reduced phosphatase activity

compared to the unbound one. The calcineurin/NFAT signaling pathway can also be enhanced by the disruption of  $\text{Ca}_v3.2$ /calcineurin binding. We also investigated the effects of calcineurin binding on  $\text{Ca}_v3.2$  T-channels and showed that the disruption of calcineurin binding to  $\text{Ca}_v3.2$  was able to increase the current densities of  $\text{Ca}_v3.2$ . Lastly, we showed that the phenylephrine-induced cardiac hypertrophy was suppressed by a cell permeable peptide containing the  $\text{Ca}_v3.2$  PCISVE motif. Our findings provide evidences for a novel reciprocal modulation of  $\text{Ca}_v3.2$  T-type  $\text{Ca}^{2+}$  channel and calcineurin in regulating calcineurin/NFAT signaling pathway.

**ABA signaling in guard cells entails a dynamic protein-protein interaction relay from the ABA receptors to SLAC1 ion channel.**

S. Lee<sup>1</sup>, C. Lim<sup>1</sup>; <sup>1</sup>Life Science, Chung-Ang University, Seoul, Korea

Plant hormone abscisic acid (ABA) serves as an integrator of environmental stress such as drought, to trigger stomatal closure by regulating specific ion channels in guard cells. We previously reported that SLAC1, an outward anion channel required for stomatal closure, was regulated via reversible protein phosphorylation events involving ABA signaling components including protein phosphatase 2C members and a SnRK2-type kinase (OST1). In this study, we reconstituted the ABA signaling pathway as a protein-protein interaction relay from the PYL/RCAR type receptors, to the PP2C-SnRK2 phosphatase-kinase pairs, to the ion channel SLAC1. The ABA receptors interact with and inhibit PP2C phosphatase activity against the SnRK2-type kinase, releasing active SnRK2 kinase to phosphorylate and activate the SLAC1 channel, leading to reduced guard cell turgor and stomatal closure. Both yeast-two hybrid and bi-molecular fluorescence complementation assays were used to verify the interactions among the components in the pathway. The biochemical assays demonstrated the activity modifications of phosphatases and kinases by their interaction partners. The SLAC1 channel activity was used as an end-point readout for the strength of the signaling pathway depending on the presence of different combinations of signaling components. Further study using transgenic plants overexpressing one of the ABA receptors demonstrated that changing the relative level of interacting partners would change the ABA sensitivity.

**Regulation of connexin hemichannels by protein kinase C.**

J. L. Vega<sup>1,2,3</sup>, A. Vargas<sup>1</sup>, E. Baeza<sup>1</sup>, P. Soto<sup>1</sup>, C. C. Naus<sup>3</sup>, J. C. Sáez<sup>1</sup>; <sup>1</sup>Departamento de Fisiología, Pontificia Universidad Católica de Chile, Santiago, Chile, <sup>2</sup>Laboratorio de Fisiología Experimental (EPhyL), Universidad de Antofagasta, Antofagasta, Chile, <sup>3</sup>Department of Cellular and Physiological Sciences, Life Science Institute, The University of British Columbia, Vancouver, BC, Canada

**Introduction:** Hemichannels are located at the cellular surface of most mammalian cells. They are formed by connexin proteins and are recognized as a membrane pathway for paracrine/autocrine signals. Our objective is to determine the regulation of connexin43 (Cx43) hemichannels by protein kinase C (PKC). **Methods:** To determine changes in hemichannel activity we measured dye uptake in real time and unitary conductance by patch-clamp in whole cell modality. The HeLa cells stably transfected with Cx43-EGFP were exposed to an inhibitor (Bisindolylmaleimide) or activator (PMA) of PKC. Changes in the plasma membrane level of Cx43 were determined by confocal microscopy. **Results:** It was found that incubation with a PKC inhibitor increased dye uptake, an effect that was blocked by lanthanum ions ( $\text{La}^{3+}$ ). The effect was characterized by two slopes, initially 0.96 AU/min, followed by a secondary slope of 0.37 AU/min. This effect was also characterized by a plateau after 10 minutes. Changing to

Ca<sup>2+</sup>/Mg<sup>2+</sup> free medium (a stimulus activating hemichannels) in the plateau did not modify the dye uptake. The slope in the absence of PKC inhibitor was 0.01 AU/min. Treatment with PMA, a PKC activator, did not modify the membrane permeability. The electrophysiological results showed that the unitary conductance more prevalent in normal condition was 220±2 pS and increased to 440±4 pS in the presence to the PKC inhibitor. Confocal microscopy observations revealed that the PKC inhibitor induced internalization of Cx43 after about 5 min. **Conclusions:** The inhibition of PKC induces a rapid increase in plasma membrane permeability mediated by Cx43 hemichannels, a phenomenon that begins to decline after 5 minutes, and is probably mediated by internalization of hemichannels. ### Identification and Characterization of a Novel Substrate of Protein Kinase C that Promotes Motility of Human Breast Cells.

X. Zhao<sup>1</sup>, X. Chen<sup>1</sup>, S. A. Rotenberg<sup>2</sup>; <sup>1</sup>Chemistry & Biochemistry, Queens College and Graduate Center of C.U.N.Y., Flushing, NY, <sup>2</sup>Chemistry & Biochemistry, Queens College, Flushing, NY

Engineered over-expression of protein kinase C- $\alpha$  (PKC $\alpha$ ) is known to promote motility of non-transformed human breast MCF-10A cells. Additional PKC isoforms may collaborate in selecting the same or different substrates to produce the motility phenotype. In an effort to compare the phosphorylation patterns of individual PKC isoforms and to identify PKC substrates that lie on the motility pathway, we applied the traceable kinase method to three PKC isoforms ( $\alpha$ ,  $\delta$ , and  $\zeta$ ). By use of a non-radioactive version of this method that entailed co-immunoprecipitation of high affinity substrates, we analyzed phospho-protein profiles by Western blot with an antibody that recognizes the phosphorylated PKC consensus site. Profiles generated by PKC- $\alpha$  and  $\delta$  were similar and differed markedly from that of PKC- $\zeta$ . Mass spectrometry of selected bands revealed known PKC substrates and several potential substrates that included the small GTPase-associated effector protein Cdc42 effector protein-4 (CEP4). Of the potential substrates tested (PAK2, ROCK, and CLASP), only CEP4 was phosphorylated by pure PKC- $\alpha$ ,  $\delta$ , and  $\zeta$  isoforms in vitro, and by endogenous PKC isoforms in MCF-10A cells treated with diacylglycerol (DAG)-lactone, a membrane permeable PKC activator. Following DAG-lactone stimulation of MCF-10A cells, the stoichiometry of CEP4 phosphorylation was 3.2 + 0.5 (mol phospho-CEP4/mol CEP4). After knock-down with isoform-specific shRNA-encoding plasmids, phosphorylation of CEP4 was substantially decreased in response to silencing of each of the three isoforms. These findings identify CEP4 as a novel intracellular PKC substrate of multiple PKC isoforms. The significance of phosphorylation at one PKC consensus site (Ser-18) was analyzed by preparing CEP4 as either the pseudo-phosphorylated mutant (S18D) or phosphorylation-resistant mutant (S18N). The pseudo-phosphorylated mutant was found to stimulate motile behavior of non-motile MCF-10A cells by 3-fold thereby recapitulating the role of DAG-activated PKC in these cells. This mutant also stimulated the motility of metastatic human breast cells (MDA-MB-231 cells) by 3-fold, whereas the phosphorylation-resistant CEP4 mutant suppressed motility of these highly motile cells by 2-fold. These studies identify CEP4 as a PKC substrate whose phosphorylation promotes the motility phenotype, thereby implicating Cdc42-related pathways in this behavior.

2275

**il-32 $\theta$ , a new il-32 isoform, inhibited il-1 $\beta$  and tnf- $\alpha$  productions through interaction with pkc $\delta$  and suppressing mapk activities in pma-treated human monocyte.**

M. Kim<sup>1</sup>, J. Kang<sup>1</sup>, Y. Park<sup>1</sup>, D. Lee<sup>1</sup>, Y. Bak<sup>1</sup>, D. Yoon<sup>1</sup>; <sup>1</sup>Department of Bioscience and Biotechnology, Bio/Molecular Informatics Center, Konkuk University, Seoul, Korea

various il-32 isoforms have been discovered as pro-inflammatory cytokines in immune response. however, il-32 $\beta$  has an anti-inflammatory effect as in our previous report. in this study, we have identified a new il-32 isoform, il-32 $\theta$ , which exhibited anti-inflammatory effect in its capacity as an intracellular mediator. we constructed thp-1 (il-32 $\theta$ ) human monocyte cells which stably express il-32 $\theta$ . stimulation of pma but not lps and poly i:c suppressed the expression levels of pro-inflammatory cytokines in thp-1 (il-32 $\theta$ ) human monocyte cells. pma directly influences novel pkcs activities because diacyl glycerol only is required for activation of novel pkcs in contrast with classical pkcs. interestingly, il-32 $\theta$  interacted with only pkc $\delta$  and also pkc $\epsilon$  to a lesser degree among the novel pkc isoforms under pma stimulation. additionally, pan-pkc inhibitor g $\delta$ 6850 and pkc $\delta$ -specific inhibitor rottlerin, inhibited these interaction of il-32 $\theta$ , but classical pkc inhibitor g $\delta$ 6976 weakly altered interaction between pkc $\delta$  and il-32 $\theta$ . furthermore, pma induced-phosphorylations of mitogen-activated protein kinases such as erk and p38, were inhibited in the presence of il-32 $\theta$ . these results suggest that interaction of il-32 $\theta$  and pkc $\delta$  is required for inhibiting pma induced il-1 $\beta$  and tnf- $\alpha$  productions through suppressing mapk activities.

**Spatial regulation of the Greatwall kinase in the cell cycle.**

P. Wang<sup>1</sup>, É. Bonneil<sup>1</sup>, P. Thibault<sup>1</sup>, V. Archambault<sup>1</sup>; <sup>1</sup>IRIC, University of Montreal, Montreal, QC, Canada

Mitotic entry depends on the phosphorylation of cyclin B-Cdk1 substrates, whereas proper mitotic exit requires their dephosphorylation. In metazoans, reversal of Cdk1-dependent phosphorylation largely depends on Protein Phosphatase 2A in complex with its B55/Twins adaptor subunits (PP2A-B55). Inactivation of PP2A-B55 at mitotic entry promotes the accumulation of phosphorylated Cdk1 substrates, and is mediated by the Greatwall kinase (Gwl), which phosphorylates and activates endosulfine and Arpp19 as inhibitors of PP2A-B55. Later, PP2A-B55 activity must rise back to allow mitotic exit. How Gwl is regulated through the cell cycle is poorly understood. We found that the subcellular localization of Gwl changes dramatically through the cell cycle. Gwl is nuclear in interphase and suddenly becomes mostly cytoplasmic in prophase, before nuclear envelope breakdown. We have identified two critical nuclear localization signals (NLS) in the central, poorly characterized region of Gwl. Moreover, we found that the Polo kinase associates with and phosphorylates Gwl in the same region. Polo activity promotes the cytoplasmic localization of Gwl. We show that a gain of Polo function in embryos with reduced Gwl levels leads to frequent failure of mitotic entry in syncytial nuclei. We propose that Gwl activity is regulated by changes in its subcellular localization through the cell cycle via a mechanism that involves the inactivation of its NLSs in its central region by Polo-dependent phosphorylation.

## Signaling Receptors (RTKs and GPCRs) II

### Semaphorin-plexin signaling: a tale of two dimers and two small GTPases.

Y. Wang<sup>1</sup>, H. He<sup>1</sup>, N. Srivastava<sup>1</sup>, S. Vikarunnessa<sup>1</sup>, Y-B. Chen<sup>1</sup>, J. Jiang<sup>1</sup>, C. W. Cowan<sup>1</sup>, X. Zhang<sup>1</sup>; <sup>1</sup>UT Southwestern, Dallas, TX

Plexins are cell surface receptors that bind to semaphorins and transduce signals for regulating neuronal development, immune response and many other essential processes. Signaling through plexins has been proposed to rely on its GTPase activating protein (GAP) activity specific for R-Ras and M-Ras. Activation of this GAP activity appears to require simultaneous binding of semaphorin and a RhoGTPase to the plexin extracellular and cytoplasmic regions, respectively. However, the plexin GAP activity has eluded detection in several recent studies, and the mechanisms by which semaphorin and RhoGTPase activate plexins remain elusive.

We discovered that, surprisingly, purified plexin cytoplasmic regions act as GAPs specific for Rap but not for R-Ras or M-Ras. Mutational analyses suggest that plexins utilize a catalytic mechanism distinct from the canonical RapGAPs. The RapGAP activity of plexins is normally autoinhibited, which can be robustly activated by induced dimerization. The crystal structure of PlexinA1 cytoplasmic region bound to a RhoGTPase was also determined. Structural and biochemical analyses demonstrate that binding of the RhoGTPases does not contribute to plexin RapGAP activation directly. Finally, semaphorin activates the RapGAP activity of full-length plexin in cells, which is required for plexin-mediated neuronal growth cone collapse.

In addition, we solved the crystal structure of PlexinA4 cytoplasmic region, which reveals a novel conformation that mediates the formation of a dimer. In the dimer structure the GAP active sites of plexin are completely buried, suggesting that plexin is kept inactive by the formation of an inhibitory dimer. Furthermore, this structure presents an elegant mechanism by which the binding of semaphorin and RhoGTPase promote the dissociation of the inhibitory dimer and simultaneously induce the formation of an activating dimer, leading to plexin activation and downstream signal transduction.

To summarize, these findings together define an essential pathway for semaphorin-plexin signaling, and provide a framework for understanding the molecular mechanisms of signal transduction through the plexin family receptors.

### Imaging of Fc<sub>γ</sub> receptor signaling complexes dynamics by TIRF.

J. Lin<sup>1</sup>, B. E. Iverson<sup>1</sup>, E. Bosworth<sup>1</sup>, S. T. Low-Nam<sup>1</sup>, A. D. Hoppe<sup>1</sup>; <sup>1</sup>Chemistry and Biochemistry, South Dakota State University, Brookings, SD

IgG-presenting supported lipid bilayers were prepared to study the maturation of signaling complexes downstream of Fc<sub>γ</sub> receptor engagement in macrophages. Time-lapse multicolor total internal reflection (TIRF) microscopy was used to demonstrate that mobile IgG caused macrophages to bind to the lipid bilayer and extend pseudopodia. Fc<sub>γ</sub>R/IgG complexes formed at the leading edge of the advancing pseudopod. These complexes then moved toward the center of the cell to form a structure reminiscent of the supramolecular complex observed in the immune synapse. Colocalization of Grb2 with nascent clusters of IgG indicated that phosphorylated receptor complexes underwent maturation as they trafficked toward the middle of the cell. Localization of AktPH domain indicated that 3'-phosphoinositides were distributed

throughout the pseudopod and were not enriched near activated receptors. This system should provide new insight into the remodeling of single receptor-associated signaling complexes.

**The expression and localization of betaglycan in the prostate of the adult brushtail possum (*Trichosurus vulpecula*).**

*N. Techataweewan*<sup>1</sup>, *M. Gould*<sup>1</sup>, *H. D. Nicholson*<sup>1</sup>; <sup>1</sup>*Department of Anatomy, University of Otago, Dunedin, New Zealand*

Benign prostatic hyperplasia is a common disease in men that is thought to be related to an abnormality of prostate growth. Understanding of the disease is hampered by a lack of a good animal model and a clear knowledge of the normal regulation of prostate growth. The brushtail possum (*Trichosurus vulpecula*) has a prostate that structurally resembles the human prostate gland and also exhibits seasonal growth and regression, thus making it a useful model to explore factors involved in physiological growth regulation. The transforming growth factor betas (TGF- $\beta$ 1-3) are important growth inhibitory cytokines, that have been implicated in the regulation of prostate growth. TGF- $\beta$  exerts its action as a growth regulator through inhibiting cell proliferation, activating differentiation, inducing apoptosis [1, 2] and initiating growth arrest [3, 4]. Betaglycan, the type III transforming growth factor- $\beta$  receptor (TGF- $\beta$ RIII), is an accessory co-receptor in the TGF- $\beta$  superfamily. Betaglycan is present as a membrane bound and a soluble form. The membrane bound form presents TGF- $\beta$  to the TGF- $\beta$ RII thereby promoting cellular responsiveness to TGF- $\beta$ , whereas the soluble form can sequester TGF- $\beta$ , reducing the effect of the ligand.

The current study investigates the expression and localization of betaglycan in the possum prostate during seasonal growth and regression. Groups of three to seven animals were sacrificed at two monthly intervals during the year. The prostate was removed, weighed and bisected with half of the tissue frozen for Western blot analysis and the remaining tissue fixed for immunohistochemistry. Prostate tissue sections were incubated with TGF- $\beta$ RIII goat polyclonal antibody raised to the ectodomain portion of betaglycan (Abcam, Sapphire Bioscience Pty Ltd, UK), negative controls were incubated with goat IgG. Western blotting was executed using the same antibody and expression quantified using the Odyssey (Li-cor Biosciences, Nebraska, USA) system.

Immunoreactivity for TGF- $\beta$ RIII was localized predominantly to the epithelial and basal cells of the periurethral acini and the epithelial cells of the glandular regions. No immunopositive cells were observed in the adjacent stromal tissue. No change in the localization of TGF- $\beta$ RIII was observed during the year. Western blotting demonstrated two immunoreactive bands with molecular size of 60 kDa and 80 kDa.

Expression of TGF- $\beta$ RIII was highest in the glandular and periurethral regions of the prostate at the end of the main breeding period ( $p < 0.05$ ) and immediately in advance of prostate regression. This corresponds with our earlier finding that changes in TGF- $\beta$ 3 expression also increase at this time. This present study suggests that TGF- $\beta$ RIII may be involved in promoting regression of the possum prostate.

Key words: betaglycan; TGF- $\beta$ RIII; prostate

### Role of the truncated form of the human growth hormone receptor (GHR) in regulating GH effects.

C. Pagano<sup>1</sup>, C. Goodyer<sup>1</sup>; <sup>1</sup>*Experimental Medicine, McGill University, Montreal, QC, Canada*

It is well known that the binding of human Growth Hormone to its receptor (GHR) on target cells leads to activation of three major intracellular signaling pathways: JAK2/STAT, PI3K/AKT and MAPK/ERK. However, in addition to the full length (FL) GHR, there exist two truncated (Tr) GHR isoforms, GHR1-279 and GHR1-277, that lack the majority of their intracellular domain as a result of alternative splicing of GHR mRNA. Tissue levels of these isoforms vary considerably, with the 1-279 form predominating over the 1-277 by ~10-fold. While both *in vitro* and *in vivo* studies suggest that the Tr GHR isoforms have a dominant negative effect on FL GHR by forming stable heterodimers, little is known about their normal physiological functions and their effects on the three major GH signaling pathways.

To address this, we have analyzed the changes in a target cell's response to GH as the ratio of Tr/FL GHR shifts. We hypothesized that Tr GHR isoforms play a functionally significant role in human cells and tissues, fine-tuning the ability of GH to activate intracellular signaling and, thus, its biological effectiveness.

We examined the effects of GH stimulation on its signaling pathways through western blot analysis of phosphorylated vs. non-phosphorylated forms of STAT5b, AKT and ERK1. In HEK293 cells, where RT-PCR and western blot analyses revealed abundant FL GHR and undetectable amounts of Tr GHR, GH stimulation resulted in rapid and transient effects on pSTAT5b, pAKT and pERK1. Increasing the Tr/FL GHR ratios, by transient transfection of a Tr GHR1-279 expression vector, resulted in a significant dose-related inhibition of GH's ability to phosphorylate STAT5b compared to non-transfected cells: a 1:1 ratio resulted in a ~2-fold decrease ( $p < 0.05$ ), and a 3:1 ratio resulted in a ~6-fold decrease ( $p < 0.05$ ). Investigations of Tr GHR's effects on the AKT and MAPK pathway are ongoing.

These data suggest that Tr GHR can limit the target cell's signaling in response to GH, revealing a possible physiological role for Tr GHR in modulating GH's biological activity differentially in its target tissues.

### A synthetic T cell receptor can activate Jurkat cells.

M. J. Taylor<sup>1</sup>, J. James<sup>1</sup>, R. D. Vale<sup>1</sup>; <sup>1</sup>*Dept. of Cellular and Molecular Pharmacology, UCSF, San Francisco, CA*

T cells are activated when the T-cell antigen receptor (TCR) binds to an antigenic peptide bound in the major histocompatibility complex (pMHC) expressed on the surface of antigen presenting cells (APC). TCR signaling is mediated by tyrosine phosphorylation but the receptor itself has no intrinsic kinase activity. The molecular mechanism by which TCR-pMHC engagement is 'read-out' to trigger T-cell activation remains unclear. Previously we developed a synthetic

monomeric receptor that can act in a similar manner to the TCR. This receptor consists of the cytoplasmic phosphorylation sites from CD3zeta fused to an extracellular FKBP domain, which in the presence of the drug rapamycin can bind to FRB presented on the surface of an APC. Here, we report that this synthetic receptor is sufficient to activate the TCR signaling cascade in immortalized Jurkat T cells. Through live cell assays using T-cell-APC conjugates and functionalized supported lipid bilayers, we demonstrate that ligand binding to our synthetic receptor is sufficient to induce cell spreading and the formation of signaling micro-clusters. The downstream kinase effector ZAP70 and the inhibitory phosphatase CD45 are recruited and excluded, respectively, from these micro-clusters. Furthermore, Jurkat T cells are able to dynamically reorganize these signaling domains into a pattern that is analogous to an immunological synapse. Our synthetic receptor does not trans-activate the TCR complex, indicating it functions in an orthogonal manner to the TCR complex. This synthetic and inducible receptor provides a useful new tool to dissect the biophysical and molecular details of T cell activation.

**Rin1, via activation of Rab5, is a key regulator of preadipocyte 3T3-L1 differentiation.**

A. Galvis<sup>1</sup>, A. Marcano<sup>1</sup>, N. Rivero<sup>1</sup>, V. Gonzales<sup>1</sup>, A. Barbieri<sup>1</sup>; <sup>1</sup>Biology, Florida International University, Miami, FL

Ras interference 1 (Rin1) is a multifunctional protein involved both in endocytosis and signal transduction of the Insulin Receptor. In this study we used the preadipocyte 3T3-L1 cells to determine the effects of Rin1 (and its domains) during the differentiation process. Several point mutations were done on key amino acids that affect the function of each domain in order to analyze their effects on preadipocyte 3T3-L1 cells differentiation. Specifically, lipid droplet formation was quantified with ORO staining and adipogenic markers (i.e. PPAR $\gamma$ , CEBP $\alpha$ , AMPK, MAPK, and AKT) were analyzed via western blotting. The data indicate that expression of Rin1 wild type has a dramatic inhibitory effect on preadipocyte differentiation as evidenced by the decrease of lipid droplet formation and the expression of selective adipogenic markers. Similarly, the expression of several Rin1 domains (i.e., VSP9 and SH2 domains) showed significant inhibition of preadipocyte 3T3-L1 cell differentiation. Taken together, these data suggest not only an important inhibitory effect of Rin1 on 3T3-L1 differentiation, but that all its functional domains are necessary for the negative effect in adipocyte formation.

**Action potentials induce Ca<sup>2+</sup> signals in Schwann cells in myelinated axons: dynamic measurements using transgenically targeted YC 3.60 cameleon Ca<sup>2+</sup> indicator.**

S. S. Patel<sup>1</sup>, S. D. Atkin<sup>1</sup>, L. A. Holtzclaw<sup>1</sup>, S. H. Weerth<sup>1</sup>, J. Pickel<sup>2</sup>, J. T. Russell<sup>1</sup>; <sup>1</sup>NICHD, NIH, Bethesda, MD, <sup>2</sup>NIMH, NIH, Bethesda, MD

At the nodes of Ranvier, the axon, the myelin sheath and the myelinating glial cell are organized to operate as an integrated ensemble, the axoglial apparatus. During action potential conduction, the axonal specializations at the node, together with the adjacent paranodal terminations of the myelin sheath interact at the nodal complex. We have previously shown that a number of proteins involved in Ca<sup>2+</sup> signaling cascade are concentrated in areas of close contact between axons and Schwann cells in the axoglial apparatus. It is likely that this architecture supports mutual signals between the axon and the Schwann cell. We tested this hypothesis in isolated sciatic nerve preparations using nerves from transgenic mice expressing the Ca<sup>2+</sup> indicator, YC 3.60 discretely in Schwann cells. Isolated sciatic nerves freed of the perineurium were held between suction electrodes and positioned under a 2-photon microscope.

YC 3.60 fluorescence was imaged at 805 nm excitation and emission was collected at 450 nm (CFP) and 560 nm (YFP) and were represented as YFP/CFP ratios. Stimulation of nerves (25V at 100 Hz, 100  $\mu$ s pulses for 60s) elicited robust action potentials which were associated with  $\text{Ca}^{2+}$  signals in cytoplasmic regions of the Schwann cells. While in some instances, the  $\text{Ca}^{2+}$  signals occurred simultaneously throughout the Schwann cell cytoplasm, in others the signals occurred in a linearly propagated manner, and in some others as  $\text{Ca}^{2+}$  oscillations. Pretreatment with tetrodotoxin (1  $\mu$ M) abolished both action potentials and the associated  $\text{Ca}^{2+}$  signals. Similarly, pretreatment with purinergic receptor antagonists (MRS 2179, Suramin or reactive blue) reversibly blocked these  $\text{Ca}^{2+}$  signals. Interestingly, blockade of  $\text{K}^+$  channels with 4-aminopyridine caused significant action potential widening but significantly reduced the amplitude of Schwann cell  $\text{Ca}^{2+}$  signals. This data might suggest a  $\text{K}^+$  accumulation mediated cellular swelling leading to volume activated anion channel gating, and ATP release. Functional purinergic receptors exist in Schwann cells that ensheath sciatic nerve axons since exposure of nerves to purinergic agonists elicited  $\text{Ca}^{2+}$  signals in Schwann cells. Using the lack of sensitivity to the absence of extracellular  $\text{Ca}^{2+}$ , and pharmacological profiling we tentatively identify the receptor type on Schwann cells to be P2Y<sub>2</sub>. Such action potential driven Schwann cell  $\text{Ca}^{2+}$  signals may serve to maintain the integrity of the myelin sheath.

2284

#### **Effect of PARs on $[\text{Ca}^{2+}]_i$ dynamics of sympathetic ganglia of rats.**

*Y-I. Satoh<sup>1</sup>, T. Saino<sup>1</sup>, H. Miura<sup>2</sup>; <sup>1</sup>Anatomy (Cell Biology), Iwate Medical University, Shiwa-gun, Japan, <sup>2</sup>Department of Oral and Maxillofacial Surgery, Iwate Medical University, Morioka, Japan*

Protease-activated receptors (PARs) mediate cellular responses to various proteases in numerous cell types, including nerve cells. The issue of whether stimulation of PARs induces responses in neurons and satellite cells of sympathetic superior cervical ganglia (SCG) of rats was examined with special reference to PAR mRNA levels and to intracellular  $\text{Ca}^{2+}$  ( $[\text{Ca}^{2+}]_i$ ) changes, since  $[\text{Ca}^{2+}]_i$  is a key factor in intracellular signaling. SCG whose essential structural integrity was maintained intact, were used. RT-PCR showed that SCG expressed mRNAs encoding PAR1, 2 and 3, among which, PAR2 expression was the highest. Confocal microscopic analysis indicated that thrombin and trypsin induced an increase in  $[\text{Ca}^{2+}]_i$  in both some neurons and many satellite cells; initially, these proteases elicited a  $[\text{Ca}^{2+}]_i$  increase in satellite cells, and subsequently, a  $[\text{Ca}^{2+}]_i$  change in neurons was observed. Synchronized  $[\text{Ca}^{2+}]_i$  changes in satellite cells were often observed. Neither the removal of extracellular  $\text{Ca}^{2+}$  nor  $\text{Ca}^{2+}$  channel blockers, affected trypsin- or PAR2-activating peptide (PAR2-AP)-induced  $[\text{Ca}^{2+}]_i$  changes in satellite cells, suggesting that these changes were caused by  $\text{Ca}^{2+}$  mobilization from an internal store, but not by  $\text{Ca}^{2+}$  influx. However, neither the phospholipase C inhibitor U73122 nor the IP<sub>3</sub> receptor antagonist heparin could inhibit the  $[\text{Ca}^{2+}]_i$  changes of satellite cells, whereas the changes of neurons were considerably inhibited. This is the first study to demonstrate the presence of PARs in sympathetic nervous tissue, and to show that proteases induce  $[\text{Ca}^{2+}]_i$  changes in both neurons and satellite cells via  $\text{Ca}^{2+}$  mobilization.

#### **ICAM-1 Ring Expression and Role in Transmigration of Leukocytes on Endothelial Cells.**

*M. E. Matthews<sup>1</sup>, H. N. Hayenga<sup>1</sup>, J. H. Aranda-Espinoza<sup>1</sup>; <sup>1</sup>Fisher Department of Bioengineering, University of Maryland, College Park, College Park, MD*

Vascular diseases, including stroke and atherosclerosis, remain the leading cause of death in the world. Intracellular adhesion molecule type 1 (ICAM-1) plays a crucial role in the evolution of vascular diseases. It has been found that risk factors such as diets high in cholesterol,

smoking, diabetes, cytokines and chemokines primes arteries for vascular disease, and increase ICAM-1 expression. It is also known, with aging and vascular disease, arteries lose their elasticity and become stiffer. What remains clear is how arterial stiffness, activation of endothelial cells and transmigration of leukocytes effect the expression and distribution of ICAM-1. To elucidate the effects of endothelial activation on the distribution of ICAM-1 we used an in vitro model of the human aortic endothelium treated with TNF- $\alpha$  (25  $\mu$ g/mL) for 0, 2, 4 and 24 hrs and stained for ICAM-1. We found an ICAM-1 expression increase proportional to the activation time. At 24 hrs there is uniform expression along with ICAM-1 rings, which were clusters of ICAM-1 in a ring shape around a circle of membrane that was absent of ICAM-1 expression. While typically ICAM-1 forms clusters around leukocytes, we observed ICAM-1 cluster in the absence of any cell interacting with the endothelial surface. These ICAM-1 rings could play a role in transmigration prior to the presence of leukocytes as a response to inflammation. However, ICAM-1 expression was localized to the nucleolus and no rings were observed when the monolayer was not treated with TNF- $\alpha$ . To determine the effects of arterial stiffness on ICAM-1 expression we added TNF- $\alpha$  to HUVEC monolayers on either soft (1 kPa), physiological (5 kPa) or stiff (70 kPa) substrates and found that the ICAM-1 rings were larger with softer surfaces. While it is known that ICAM-1 plays a role in adhesion of leukocytes to vascular surfaces, our research is observing if ICAM-1 also plays a role beyond adhesion, and actually travels with the leukocyte throughout diapedesis. We stained for ICAM-1 prior to leukocyte transmigration and post-transmigration, to observe any variations in the ICAM-1 apical-basal ratio, suggesting that ICAM-1 is involved in more than just adhesion. A full understanding of how ICAM-1 is involved in transmigration could give us a better understanding of the effects of vascular disease.

**Cbl and Cbl-b attenuate macrophage proliferation and facilitate macrophage colony stimulating factor receptor traffic into nascent macropinosomes.**

J. Lou<sup>1</sup>, D. M. Kapperman<sup>1</sup>, H. Band<sup>2,3</sup>, W. An<sup>2,3</sup>, S. Nadeau<sup>2,3</sup>, O. Adepegba<sup>2,3</sup>, A. D. Hoppe<sup>1</sup>; <sup>1</sup>Chemistry & Biochemistry Department, South Dakota State University, Brookings, SD, <sup>2</sup>Eppley Institute for Research in Cancer and Allied Diseases and Eppley Cancer Center, University of Nebraska Medical Center, Omaha, NE, <sup>3</sup>Departments of Genetics, Cell Biology & Anatomy, Biochemistry & Molecular Biology, Pathology & Microbiology, and Pharmacology & Neuroscience, College of Medicine, University of Nebraska Medical Center, Omaha, NE

Casitas B-cell lymphoma (Cbl) family E3 ubiquitin ligases are critical negative regulators for receptor tyrosine kinase signaling. Cbl and Cbl-b double deficient (Cbl/Cbl-b dKO) bone marrow cells are hypersensitive to multiple cytokines. Cbl promotes M-CSF receptor (M-CSFR) multiubiquitination and endocytosis, and can significantly attenuate bone marrow macrophage proliferation in response to M-CSF. Here we show that Cbl/Cbl-b dKO bone marrow cells are hypersensitive to M-CSF, producing approximately 50 times more macrophages at day 7 compared to wild type cells. Immunofluorescence staining against plasma membrane M-CSFR revealed that activated M-CSFR was internalized at similar rate in both wild type and Cbl/Cbl-b dKO macrophages. However, the endocytic trafficking of internalized receptor is significantly changed. Previously, we demonstrated that nascent macropinosomes are important repositories for activated M-CSFR and may play a role in suppressing M-CSFR signaling. In wild type macrophages, most of the receptor traffics to large-dextran positive macropinosomes by 15 minutes after exposure to M-CSF. Strikingly, in Cbl/Cbl-b dKO macrophage there is almost no receptor trafficking into macropinosomes. Therefore, we propose that Cbl and Cbl-b mediate targeting of activated M-CSFR to macropinosomes as a novel mechanism of receptor down-regulation.

**Connexin-mediated release of pro-fibrotic ATP and hydrolysis of ATP to anti-fibrotic adenosine regulates the fibrogenic set-point of cardiac fibroblasts.**

*D. Lu<sup>1</sup>, P. A. Inse<sup>2</sup>; <sup>1</sup>Pharmacology, UCSD, La Jolla, CA, <sup>2</sup>Pharmacology and Medicine, UCSD, La Jolla, CA*

Cardiac fibroblasts (CFs) maintain the extracellular matrix (ECM) in the heart, contributing to both basal formation of ECM and the enhanced ECM generation that occurs with cardiac remodeling after injury. Myocardial stress or injury can trigger excessive deposition of collagens and other ECM proteins by CFs, resulting in cardiac fibrosis, a response that may involve signaling by extracellular nucleotides. Cellular stretch and swelling release nucleotides from rat CFs via connexin (Cx) hemi-channels. siRNA knockdown of Cx43 reduced swelling-induced release of ATP in CFs by 47% ( $p < 0.001$ ); similar results were seen with Cx45 knockdown. ATP stimulates  $\alpha$ -smooth muscle actin ( $\alpha$ SMA) and collagen synthesis via P2Y<sub>2</sub> receptors, but nucleotide hydrolysis, achieved by adding apyrase, substantially blunts production of  $\alpha$ SMA protein and collagen (>90%,  $p < 0.001$  and 40%,  $p < 0.001$ , respectively). Release of nucleotides thus likely plays a major role in both activating CFs during injury and maintaining the "set-point" of resting CFs. Because rat CFs express at least two ectonucleoside triphosphate diphosphohydrolase isoforms, ENTPD-1 and -2, which convert ATP to AMP/adenosine, we hypothesized that release of ATP and subsequent hydrolysis by ENTPDs represents counterbalancing pro- and anti-fibrotic pathways via nucleotide/P2Y and adenosine/P1 signaling, respectively. We found that inhibition of ENTPDs in CFs by polyoxometalate (POM)-1 increased  $\alpha$ SMA protein expression and collagen accumulation by 90% ( $p < 0.05$ ) and 2-fold ( $p < 0.001$ ), respectively. Furthermore, POM-1 increased CF-mediated collagen gel contraction. Adenosine signaling in CFs is anti-fibrotic, via Gs-coupled P1 receptor activation and generation of cAMP. We find that degradation of extracellular adenosine by adenosine deaminase (ADA) increases basal collagen accumulation by 67% ( $p < 0.01$ ) and  $\alpha$ SMA protein expression by ~2-fold ( $p < 0.05$ ). Moreover, ATP treatment was additive with ADA in increasing  $\alpha$ SMA expression. Thus, basal nucleotide signaling is pro-fibrotic in CFs but is blunted by ENTPDs that generate adenosine. We conclude that cellular release of ATP, which activates pro-fibrotic P2Y<sub>2</sub> receptors, also signals via anti-fibrotic receptors for adenosine, which is generated by endogenous ENTPDs. Nucleotide signaling, degradation and adenosine generation thus regulate the set-point of CFs, and the rate and extent of ATP release and hydrolysis may determine the fibrotic response of CFs during injury or in pathological states.

**Adenosine-Induced Intracellular Signaling in Rabbit Lacrimal Gland Cells.**

*S. K. Carlsson<sup>1</sup>, J. Gierow; <sup>1</sup>School of Natural Science, Optometry & Vision Science, Linnaeus University, Kalmar, Sweden*

The objective of the current study was to study the intracellular signaling events following adenosine stimulation of rabbit lacrimal gland (LG) cells. The LG produces fluid and proteins for the tear film aqueous layer. Dry eye conditions can be caused by LG dysfunction, leading to high discomfort, corneal infections and damage to the ocular surface. To understand the pathophysiology of dry eye, the normal physiology of the LG must be studied. In the current study, signal transduction pathways of the protein secretion process in LG acinar cells were investigated. Adenosine and carbachol have been shown to act synergistically on rabbit lacrimal gland cell protein secretion. To assess the intracellular mechanism of this synergy, rabbit lacrimal acinar cells in primary culture were stimulated with carbachol and adenosine. Activity, levels of key elements were measured as well as secretory response. The results of the study include a significant increase of cAMP levels in cells co-stimulated with adenosine and

carbachol compared to cells treated with only one of them, with adenosine and carbachol yielding a 2-fold increase in cAMP concentration compared to adenosine alone, and an approximate 8-fold increase compared to cAMP levels found following carbachol stimulation alone. Adenosine is traditionally known to affect cAMP levels, while carbachol is not. Studies with specific adenosine receptor agonists reveal that the effect is mainly due to the A<sub>2</sub> receptors. However, preliminary results of treatment with an adenylate cyclase inhibitor reveal that the changes of cAMP levels are not connected to the secretory responses. Phosphorylation of ERK1/2 has previously been shown to be important for the corresponding synergy in rat LG. Our results from Western blotting show no change in ERK1/2 phosphorylation following co-stimulation with adenosine and carbachol. Another MAPK, p38, has recently been shown important for carbachol signaling in the lacrimal gland. However, the results of this study indicate that p38 have minor or no importance in the synergy of adenosine and carbachol. The study concludes that cAMP formation and ERK1/2 and p38 phosphorylation do not have major roles in the adenosine-carbachol synergy in rabbit LG cells.

2289

### **CB1 Cannabinoid Receptor Regulation of Focal Adhesion Kinase Signaling in Neuronal Cells.**

*G. D. Dalton<sup>1</sup>, A. C. Howlett<sup>1</sup>; <sup>1</sup>Physiology and Pharmacology, Wake Forest University School of Medicine, Winston-Salem, NC*

Our laboratory examined the signaling pathways that regulate CB1 cannabinoid receptor (CB1R)-stimulated FAK tyrosine phosphorylation (Tyr-P) in murine N18TG2 neuroblastoma cells that express endogenous CB1Rs. FAK regulation involves phosphorylation at multiple Tyr residues including Tyr 397 (autophosphorylation site) and Tyr 576/577 (for maximal catalytic activity). Site-specific antibodies were used in immunoblotting experiments to examine the time-course of CB1R-stimulated FAK phosphorylation at Tyr 397 and Tyr 576. The synthetic CB1R agonist WIN55212-2 (WIN, 10 nM) and the endogenous cannabinoid 2-arachidonoylglycerol (1  $\mu$ M) produced three distinct phases of 576/577 Tyr-P: Phase I (0-5 min) involved maximal Tyr-P, Phase II (5-20 min) involved a decline in Tyr-P, and Phase III (> 20 min) involved a plateau in Tyr-P at submaximal levels. In contrast, 397 Tyr-P was sustained and was less robust in magnitude compared to Tyr 576/577. Phase I 576/577 Tyr-P was blocked by the CB1R antagonist SR141716A (1  $\mu$ M) and pertussis toxin (100 ng/mL) which indicates CB1Rs and Gi/o proteins are required for maximal FAK activation. The Src inhibitor PP2 (2  $\mu$ M) abolished Phase I 576/577 Tyr-P which demonstrates 576/577 Tyr-P is Src-dependent. Experiments confirmed N18TG2 cells express Flk-1 vascular endothelial growth factor receptors (Flk-1 VEGFR) and epidermal growth factor receptors (EGFR). Phase I 576/577 Tyr-P was inhibited by the Flk-1 VEGFR antagonist SU5416 (1  $\mu$ M) and EGFR antagonist AG 1478 (2  $\mu$ M) which suggests maximal FAK activation involves Flk-1 VEGFR/EGFR transactivation. Studies confirmed N18TG2 cells express fibronectin ( $\alpha$ 5 $\beta$ 1) and laminin ( $\alpha$ 6 $\beta$ 1,  $\alpha$ 7 $\beta$ 1) integrin receptors. Phase I 576/577 Tyr-P was blocked by the integrin antagonist RGDS peptide (100  $\mu$ M). CB1R agonists did not stimulate FAK Tyr-P in the absence of integrin activation in suspended N18TG2 cells. Cells grown on fibronectin and laminin displayed increased FAK Tyr-P that was augmented by CB1R agonists and blocked by PP2 (2  $\mu$ M). Finally, the actin disrupting drugs Cytochalasin D (2  $\mu$ M) and Latrunculin A (1  $\mu$ M) abolished Phase I 576/577 Tyr-P which indicates maximal FAK activation depends on the integrity of the actin cytoskeleton. Co-immunoprecipitation experiments revealed WIN (10 nM) induces  $\beta$ -actin association with FAK during Phase I, while FAK was associated with the actin polymerizing protein neuronal Wiskott-Aldrich syndrome protein (N-WASP) during Phase I. Given FAK's role in cell migration and cell survival, this cellular model provides a better understanding of the signaling mechanisms that mediate the

neuroprotective and neurodevelopmental effects of endocannabinoids. Supported by NIDA grants R01DA003690 (ACH), F32DA026295 (GDD).

**CB<sub>1</sub> Cannabinoid Receptors Induce Akt Phosphorylation At Serine 473 Via An RGD Integrin/FAK/PI-3K Pathway In Neuronal Cells.**

G. D. Dalton<sup>1</sup>, A. C. Howlett<sup>1</sup>; <sup>1</sup>Physiology and Pharmacology, Wake Forest University School of Medicine, Winston-Salem, NC

Our laboratory investigated the signaling pathways utilized by CB<sub>1</sub> cannabinoid receptors (CB<sub>1</sub>Rs) to activate the phosphatidylinositol 3-kinase (PI-3K)/Akt pathway in murine N18TG2 neuronal cells. Immunoblotting experiments revealed a maximally efficacious concentration of the synthetic CB<sub>1</sub>R agonist WIN55212-2 (WIN, 10 nM) produces an increase in Akt phosphorylation/activation at Serine 473 (Akt-pSer) that peaked maximally between 0-5 min and declined to near basal levels by 10-20 min. It is well established that focal adhesion kinase (FAK) is an important regulator of Akt phosphorylation/activation. In N18TG2 cells, the time-course of WIN-stimulated FAK tyrosine phosphorylation (Tyr-P)/activation exhibited similar kinetics to WIN-induced Akt-pSer. WIN-stimulated Akt-pSer and FAK Tyr-P were both blocked by the CB<sub>1</sub>R antagonist SR141716A (1 μM) and pertussis toxin (100 ng/mL) which indicates CB<sub>1</sub>Rs and G<sub>i/o</sub> proteins are required for Akt/FAK activation. The Src inhibitor PP2 (2 μM) also abolished WIN-stimulated Akt-pSer and FAK Tyr-P which demonstrates Akt/FAK activation are Src-dependent. Previous studies have shown the p85 subunit of PI-3K binds directly to FAK that is phosphorylated at Tyr residue 397 and this initiates activation of the major downstream PI-3K effector Akt. In N18TG2 cells, WIN stimulated an increase in FAK phosphorylation at Tyr 397, while co-immunoprecipitation experiments confirmed WIN induces a 43% increase in the association of the p85 regulatory subunit of PI-3K with FAK. Additionally, the PI-3K inhibitor LY294002 (20 μM) abolished WIN-stimulated Akt-pSer, but did not affect WIN-stimulated FAK Tyr-P. Immunoblotting experiments confirmed N18TG2 cells express RGD fibronectin (α5β1) integrin receptors. WIN-stimulated Akt-pSer and FAK Tyr-P were inhibited by the integrin antagonist RGDS peptide (100 μM). WIN did not stimulate Akt-pSer or FAK Tyr-P in the absence of integrin activation in suspended N18TG2 cells, but this response was restored in cells plated on fibronectin (10 μg). Finally, studies have shown that Akt activation requires Akt recruitment to the plasma membrane. In N18TG2 cells, disruption of the actin cytoskeleton by the actin depolymerizing agents, Cytochalasin D (2 μM) and Latrunculin A (1 μM), abolished WIN-stimulated Akt-pSer and FAK Tyr-P which indicates Akt/FAK activation require an intact actin cytoskeleton. In summary, these studies demonstrate that CB<sub>1</sub>Rs utilize RGD α5β1 integrin receptors to activate FAK, which functions upstream of PI-3K, and transduces a signal that ultimately activates Akt in neuronal cells. Supported by NIDA grants R01DA003690 (ACH), F32DA026295 (GDD).

**ET-1 induces COX-2 expression via an ET<sub>A/B</sub> receptor/c-Src/PDGFR/PI3K/Akt/ERK1/2/AP-1 pathway in Murine osteoblast-like MC3T3-E1 cells.**

C-M. Yang<sup>1</sup>; <sup>1</sup>Physiology/Pharmacology, Chang Gung University, Kwei-San, Tao-Yuan, Taiwan

Bone structure and metabolism are maintained by bone remodeling cycle in the process of the osteoblasts formation and resorption. Induction of COX-2 expression and PGE<sub>2</sub> secretion through various intracellular signaling pathways by endothelin-1 (ET-1) may play an important role in inflammation and directly stimulate osteoblastic activity. However, the molecular mechanisms underlying ET-1-induced COX-2 expression in murine osteoblast-like cell line

(MC3T3-E1) were largely unknown. Here, we found that ET-1-induced COX-2 protein and mRNA expression, and PGE<sub>2</sub> synthesis which were attenuated by the inhibitor of ET<sub>A</sub> receptor (BQ123), ET<sub>B</sub> receptor (BQ788), Gi protein (GPAnt2), Gq protein (GPAnt2A), c-Src (PP1), PDGF receptor (AG1296), PI3K (LY294002), Akt (SH-5), or MEK1/2 (U0126) and transfection with siRNA of ETA, ETB, Gi, Gq, Akt, or ERK2. In addition, ET-1-stimulated phosphorylation of Src, Akt, and ERK1/2 was attenuated by PP1. Inhibition of PI3K/Akt by LY294002 and SH-5 attenuated Akt and ERK1/2 phosphorylation, but had no effect on Src phosphorylation, suggesting that Src may be an upstream component of PI3K/Akt and ERK1/2 in these responses. Pretreatment with U0126 attenuated the ERK1/2 phosphorylation stimulated by ET-1, but had no effect on Akt activation, suggesting that Akt may be an upstream component of ERK1/2 in these responses. Moreover, ET-1-stimulated c-Fos expression and c-Jun phosphorylation in the nuclear fraction was also attenuated by PP1, AG1296, LY294002, SH-5, and U0126. These results suggested that ET-1-induced COX-2 expression and PGE<sub>2</sub> synthesis mediated through an ET<sub>A/B</sub> receptor/c-Src/PDGFR/PI3K/Akt/ERK1/2/AP-1 pathway in MC3T3-E1 cells.

**Suppression of neurite elongation in PC12 cells due to NF-YA and NF-YC knockdown.**

*K. Matuoka<sup>1</sup>, K. Sasaki<sup>1</sup>, K. Y. Chen<sup>2</sup>; <sup>1</sup>Chiba Institute of Science, Chiba-ken, Japan, <sup>2</sup>Rutgers University, Piscataway, NJ*

Heterotrimeric transcription factor NF-Y controls various genes, through interaction with the CCAAT-boxes, and various cellular events: cell growth, aging, survival, cyto-architecture etc. For the analysis of its functions, we examined effects of NF-Y knockdown on nerve growth factor (NGF)-induced neurite outgrowth in PC12 rat adrenal pheochromocytoma cells. For the tetracycline-dependent gene expression-regulatory system, PC12 and HeLa cells stably expressing a tetracycline repressor were employed. Constructs used were pCMV-GFP (a green fluorescent protein) plasmids constitutively expressing GFP-NF-Y fusion proteins, pTRE-GFP plasmids expressing GFP-NF-Y fusion proteins under tetracycline control, pRNATin plasmids expressing shRNA targeting human or rat NF-Y mRNA under tetracycline control and also bearing a GFP reporter gene, and their related plasmids. These were introduced into the cells by lipofection to examine for neurite elongation by microscopy and for mRNA amounts by real-time RT-PCR. Subcellular localization of NF-Y subunits was analyzed by using their GFP-fusion proteins: NF-YA was found in the nucleus, whereas NF-YB and NF-YC were distributed mainly to the cytoplasm but also present in the nucleus to a lesser extent. It is considered that under reductive intracellular conditions NF-YB forms a dimer with NF-YC and moves into the nucleus, followed by association with NF-YA to form a functional heterotrimer. Also, NF-Y has been suggested to enter the nucleus by the action of p38 MAP kinase and to lead to p53 elevation and SHP-1 suppression, which keeps the NGF receptor TrkA active. Herein, upon treatment with hydrogen peroxide or a p38 MAP kinase inhibitor SB203580, NF-YA appeared to be diffused in the cytoplasm, suggesting disturbance in its nuclear localization. Since neurite formation is known to involve MEK/ERK signaling, effects of shRNA targeting GRB2 (an adaptor protein working at the upper part of MEK-ERK pathways) were checked as a control experiment: the GRB2 shRNA suppressed NGF-induced neurite elongation in Dox-treated cells, but not in Dox-untreated cells. Next, with NF-Y subunit shRNA, targeting NF-YA and NF-YC was found to suppress neurite elongation. Targeting NF-YB did not much affect the neurites, presumably reflecting a difference in the limiting effects of the NF-Y subunits. These observations showed NF-Y control of the NGF and MEK-ERK signaling, which might be modulated by its nuclear localization, implying the mechanisms for physiological fine-tuning through such subcellular conditions as redox and stress affecting the NF-Y functions.

**Evidence for a Cell Fate Refinement Mechanism in Sensory Neurons.**

I. Abdus-Saboor<sup>1</sup>, B. Shykind<sup>1</sup>; <sup>1</sup>Cell and Developmental Biology, Weill Cornell Medical College Qatar, Doha, Qatar

The olfactory receptors (ORs), which are G-protein coupled receptors, number more than 1,000 and comprise the largest gene family in the mammalian genome. ORs are expressed both monogenically and monoallelically in olfactory sensory neurons (OSNs) and the mechanism that controls their regulation is largely unknown. ORs reside in constitutive heterochromatin and selection of one OR and from one allele occurs stochastically. To ensure singular monoallelic OR expression, a negative feedback mechanism is elicited by the first selected OR to suppress non-selected ORs in a given neuron.

Here we describe results for mice with a 'monoclonal' nose that express one OR, M71, in 95% of all mature OSNs. The M71 transgene suppresses expression of endogenous ORs, and remaining endogenous expression is mostly restricted to immature neurons in the olfactory epithelium. We show that the endogenous OR repertoire are expressed prior to suppression by M71 transgene expression, contrary to current models. When we introduced a second transgene into M71 mice that expressed another OR in most mature OSNs, OSNs uncharacteristically expressed both of the ORs. We hypothesize that unresolved OR competition compromised the neuron's ability to express only one receptor. We further show that suppression of endogenous ORs by M71 is not reversible, and that M71 does not need to be continuously expressed for endogenous ORs to remain suppressed.

In these experiments, we have engineered OSNs to express more than one OR in an OSN at a time, which is normally a low probability event. We believe that these experiments reveal the existence of a backup pathway that ensures only one OR will be expressed per neuron. It is possible that mammals have evolved similar mechanisms in other examples of stochastic, monoallelic gene expression, such as in random X-chromosome inactivation or lymphocyte receptor expression.

**Sphingolipids cause release from meiotic arrest and onset of apoptosis in *Xenopus* oocytes.**

A. A. Bulow<sup>1</sup>, M. Kunitsyna<sup>1</sup>, D. W. Petcoff<sup>1</sup>; <sup>1</sup>Biology, Metropolitan State University of Denver, Denver, CO

Neutral sphingomyelinase (SMase) and progesterone (PG) each bring about both release from meiotic arrest and the onset of apoptosis in *Xenopus laevis* oocytes. These events are transduced by a G protein-coupled cell surface receptor and are oxidant-dependent. *Xenopus* oocyte maturation has been studied for many years, and it has been established that the G protein-coupled receptor activates the MAP kinase pathway. More recently, evidence has accumulated that demonstrates the activation of a parallel pathway involving the generation of ceramide, the activation of JNK, and the phosphorylation of Bad, culminating in caspase-3 activation and apoptosis in oocytes that are not quickly fertilized. Both oocyte maturation and apoptosis are sensitive to the redox environment of the cell; oxidative stress (e.g. H<sub>2</sub>O<sub>2</sub> treatment, or simply the passage of time in media lacking nutritional supplements) result in apoptosis. Adding glutathione (GSH, 10 mM) to the medium inhibits apoptosis, but also blocks the ability of PG or SMase to cause maturation. The apoptotic death that is triggered by release from meiotic arrest correlates with an increased phosphorylation of Bad on residue S128, as evidenced by western blotting with an anti-S128 Bad phospho-specific antibody. We are

currently using both pharmacologic and genetic tools to study the relationships between sphingolipid metabolism, JNK activity, Bad S128 phosphorylation, redox status, and caspase-3 activity in *Xenopus* oocyte maturation and cell death.

**Lipopolysaccharide-induced 5-lipoxygenase expression in THP-1 monocytes is regulated by Akt mediated NF- $\kappa$ B and Sp1 pathways.**

*E-K. Choi<sup>1,2</sup>, S-J. Lee<sup>1,2</sup>, Y-S. Lee<sup>1,2</sup>, K-W. Seo<sup>1,2</sup>, C-D. Kim<sup>1,2</sup>; <sup>1</sup>Pharmacology, School of Medicine, Pusan National University, Yangsan, Korea, <sup>2</sup>MRC for Ischemic Tissue Regeneration, Pusan National University, Pusan, Korea*

Monocyte adhesion to the vascular endothelium of blood vessels is key early event from inflammatory responses that lead to the development and progression of atherosclerosis in cardiovascular disease. However, the underlying mechanisms of monocyte adhesion to endothelium are still not completely understood. This study investigated the effects of LPS on monocyte adhesion to endothelial cells and the potential role for 5-LO in LPS-induced monocyte adhesion to endothelial cells. LPS-stimulated monocytes led to an increased adhesion to endothelial cells in a concentration-dependent manner. LPS-induced monocyte adhesion to endothelial cells were blunted by inhibition of 5-LO with MK886, a 5-LO inhibitor as well as monocytes from 5-LO deficient mice (5-LO<sup>(-/-)</sup>). These results suggest that 5-LO is a pivotal role for LPS-induced monocyte adhesion to endothelial cells. Furthermore, to determine the potential role for LPS on the regulation of 5-LO expression, the molecular mechanisms of 5-LO was evaluated in LPS-stimulated THP-1 monocytes. LPS induced 5-LO mRNA and protein expression in associated with an enhanced promoter activity. The transcription factor of 5-LO promoter region including Sp1 and NF- $\kappa$ B were associated with up-regulation of LPS-induced 5-LO expression. Linked to these results, the LPS-induced 5-LO expression was attenuated by AI, an Akt inhibitor. In parallel, LPS exclusively increased the phosphorylation of Akt in a time-dependent manner, suggesting that Akt pathways is a major element for LPS-induced 5-LO expression. Collectively, these data suggest that 5-LO expression is regulated by NF- $\kappa$ B and Sp1 pathways through Akt activation in LPS-induced monocyte adhesion to endothelial cells. This mechanism may participate in the initiation of atherosclerosis in cardiovascular disease.

## Signaling from the PM/Cytoplasm to the Nucleus

2296

**Single-cell signaling dynamics reveal the logic of early response gene transcription driven by NF- $\kappa$ B.**

*R. E. Lee<sup>1,2</sup>, K. Savery<sup>1</sup>, S. Gaudet<sup>1,2</sup>; <sup>1</sup>Cancer Biology, Dana-Farber Cancer Institute, Boston, MA, <sup>2</sup>Genetics, Harvard Medical School, Boston, MA*

NF- $\kappa$ B is a family of dimeric transcription factors that regulate many genes→ associated with inflammation, cellular proliferation and survival as well as carcinogenesis. In the absence of extracellular signals, NF- $\kappa$ B exists in complexes with inhibitory I $\kappa$ B proteins. The I $\kappa$ B/NF- $\kappa$ B complexes are actively exported from the nucleus and NF- $\kappa$ B is therefore predominantly localized to the cytoplasm. Inducers of the canonical NF- $\kappa$ B pathway promote rapid degradation of I $\kappa$ B proteins, releasing NF- $\kappa$ B. The unmasked nuclear localization sequence of free NF- $\kappa$ B directs it to the nucleus, where it can access the promoter regions of its target genes. For this reason, the degree of NF- $\kappa$ B pathway activation is often equated with the amount of nuclear NF- $\kappa$ B even though the correlation between NF- $\kappa$ B localization and the NF- $\kappa$ B-dependent

transcriptional response has not been determined in single cells. What does an individual cell 'read' from a translocation event? Does the transcriptional response reflect a simple ON/OFF switch, or is the response proportional to a specific aspect of this dynamic translocation event? In this work we examine the relationship between tumor necrosis factor (TNF)-induced NF- $\kappa$ B translocation dynamics and the associated transcriptional response. We have developed a live-cell to fixed-cell workflow where we first image TNF-induced NF- $\kappa$ B (p65/RelA) translocation dynamics and then count, in the same cells, the number of mRNA transcripts for NF- $\kappa$ B target genes detected by single-molecule fluorescence in situ hybridization (smFISH). Correlating NF- $\kappa$ B translocation dynamics to the number of transcripts for three rapidly induced NF- $\kappa$ B-driven genes, we find that the quantity of nuclear NF- $\kappa$ B at any single time point provides little information about its activation state. Instead, cells interpret changes in NF- $\kappa$ B localization, measuring fold-change of nuclear NF- $\kappa$ B. Each cell retains a 'memory' of its pre-ligand state and evaluates translocation events relative to this previous state. We found that the relationship between fold-change of nuclear NF- $\kappa$ B and transcription in individual cells could not be predicted from existing computational models of the NF- $\kappa$ B pathway. These observations have led us to a new model that provides insight into the regulatory circuitry that quantitatively controls NF- $\kappa$ B-dependent early response gene transcription. Our results strongly suggest that competitive protein-DNA interactions provide a 'memory' required for fold-change detection.

2297

#### **Inhibition of NF $\kappa$ B activity upon loss of calreticulin function.**

*H. Massaeli<sup>1</sup>, S. Jalali<sup>2</sup>, D. Viswanathan<sup>1</sup>, A. Liberska<sup>1</sup>, K. AlDabhani<sup>1</sup>, N. Meseali<sup>3</sup>; <sup>1</sup>Weill Cornell Medical College Qatar, Doha, Qatar, <sup>2</sup>Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, MB, Canada, <sup>3</sup>Biochemistry, Weill Cornell Medical College Qatar, Doha, Qatar*

Transcription factor NF $\kappa$ B is activated by several processes including inflammation, endoplasmic-reticulum (ER) stress, increased Akt signaling and enhanced proteasomal degradation. Calreticulin (CRT) is an ER Ca<sup>2+</sup> binding chaperone, which regulates many of cellular processes. Previously, we showed that CRT deficient cells are under ER stress and have elevated proteasome activity. A role for CRT has also been described in the regulation of immune response. These data collectively led us to hypothesize that loss of CRT function results in the activation of NF $\kappa$ B signaling leading to enhanced resistance to apoptosis of these cells.

Wild type and CRT knockout mouse embryonic fibroblast were used to examine changes in the NF $\kappa$ B signaling pathway. In contrast to our hypothesis, reporter gene assays showed a significant reduction in the basal NF $\kappa$ B transcriptional activity. Furthermore, treatment with lipopolysaccharide increases the transcriptional activity of NF $\kappa$ B in both the wild type and CRT deficient cells, however, the transcriptional activity of NF $\kappa$ B was still significantly lower in the CRT deficient cells. Our data also shows that the reduced NF $\kappa$ B activity in CRT deficient cells is not due to decreased p65 or p50 protein levels. To determine the mechanism of decreased NF $\kappa$ B activity we examined changes in I $\kappa$ B protein stability and showed a significant increase in the I $\kappa$ B $\alpha$  protein level, which was abolished by Okadaic acid treatment.

We conclude that in the absence of CRT NF $\kappa$ B signaling is inhibited due to decreased I $\kappa$ B degradation and decreased NF $\kappa$ B p65 nuclear translocation.

2298

**Neuregulin1 Signaling Targets SRF and CREB and Activates the Muscle Spindle-specific Gene Egr3 Through a Composite SRF-CREB-binding Site.**

*C. Herndon<sup>1</sup>, L. Fromm<sup>1</sup>; <sup>1</sup>Indiana University School of Medicine-Muncie and Ball State University, Muncie, IN*

Muscle spindles are sensory receptors embedded within muscle that detect changes in muscle length. Each spindle is composed of specialized muscle fibers, known as intrafusal muscle fibers, along with the endings of axons from sensory neurons that innervate these muscle fibers and that convey length information to the CNS. Formation of muscle spindles involves neuregulin1 (NRG1) being released by sensory axons and activating ErbB receptors in muscle cells that are contacted, thereby triggering these cells to become intrafusal fibers. A critical component of the intracellular pathway that acts downstream of ErbBs is the transcription factor Egr3, which is transcriptionally induced as part of NRG1-ErbB signaling and in turn activates various target genes involved in formation of muscle spindles. The signaling relay within the NRG1-ErbB pathway that acts to induce Egr3 is presumably critical for muscle spindle formation but for the most part has not been determined. In the current studies, we examined, using cultured muscle cells, transcriptional regulatory mechanisms by which Egr3 responds to NRG1. We identified two adjacent upstream regulatory elements in the Egr3 gene, conforming to binding sites for cAMP response element binding protein (CREB) family members and for serum response factor (SRF), that are each involved in NRG-1 induced transcription. In myotube nuclear extracts, these elements bind protein complexes containing CREB and SRF. NRG1 signaling does not alter the DNA binding activity of CREB or SRF but instead targets CREB and SRF to presumably stimulate their transcriptional activity. To target SRF, we show that NRG1 signaling acts on the SRF coactivators myocardian-related transcription factor (MRTF)-A and MRTF-B, which are known to activate SRF-mediated transcription, by stimulating their translocation from the cytoplasm to the nucleus. CREB is phosphorylated in response to NRG1, which is consistent with it becoming activated. These results suggest that NRG1 induces expression of the muscle spindle-specific gene Egr3 by stimulating the transcriptional activity of CREB and SRF.

2299

**Protein inhibitors of activated STAT (PIAS) proteins are new negative regulators of Runx2.**

*N. Funato<sup>1</sup>, M. Nakamura<sup>1</sup>; <sup>1</sup>Human Gene Sciences Center, Tokyo Medical and Dental Univ., Tokyo, Japan*

Protein inhibitors of activated STAT (PIAS) proteins were initially identified as specific cofactors inhibiting DNA binding and transcriptional activation by the STAT family of transcription factors. PIAS family genes are expressed in osteoblasts. However, it still remains unknown whether any member of the PIAS family has any specific action on osteoblast differentiation. Here we report that PIAS proteins regulate the transcription factor Runx2, a master regulator of osteoblast differentiation. PIAS proteins, Pias1, Pias3 and Piasy, inhibit Runx2 transactivation activity. PIAS proteins and Runx2 showed colocalization to the same intranuclear regions in cotransfected COS1 cells. Piasy sequesters Runx2 from nuclear foci to the nuclear periphery. Histone deacetylases (HDACs) are also known to directly interact with Runx2 and inhibit its transactivation activity; however, PIAS-mediated repression was unaffected by the HDAC inhibitor Trichostatin A, suggesting that the repression was independent of HDAC catalytic activity. These results indicate that PIAS proteins function as new negative regulators of Runx2.

### Modulation of Cell Cycle Progression of Spermatocytes by Cigarette Smoke Condensate (CSC) via AHR-NRF2 Pathway.

P. Esakky<sup>1,2</sup>, D. A. Hansen<sup>2</sup>, A. M. Drury<sup>1,2</sup>, K. H. Moley<sup>1</sup>; <sup>1</sup>Obstetrics and Gynecology, Washington University School of Medicine, St. Louis, MO, <sup>2</sup>Research, Department of Veterans Affairs Medical Center, St Louis, MO

Aryl hydrocarbon receptor (AHR) is a ligand dependent transcription factor that regulates a battery of down stream targets in response to endogenous growth factors and exogenous environmental pollutants. *In vitro* and *in vivo* studies from our lab have demonstrated that AHR is expressed in murine spermatocytes and that its activation by CSC regulates several antioxidant enzymes. In this study, we show that exposure of a spermatocyte cell type [GC-2spd(ts)] to CSC *in vitro* induces the expression of nuclear factor erythroid 2-related factor 2 (NRF2), and translocation into the nucleus, where it is believed to modulate AHR expression by feedback mechanism. In addition, we demonstrate that the expression of NRF2 coincides with the activation of AHR as demonstrated by its prototypical indicator protein, CYP1A1. Results from pharmacological inhibition by AHR-antagonist (CH223191), as well as transfection of spermatocytes with *Ahr*-and *Nrf2*-siRNA and analysis of *Ahr*-KO mice testis by laser microdissection implicate the *Ahr-Nrf2* pathway in DNA damage and cell cycle arrest. *Ahr*-and *Nrf2*-siRNA transfection followed by q-RTPCR revealed the difference in the expression profiles of *Ahr*, *Nrf2*, *Cyp1a1*, *Ahr-R*, *Hsp90*, *Sod2*, *P21* and *Gadd45a* in the CSC treated spermatocytes. The regulatory role of AHR-NRF2 signaling in cell cycle progression was assessed through the regulation of cyclin D1 expression with or without CSC. Western blot and confocal localization of CSC exposed spermatocytes demonstrated that the cyclin D1 protein though unaltered in expression undergoes nuclear translocation, which was inhibited by AHR-antagonist and *Ahr*-siRNA. AHR knockdown by siRNA transfection significantly reduced the basal level of cyclin D1 expression. This observation was further strengthened with the identification of two AHR elements in the 5' UTR region of the *Cyclin D1* gene. Immunoprecipitation analysis of CSC treated spermatocytes demonstrated the interaction between AHR, NRF2 and cyclin D1 proteins. Thus the data obtained from these studies suggest that the cigarette smoke condensate has several AHR-agonists that are capable altering the growth pattern of spermatocytes through the AHR-NRF2 combined signaling mechanism.

### Nuclear translocation of the canonical Wnt-regulator Jade-1 is phosphorylation-dependent.

L. Borgal<sup>1</sup>, M. Rinschen<sup>1</sup>, T. Benzing<sup>1,2</sup>, B. Schermer<sup>1,2</sup>; <sup>1</sup>Department II of Internal Medicine and Center for Molecular Medicine Cologne, University of Cologne, Cologne, Germany, <sup>2</sup>Cologne Excellence Cluster on Cellular Stress Responses in Aging-Associated Diseases, Cologne, Germany

Canonical Wnt signaling regulates cell-fate determination during embryogenesis, and more recently has been shown to be vital for a regenerative injury response in adult tissue. However, Wnt signaling must be strictly regulated as a lack of repression is associated with uncontrolled cell division leading to cyst formation or cancer. Jade-1 has recently been identified as a novel E3 ubiquitin ligase that targets the canonical Wnt effector beta-catenin for proteasomal degradation. Previous work in our laboratory demonstrated that Jade-1 localizes to the primary cilium, a hair-like organelle which projects from the apical surface of virtually every eukaryotic cell and is a critical regulator of several signaling pathways including Wnt. The ability of Jade-1 to negatively regulate canonical Wnt reporter activity was enhanced by nephrocystin-4 (NPHP4), a member of the nephronophthisis (NPH) protein complex, which co-localizes with

Jade-1 at the primary cilium. NPH is a cystic kidney disease and a leading genetic cause for renal failure in children. NPHP4 stabilized protein expression and nuclear translocation of Jade-1, and additively increased negative regulation of canonical Wnt reporter activity. Our results indicated that NPHP4 influences the phosphorylation status of Jade-1, and that inhibiting phosphatase activity blocked Jade-1 from entering the nucleus and blocked NPHP4-mediated Jade-1 stabilization. New findings confirm phosphorylation of Jade-1 using mass spectrometry, and identify a candidate kinase and corresponding phosphorylation site. A Jade-1 mutant lacking this phosphorylation site displays altered intracellular localization and WNT reporter activity. Currently, we address the role of Jade-1 phosphorylation in cilia biology and the pathogenesis of polycystic kidney diseases.

**MAP Kinase-Ternary Complex Factor exchange regulates a transcriptional switch to mediate adhesion-regulated proliferation.**

*M. A. Wozniak<sup>1</sup>, C. Q. Cheng<sup>1</sup>, C. J. Shen<sup>1</sup>, L. Gao<sup>1</sup>, C. S. Chen<sup>1</sup>; <sup>1</sup>Bioengineering, University of Pennsylvania, Philadelphia, PA*

Cooperative signaling between cell adhesion to the extracellular matrix (ECM) and growth factors plays a central role in regulating immediate early gene expression and proliferation. Growth factors regulate the activity of the ternary complex factors (TCFs; Elk1, Net, and Sap-1), which act as transcription co-factors of serum response factor (SRF) that are activated by map kinase (MAPK) phosphorylation to regulate immediate early gene transcription. Although cell adhesion also can regulate immediate early gene expression and proliferation, it is unclear how adhesion to the ECM impinges upon MAPK/TCF signaling. Restricting adhesion and spreading of G<sub>0</sub>-synchronized cells on substrates with decreasing size of micropatterned islands of fibronectin suppressed serum-induced immediate early gene expression and S-phase entry. Knockdown of Sap-1 decreased expression of the immediate early genes *egr1* and *fos* and subsequent proliferation normally present with high adhesion. Conversely, knockdown of Net rescued *egr1* and *fos* expression and proliferation normally suppressed by low adhesion. ChIP studies showed increased occupancy of *egr1* and *fos* promoters by Sap-1 with high adhesion, while low adhesion increased Net occupancy. This switch in TCF promoter binding was regulated by an adhesion-mediated switch in MAPK activity. Increasing adhesion enhanced serum-induced JNK activity while suppressing p38 activity, leading to increased Sap-1 phosphorylation and Net dephosphorylation, and switching Net with Sap-1 at *egr1* and *fos* promoters to support proliferation. Microarray studies confirmed this switch in TCF regulation of proliferative genes and uncovered novel gene targets and functions co-regulated by Sap-1 and Net. These data demonstrate a key role for the TCFs in adhesion-induced transcription and proliferation, and reveals a novel MAPK/TCF transcriptional switch that controls this process.

**Early Growth Response-1 Accelerates Liver Regeneration after Partially Hepatectomized Mice through GGPPS/MAPK signaling.**

*S. S. Lai<sup>1</sup>, N. Shen<sup>2</sup>, J. C. Li<sup>2</sup>, B. Xue<sup>2</sup>; <sup>1</sup>Life Science College, Nanjing Normal University, Nanjing, China, <sup>2</sup>MOE Key Laboratory of Model Animals for Disease Study, Model Animal Research Center and the School of Medicine, Nanjing University, National Resource Center for Mutant Mice, Nanjing, China*

**Abstract**

**Background & Aims:** Liver regeneration comprises a series of complicated processes, in which several transcription factors play an important role. Egr-1 is rapidly induced as part of the

immediate early gene response of the regenerating liver. Previous studies indicated that EGR-1<sup>-/-</sup> mice exhibit delayed hepatocellular mitotic progression after partial hepatectomy. Whereas, the mechanism that Egr-1 in regulating regeneration progress is still unknown. Here we revealed a novel and important signal pathway mediated by Egr-1 in this process.

Methods: 70% partial hepatectomy (PH) were performed on mice after tail vein injection of adenoviral vectors, which expressing GFP (Ad-GFP), Egr-1(Ad-Egr-1) or Dominant negative Egr-1(Ad-DNEgr-1) to increase or down-regulate hepatic Egr-1 levels. Animals were sacrificed at intervals after the surgery, and the remnant livers were harvested and analyzed. In vitro study, serum starvation recovery model was selected to mimic liver regeneration process in normal human hepatic cells. The activities of proliferative- and cell-cycle-related signaling pathways were measured by Western blotting. The downstream of GGPPS was examined in the regenerating liver and human hepatic cells.

Results: Compared with wild mice, Loss of Egr-1 significantly inhibited liver recovery 5 days after PH. Consistent with the observation, the expression levels of key cell-cycle regulatory proteins, including CyclinD1, CyclinE and PCNA were markedly altered. The expression of GGPPS and the activity of downstream RAS/ERK/signaling pathway were inhibited by the DN-Egr-1 after partial hepatectomy, which is consistent with the serum-induced cell model. In addition, loss of Egr-1 aggravates the liver function with the increase serum ALT and AST level.

Conclusions: Egr-1 plays an important role in regulating the cell cycle of hepatocytes induced by partial hepatectomy. Egr-1 induced the expression of GGPPS and thus positive the regulation RAS/MAPK signaling, which could be an important mechanism underlying the regulated liver regeneration of Egr-1 in the liver.

### **SmgGDS antagonizes BPGAP1-induced Ras/ERK activation and neuriteogenesis in PC12 cells differentiation.**

A. Ravichandran<sup>1,2</sup>, B. C. Low<sup>1,2</sup>; <sup>1</sup>*Mechanobiology Institute Singapore, Singapore, Singapore*, <sup>2</sup>*Department of Biological Sciences, National University of Singapore, Singapore, Singapore*

The process of cellular differentiation involves the intricate integration and control of multiple signaling networks. The Rho and Ras family of small GTPases and its regulators such as GAPs and GEFs play important roles in controlling cellular processes. BPGAP1 is a multidomain RhoGAP that regulates cell migration, endocytosis and ERK signaling via the concerted action of its proline-rich region (PRR), RhoGAP domain and the BNIP-2 and Cdc42GAP Homology (BCH) domain interacting with cortactin, endophilin, Rho, Cdc42, Mek2 and Pin1. Here, we further show that the BCH domain of BPGAP1 specifically targets K-Ras to induce a robust activation of ERK, leading to the differentiation of PC12 cells. However, such stimulatory effect was inhibited by both dominant negative mutants of Mek2 (Mek2K101A) and K-Ras (K-RasS17N) and also by the Small G-protein GDP Dissociation Stimulator (SmgGDS). Using live imaging to track the differentiation of PC12 cells, we have established that the interaction of BPGAP1 and SmgGDS affects not only the initiation of neurite outgrowth but also growth cone maturation and dynamics. These results demonstrate the versatility of the BCH domain of BPGAP1 in regulating ERK signaling by interacting with K-Ras and SmgGDS and support the unique role of BPGAP1 as a dual regulator for Ras and Rho signaling in cell morphogenesis and differentiation. This work was supported by a grant from the Ministry of Education, Singapore and in part by the Mechanobiology Institute, co-funded by the National Research Foundation and the Ministry of Education, Singapore.

**Modulation of Hedgehog signaling in renal cystogenesis is associated with changes in intracellular Ca<sup>2+</sup> levels.**

D. T. Jacobs<sup>1</sup>, G. C. Talbot<sup>2</sup>, M. P. Schonfeld<sup>1</sup>, J. A. Christianson<sup>3</sup>, D. R. Beier<sup>2</sup>, P. V. Tran<sup>1</sup>;  
<sup>1</sup>Anatomy and Cell Biology; Kidney Institute, University of Kansas Medical Center, Kansas City, KS, <sup>2</sup>Medicine, Brigham and Women's Hospital, Boston, MA, <sup>3</sup>Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS

Primary cilia are slender cellular extensions that are present on most vertebrate cells and regulate signal transduction pathways. Defects in primary cilia are associated with severe human conditions such as cystic kidney disease, cystic liver disease, cognitive impairment, blindness and obesity. THM1 is a ciliary protein required for proper cilia structure and is a negative modulator of Hedgehog (Hh) signaling (Tran et al. *Nat. Genet.* 2008). Deletion of murine *Thm1* during late embryogenesis results in large, fluid-filled cysts in the adult kidney. Importantly, deletion of *Thm1* together with *Gli2*, the primary transcriptional activator of the Hh pathway, significantly attenuates renal cyst formation, indicating a causal role for elevated Hh activity in *Thm1* renal cysts. Polycystic kidney disease (PKD) is a common and widely studied renal cystic pathology caused by genetic alteration of Polycystin 1 (PC1) or of Polycystin 2 (PC2) proteins. Since PC1 and PC2 (a GPCR and a Ca<sup>2+</sup> channel, respectively) localize to primary cilia and regulate intracellular Ca<sup>2+</sup> levels, the current hypothesis is that cilia-mediated changes in intracellular Ca<sup>2+</sup> levels underlie cyst formation in the kidney ductal epithelium. To determine whether Hh signaling induces changes in intracellular Ca<sup>2+</sup>, we are using M1 mouse renal medullary collecting duct cells. Our initial characterization of M1 cells shows that ciliary proteins, THM1, Arl13B, Polaris, IFT52, PC1 and PC2, localize to primary cilia. M1 cells respond appropriately to small molecule Hh modulators; Hh agonist, SAG, increased expression of Hh target genes, *Ptch1* and *Gli1*, by 2.3 fold and 4.4 fold, respectively, while addition of Hh antagonists, Sant2 or Gant61, inhibited this up-regulation. Sant2 and Gant61 attenuated renal cyst formation in an embryonic metanephric organ culture assay, and caused 3- and 6-fold increases, respectively, in intracellular Ca<sup>2+</sup> levels in M1 cells. We are currently investigating the source of increased intracellular Ca<sup>2+</sup> by Hh antagonists and the effect of THM1 deficiency on intracellular Ca<sup>2+</sup> levels using shRNA knock-down of *Thm1*. Together, our data suggest a role for Hh signaling in renal cystogenesis by possibly altering levels of intracellular Ca<sup>2+</sup>.

**Masparidin Effects on BMP Signaling Molecules.**

L. E. Bailey<sup>1</sup>, D. M. Sun<sup>1</sup>, M. C. Hanna<sup>1</sup>; <sup>1</sup>Biological and Environmental Sciences, Texas A&M University - Commerce, Commerce, TX

The hereditary spastic paraplegias are a group of upper motor neuron disorders characterized by continuous degradation of motor neurons trailing through the motor cortex, down the spinal cord, and out to the periphery. Mast syndrome (SPG21) is an autosomal-recessive complicated form of HSP that originates from a mutation of the ACP33/masparidin gene.

Bone Morphogenetic Proteins (BMPs) are a group of multifunctional growth factors that, along with forming bone and cartilage, influence axonal synaptic growth and function. Upon activation by BMP ligand, type II BMP receptors phosphorylate type I receptors. This activates intracellular signaling molecules Smad 1, 5 and 8. These bind Smad 4 and the Smad complex enters the cell nucleus to drive gene transcription.

Previous studies have shown multiple HSP-associated proteins to be inhibitors of BMP signaling. Therefore, our objective is to prove that masparidin is an additional BMP inhibitor. Veritably, masparidin-depleted neurons have exhibited increased axonal branching.

Preliminary results have demonstrated increases in BMP signaling in knockout MEFs over a series of five timepoints as compared to wildtype. BMP4 ligand stimulation will be done over the same series of timepoints for a more accurate comparison. Results have also demonstrated increases in knockout MEFs stimulated with BMP4 ligand for 1 Hr as compared to wildtype. Phosphorylated Smad 1/5 levels will be examined via western blot and compared to total Smad levels after stimulation with BMP4 ligand.

GFP-masparidin will be overexpressed in wildtype MEFs and compared against knockout MEFs to determine whether overexpression of masparidin changes BMP signaling levels and restore knockout levels to those found in wildtype. GFP-masparidin will also be overexpressed in Cos-7 cells and compared to control. Comparable experiments will be done using primary neuron cultures from wildtype and knockout mice.

### **A Wnt-Id1 signaling pathway maintains self-renewal capacity in adult mouse neural stem cells.**

*P. J. Cook<sup>1</sup>, R. Benezra<sup>1</sup>; <sup>1</sup>Cancer Biology and Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY*

It is critical for populations of adult tissue-resident stem cells to maintain self-renewal capacity in order to avoid progressive cell depletion with increasing age. However, little is currently known regarding the signaling pathways and transcriptional networks that govern stem cell self-renewal in-vivo. Id family transcriptional regulators are expressed throughout life in multiple adult stem cell niches, including the subventricular zone (SVZ) of the mammalian brain. Induced loss of function of the Id homologues Id1 and Id3 leads to significant loss of self renewal capacity in primary cultures of adult mouse neural stem cells, along with increased propensity toward neural differentiation and increased expression of p16-INK4a and p21-CIP1. We examined the consequences of induced overexpression of Id1 in mouse primary cultures derived from transgenic animals and observed a simultaneous decrease in proliferation and increase in self-renewal capacity. This cellular phenotype is similar to that seen in adult neural stem cells treated with Wnt3a, an activator of canonical Wnt signaling. Wnt3a treatment strongly activated expression of Id1 in cultured cells, suggesting that Id may be a key mediator of the self-renewal program downstream of Wnt signaling in adult neural stem cells. Id factor loss of function blocked the ability of Wnt3a to up-regulate self-renewal capacity, and treatment with the small-molecule Wnt-signaling inhibitor JW74 led to a clear decrease in self-renewal capacity and Id1 expression level. Ongoing in-vivo experiments will explore the significance of this regulatory relationship in the SVZ of adult mice and in a mouse model of spontaneous glioma.

### **The p66<sup>Shc</sup> adapter protein regulates the morphogenesis and epithelial maturation of fetal mouse lungs.**

*M. K. Lee<sup>1</sup>, S. M. Smith<sup>1</sup>, M. V. Volpe<sup>2</sup>, H. C. Nielsen<sup>2</sup>; <sup>1</sup>Ctr for Craniofacial Molec Biology, University of Southern California, Los Angeles, CA, <sup>2</sup>Newborn Medicine, Tufts Medical Center, Boston, MA*

Multiple growth factor signaling pathways are mediated by Shc adapter proteins that, in turn, are expressed as three transcriptional and translational variants with distinct and opposing functions. The p66<sup>Shc</sup> isoform has anti-mitogenic properties, regulates oxidative stress responses, and participates in mitochondria-mediated apoptosis. It is also highly expressed in the canalicular but not the saccular or alveolar stages of mouse lung development, suggesting an important morphogenetic function. Moreover, p66<sup>Shc</sup> expression persists in the lungs of

infants with bronchopulmonary dysplasia, a chronic lung disease that is induced by premature birth. However, constitutive p66<sup>Shc</sup> deletion yields no morphologic phenotype and the structure of the Shc gene precludes the development of an inducible isoform-specific knockout mouse. To elucidate its role in lung development, we microinjected Oligofectamine (Invitrogen) suspensions containing 6.6 nM isoform-specific p66<sup>Shc</sup> or nonsilencing siRNA into the tracheae of E12 mouse lungs. The lung explants were maintained in serum-free organ culture for three days, then subjected to morphometric analysis. To assess cellular proliferation and differentiation, sections were also immunostained for p66<sup>Shc</sup>; smooth muscle actin (SMA); proliferating cell nuclear antigen (PCNA); the proximal airway differentiation antigens Clara cell 10-kDa protein (CC10) and thyroid transcription factor (TTF)-1; and the alveolar surfactant proteins (SP) -A, B, and C. Explants injected with nonsilencing siRNA demonstrated specific epithelial uptake and normal morphological development relative to uninjected control explants. In contrast, explants injected with p66<sup>Shc</sup> siRNA had significantly increased luminal cross-section areas, decreased branching, and increased epithelial proliferation ( $p < 0.05$  for all) as well as decreased epithelial p66<sup>Shc</sup> expression. Relative to controls, the expression of SP-B, SP-C, CC10, and TTF-1 were decreased by p66<sup>Shc</sup> knockdown. SP-A was not expressed in lungs transfected with either p66<sup>Shc</sup> or control siRNA, and SMA expression was not altered by p66<sup>Shc</sup> silencing. These data suggest that p66<sup>Shc</sup> attenuates epithelial proliferation while promoting both distal and proximal epithelial maturation during normal and pathological lung development.

#### **Recombinant OA/gpnmb induces differentiation and Src/ERK/AKT activation in osteoblast.**

*G. R. Sondag<sup>1</sup>, O. Ali<sup>1</sup>, T. Mbimba<sup>1</sup>, C. Fulp<sup>1</sup>, S. Abdelmagid<sup>1</sup>, F. Safadi<sup>1</sup>; <sup>1</sup>Anatomy and Neurobiology, Northeast Ohio Medical University, Rootstown, OH*

Osteoactivin (OA)/gpnmb is a type I transmembrane protein (576 amino acids) containing an extracellular domain with an RGD motif, and intracellular domain with an immunotyrosine inhibitory motif (ITIM) and has been linked to osteoblast and osteoclast differentiation and function. Our laboratory previously showed that OA induces osteoblast differentiation and function in vitro and bone formation in vivo. In this study, we investigated the effects of recombinant OA (rOA) on osteoblast differentiation and signaling. First, we examined the effects of rOA treatment on osteoblast proliferation and survival. MC3T3-E1 osteoblast-like cells or primary osteoblast cultures were treated with different doses of rOA and proliferation and survival were evaluated at different time points. rOA treatment had no significant effects on proliferation and survival. Next, we examined the effects of rOA on markers of osteoblast differentiation. rOA treated cells showed a significant increase in Runx2, Osterix, Osteocalcin, Alkaline Phosphatase and Type I Collagen expression at days 7 and 14 in culture. These data suggest that the effect of rOA on osteoblast differentiation is independent of cell proliferation and/or survival. Furthermore, we examined OA signaling in osteoblasts and determined whether rOA treatment causes activation of Src, ERK1/2 and AKT in osteoblasts. These signaling molecules have been shown to be involved in differentiation and proliferation in osteoblasts. MC3T3-E1 cells were treated with rOA (50 ng/ml) at different time points. ERK phosphorylation reached its highest between 10 and 30 minutes following OA treatment, while AKT was maximally phosphorylated after 30 minutes of OA induction. In addition, Src phosphorylation increased gradually and reached a maximum after 1 hour of treatment. These results show that OA is acting through an out-side-in signaling that activates Src/ERK/AKT signaling pathways. Taken together, these data suggest that OA induces osteoblast differentiation and function, at least in part, through Src/ERK/AKT activation. Further studies are directed towards examining whether OA regulates osteoblast differentiation via Erk/Runx2 pathway.

**YAP translocation in human trabecular meshwork cells.**

I. Ly<sup>1</sup>, J. T. Morgan<sup>1</sup>, V. K. Raghunathan<sup>1</sup>, C. J. Murphy<sup>1,2</sup>, P. Russell<sup>1</sup>; <sup>1</sup>Department of Surgical and Radiological Sciences, University of California, Davis, School of Veterinary Medicine, Davis, CA, <sup>2</sup>Department of Ophthalmology and Vision Science, University of California, Davis, School of Medicine, Davis, CA

**Objective:** Yes-associated protein (YAP) is a transcriptional co-activator and a component of the Hippo pathway. It is only transcriptionally active while in the nucleus, and can be sequestered in the cytoplasm for degradation. Little is known about YAP in ocular tissue with the current literature primarily focusing on its role in organ size control, tumorigenesis, and proliferation. Glaucoma, a major cause of irreversible blindness, has been associated with loss of cellularity in the human trabecular meshwork (HTM). Additionally, soluble cytoactive factors are known to be altered in the aqueous humor of patients with glaucoma. Serum, used for cell culture *in vitro*, is a rich reservoir of soluble factors and its presence has a direct impact on various cellular functions such as proliferation, migration and stress response. Previous research has demonstrated that serum starvation induces YAP phosphorylation and cytoplasmic retention across a range of immortalized cell lines, and that nuclear localization can be induced with serum. In order to better understand the regulation of this important proliferative pathway in HTM cells, we wished to investigate the role of serum-induced YAP regulation by examining the expression and localization of YAP in SV40 immortalized HTM cells (TM-1) and primary (HTM) cells.

**Methods:** TM-1 cells and HTM cells from normal donors were cultured in DMEM containing 10% fetal bovine serum. They were then serum starved for 24 hours and then treated with either 10% serum containing media or serum free media as a control. The treatment lasted for 3 hours, after which they were fixed in and immuno-stained for YAP. YAP localization was then determined using immunofluorescence microscopy. Additionally, we serum starved the primaries for extended periods (1-8 days) before fixation and staining.

**Results:** In control (serum-free) TM-1 cells, YAP localized predominantly to the cytoplasm. With serum treatment, the TM-1 cells exhibited strong YAP nuclear localization. Primary HTM cells demonstrated nuclear localization of YAP in both the presence and absence of serum. To confirm if this was a lingering effect of serum during initial culture, we also fixed and stained HTM cells at 1, 4, 6, and 8 days. At all timepoints, primary HTM cells exhibited strong nuclear localization of YAP.

**Conclusions:** The serum-starved TM-1 cells are consistent with previous reports of cytoplasmic retention of YAP and provide further evidence for YAP nuclear translocation following serum treatment. These results demonstrate that there are serum-derived factors that modulate the activation of YAP in TM-1 cells. Furthermore, these results indicate that this is not the dominant regulatory mechanism in primary HTM cells *in vitro*. Additional research will investigate the significance of YAP nuclear localization in HTM cells under serum-free conditions *in vitro*. Such differences are critical in considering choices of cell type for investigating signaling pathways pertaining to glaucoma or other diseases. Overall, these results provide insight on the function of YAP in the HTM and have broader implications in the study of glaucoma.

### **Palladin Cycles Between the Stress Fibers and the Nucleus to Regulate Transcription During Myofibroblast Differentiation.**

*M. L. Kerber<sup>1</sup>, S. Goicoechea<sup>1,2</sup>, T. De Buysscher<sup>3</sup>, R. Hwang<sup>4</sup>, R. Garcia-Mata<sup>1,2</sup>, H. J. Kim<sup>5</sup>, C. Otey<sup>1</sup>; <sup>1</sup>Cell and Molecular Physiology, UNC Chapel Hill, Chapel Hill, NC, <sup>2</sup>Department of Biological Sciences, University of Toledo, Toledo, OH, <sup>3</sup>Center for Bioinformatics, UNC Chapel Hill, Chapel Hill, NC, <sup>4</sup>MD Anderson Cancer Center, University of Texas, Houston, TX, <sup>5</sup>Department of Surgery and Lineberger Comprehensive Cancer Center, UNC Chapel Hill, Chapel Hill, NC*

Fibrosis is a pathological process that resembles exaggerated wound-healing. The primary cellular mediator of fibrosis is the myofibroblast, which can arise through multiple mechanisms. Myofibroblast differentiation is regulated by the transcription factor Serum Response Factor (SRF) and its coactivator Myocardin-Related Transcription Factor (MRTF). Monomeric G-actin associates with MRTF in the cytoplasm and prevents its translocation to the nucleus. When the G to F-actin ratio is low, MRTF is released and can shuttle into the nucleus where it modulates transcription of SRF target genes. MRTF has recently been shown to bind directly to palladin, implicating this actin-crosslinking protein as a novel player in the SRF/MRTF molecular pathway, possibly as a transcriptional co-factor. To investigate the role of palladin in pancreatic fibrosis, we performed immunoblot analysis on human pathological specimens, and found that palladin is significantly upregulated in fibrotic vs normal pancreas. To probe the molecular function of palladin in fibrosis, a line of immortalized human pancreatic myofibroblasts was used as an in vitro model system. Cellular fractionation combined with immunoblot analysis revealed that palladin is detected in both the stress fibers and the nucleus of these cells, suggesting that it may participate in signaling between the two compartments. To investigate the role of palladin in regulating gene expression in pancreatic myofibroblasts, we used lentiviral expression of shRNA to generate two sub-lines of cells in which palladin was stably knocked down. Total RNA from knockdown and control cells was isolated and subjected to transcriptomic analysis (RNAseq). The results showed that the levels of expression of multiple genes involved in establishing a mesenchymal phenotype were significantly altered when palladin was knocked down in pancreatic myofibroblasts. As this pathway is likely to be conserved among the different cell types that are capable of differentiating into myofibroblasts, the current project could yield benefits for the entire field of fibrosis-related disorders. Supported by NIH and NSF.

### **Biological roles of Carabrone originated from Carpesium A. as an immune modulator.**

*J. Kim<sup>1</sup>, D. Jee<sup>1</sup>, H-B. Kang<sup>1</sup>, H. Lee<sup>1</sup>, S-R. Oh<sup>2</sup>, D-Y. Yoon<sup>3</sup>; <sup>1</sup>Medical Genomics Research Center, KRIBB, Daejeon, Korea, <sup>2</sup>Immune Modulator Research Center, KRIBB, Cheongwon, Korea, <sup>3</sup>Department of Bioscience and Biotechnology, Konkuk University, Seoul, Korea*

This study was being tried to reveal the biological roles of Carabrone originated from Carpesium abrotanoides as a modulator of immune activation. To reveal the Carabrone function as NF-κB modulator, ELISA, RT-PCR, promoter analysis, Western blot and confocal were carried out. The results obtained from ELISA showed that an induced IFN $\gamma$  in the activated NK92 cells was dramatically reduced with treatment with Carabrone. And RT-PCR analysis suggested that Carabrone has effects on the modulation of transcriptional regulation for cytokine, IFN $\gamma$  expression. The promoter analysis for NF-κB also showed that Carabrone have an effect of modulation of NF-κB transcriptional activity. The intra-cellular role of Carabrone as modulator of NF-κB signal pathway was further investigated through an analysis of phosphorylated signal molecules, which showed that Carabrone was not able to affect on the modulation of

phosphorylated ERK, IKK and I $\kappa$ B degradation. And extraction of nucleus from cytosol was analyzed for the purpose of identifying NF- $\kappa$ B complex, p65 and p50 translocate cytoplasm to nuclear. This analysis suggested that Carabrone did not have an effect on the translocation of p65 from cytosol to nucleus. Therefore, Carabrone function as a modulator of NF- $\kappa$ B may be involved in interference of DNA binding to NF- $\kappa$ B transcriptional factors. As summary, results from ELISA, promoter analysis, RT-PCR and western blot analysis indicate that Carabrone might be working as a potent NF- $\kappa$ B inhibitor in the activated NK92 cells via blocking DNA binding to p65 and p50 and also could be used as a possible therapeutic material for modulating inflammation.

Keywords: Carabrone, NF- $\kappa$ B, IFN $\gamma$ , Immune modulator

**Nrf2 deficiency promotes RANKL-induced osteoclast differentiation and bone resorption.**

S. Hyeon<sup>1</sup>, H. Lee<sup>1</sup>, W. Jeong<sup>1</sup>; <sup>1</sup>Department of Life Science, Division of Life and Pharmaceutical Sciences, and Center for Cell Signaling and Drug Discovery Research, Ewha Womans University, Seoul, Korea

Nuclear factor-erythroid 2-related factor 2 (Nrf2) is a redox-sensitive transcription factor, which regulates the expression of a variety of antioxidant and detoxification genes through an antioxidant-response element. Reactive oxygen species (ROS) have known to act as a signaling mediator for osteoclast (OC) differentiation. Thus we here examined the effect of Nrf2 deficiency on OC differentiation. In Nrf2-null bone marrow derived macrophage cells, the expression of several antioxidant enzymes including peroxiredoxins I, V and VI, thioredoxin 1, thioredoxin reductase 1 and sulfiredoxin profoundly decreased, and intracellular ROS level in both basal and receptor activator of NF- $\kappa$ B ligand (RANKL)-exposed conditions was much higher compared with wild-type cells. Nrf2 deficiency augmented RANKL-induced OC differentiation, actin ring formation, and osteoclastic bone resorption. Nrf2 deficiency promoted RANKL-induced activation of mitogen-activated protein kinases including c-Jun N-terminal kinase, extracellular signal-regulated kinase and p38, and induction of c-Fos as well as consequent induction of nuclear factor of activated T cell, cytoplasmic 1 that is a pivotal determinant of OC differentiation. In addition, antioxidant N-acetylcysteine pretreatment considerably reduced the acceleration of RANKL-induced OC differentiation in Nrf2-null cells by decreasing intracellular ROS. Thus, our results suggest that Nrf2 may regulate RANKL-induced OC differentiation by modulating intracellular ROS, and provide a new strategy for treating osteoporosis and other bone diseases.

**Molecular hydrogen alters signaling pathways and gene expression profiles in multiple mouse organs.**

S. Sobue<sup>1</sup>, K. Yamai<sup>1,2</sup>, M. Ito<sup>3</sup>, K. Ohno<sup>3</sup>, M. Ito<sup>4</sup>, T. Ohkuwa<sup>2</sup>, M. Ichihara<sup>1</sup>; <sup>1</sup>Department of Biomedical Sciences, College of Life and Health Sciences, Chubu University, Kasugai, Japan, <sup>2</sup>Department of Materials Science and Engineering, Nagoya Institute of Technology Graduate School of Engineering, Nagoya, Japan, <sup>3</sup>Division of Neurogenetics, Center for Neurological Diseases and Cancer, Nagoya University Graduate School of Medicine, Nagoya, Japan, <sup>4</sup>Research Team for Mechanism of Aging, Tokyo Metropolitan Institute of Gerontology, Tokyo, Japan

Recent studies have indicated that molecular hydrogen is a promising anti-oxidative and anti-inflammatory agent for medical applications. However, the molecular mechanism for these

therapeutic effects of hydrogen is yet to be elucidated. Molecular hydrogen is administered mainly by inhalation of air containing 2–4% hydrogen gas (hydrogen-containing air, HCA) or by oral intake of hydrogen-dissolved water (hydrogen-rich water, HRW). To investigate its mechanism of action, we first examined hydrogen concentrations in blood and organs after its in vivo administration to Wistar rats, and found that oral intake of HRW rapidly but transiently increased hydrogen concentrations in the liver and atrial blood, while hydrogen concentrations in arterial blood and kidneys were only one-tenth of those in the liver and atrial blood. In contrast, we observed that inhalation of HCA increased hydrogen concentrations equally in both atrial and arterial blood. We next examined whether molecular hydrogen modifies gene expression levels in mouse livers by DNA microarray analysis to determine the biological functions of hydrogen other than scavenging hydroxyl radicals. We identified 140 mouse genes that were upregulated (31 genes) or downregulated (109 genes) by administration of hydrogen in the form of HCA and HRW. Ingenuity Pathway Analysis revealed that hydrogen influenced expression of NF- $\kappa$ B- and NFAT-regulated genes. Western blot analysis showed that hydrogen attenuated Erk, p38 MAPK, and NF- $\kappa$ B signaling in mouse livers. Finally, we evaluated whether the change in gene expression was influenced by the route of hydrogen administration, and found that both HRW and HCA had the most potent suppressive effects on signaling pathways and gene expression in systemic organs, suggesting that hydrogen may be a systemic signaling modulator that acts in a concentration-independent manner.

2315

#### **Identification of biological pathways that mediate fungal response to occidiofungin exposure.**

*D. L. Emrick<sup>1</sup>, J. Gosai<sup>1</sup>, V. Graham<sup>1</sup>, J. L. Smith<sup>2</sup>, D. M. Gordon<sup>1</sup>; <sup>1</sup>Biological Sciences, Mississippi State University, Mississippi State, MS, <sup>2</sup>Department of Biology, Texas A&M University, College Station, TX*

Azoles are the most widely used antifungal agents. However, the rise in azole-resistant fungal pathogens has increased the demand for new antifungals. A unique antifungal compound, occidiofungin, was recently identified as a non-ribosomally synthesized cyclic glycolipopeptide produced by *Burkholderia contaminans* MS14. Previous work has determined that the peptide is fungicidal and stable against environmental extremes. Although the biological target of occidiofungin is unknown, it is clear that occidiofungin does not function by binding to ergosterol, or inhibiting enzymes required for ergosterol or 1,3- $\beta$ -glucan synthesis, all common mechanisms of action for clinically available antifungals. To further compare occidiofungin with other antifungal compounds, the role of two cellular pathways previously shown to be involved in modulating antifungal activity were evaluated: the cell wall integrity pathway (CWI) and calcium signaling. We found that cells treated with subinhibitory concentrations of occidiofungin showed increased levels of chitin as measured by Calcofluor White staining. Elevated chitin suggests occidiofungin exposure results in cell wall disruption. To directly measure whether occidiofungin activates the cell wall integrity pathway, the phosphorylation status of the p44/p42 MAP kinase, Slt2p, was analyzed by Western blot analysis. In *S. cerevisiae*, *C. albicans*, and *C. glabrata*, Slt2p phosphorylation was activated in both a dose- and time-dependent manner. The importance of the CWI pathway in occidiofungin bioactivity was tested using haploid *S. cerevisiae* mutants deleted for components of the CWI pathway. For all mutants tested, occidiofungin based MIC values were similar to wild type. The addition of extracellular calcium (3mM) to standard yeast media has been shown to reduce the activity of azole compounds in a calmodulin and calcineurin dependent manner. To determine a role for calcium in occidiofungin bioactivity, MIC assays were carried out. Similar to azoles, we found that low levels of extracellular calcium resulted in a 2X decrease in occidiofungin activity, although the importance

of calmodulin and calcineurin in this response is currently unclear. Together these data suggest that while occidiofungin activates the CWI pathway in yeast, it is likely an indirect response to the antifungal. The 2-fold reduction in activity of occidiofungin is similar to the reduction observed with azoles. Further studies are needed to determine whether the classic calcium-calmodulin signaling pathway is mediating calcium resistance to occidiofungin.

## Gene Structure and Transcription

2316

### Single-molecule dynamics of transcription by human RNA Polymerase II.

A. Revyakin<sup>1</sup>, Z. Zhang<sup>1</sup>, Y. Li<sup>1</sup>, R. Coleman<sup>2</sup>, S. Chu<sup>3</sup>, R. Tjian<sup>1</sup>; <sup>1</sup>Janelia Farm Research Campus, Ashburn, VA, <sup>2</sup>Albert Einstein School of Medicine, New York, NY, <sup>3</sup>US Dept of Energy, Washington, DC

Gene expression is regulated primarily at the transcription step – the synthesis of RNA on DNA template. Transcription of messenger RNA in eukaryotes is carried out by RNA polymerase II (Pol II). The machinery involved in Pol II transcription initiation is very complex (six General Transcription Factors, several regulatory complexes, >50 polypeptides in total), and the mechanism of assembly of the Pol II transcription initiation machinery on promoters remains poorly understood. We have developed the first single-molecule system for studying the mechanism of assembly of the Pol II pre-initiation complex in a fully reconstituted in vitro system. We used this system to detect consecutive Pol II transcription initiation rounds from single DNA templates, to detect transcriptional modulation by the promoter sequence, and to detect transcriptional activation by a human activator protein. We found that consecutive rounds of transcription from the same DNA molecule were independent of each other (that is, a given DNA molecule did not have a memory of whether it has been transcribed before). This result suggests that the Pol II pre-initiation complex disassembles after each transcription round, and assembles at the promoter again for the next round to occur. We are in the process of deciphering the mechanism of assembly of the Pol II pre-initiation complex at the single-molecule level. The work required development of new imaging instruments, new surface chemistry, new RNA detection probes, and new data analysis algorithms.

### Direct quantification of mRNA production in living embryos suggests a novel mechanism for noise reduction between nuclear transcriptional activity and cytoplasmic mRNA distributions.

H. G. Garcia<sup>1</sup>, A. Lin<sup>1</sup>, M. Tikhonov<sup>1</sup>, T. Gregor<sup>1</sup>; <sup>1</sup>Physics, Princeton University, Princeton, NJ

Noise in gene expression has been shown to play an important role in various organisms. In particular, transcriptional bursts are thought to be a common mode for mRNA output. Yet, the final patterns of gene expression, especially in the case of multicellular organisms such as *Drosophila melanogaster*, are highly precise and reproducible. In order to address this apparent contradiction, we present a strategy to measure transcriptional dynamics in living fly embryos by monitoring the production of mRNA at their sites of transcription on DNA loci in real time simultaneously in hundreds of individual nuclei. In particular, we measure the transcriptional activity of the hunchback promoter as a function of the position along the embryo throughout the first three hours of development. We observe “waves” of transcription associated with the progressing mitotic cycles, where transcription rises steadily in the beginning of the nuclear

cycle, peaks mid-way through it and disappears during mitosis. Although the overall shape of these transcription waves is similar, we see a high degree of variability among nuclei. However, we see no evidence of transcriptional bursting. Single molecule mRNA FISH reveals that this variability in transcription rate does not translate into noise in the cytoplasmic mRNA distribution suggesting the need for a mechanism of noise rectification. In fact, we observe an overall 4-fold noise reduction between nuclear activity and cytoplasmic mRNA levels. Using a simple stochastic model we demonstrate that our noise measurements can only be explained through a combination of both temporal and spatial averaging.

2318

**Local and origin specific determinants modulate global DNA replication controls**C. Richardson<sup>1</sup>, J. J. Li<sup>1</sup>;<sup>1</sup>Microbiology and Immunology, University of California, San Francisco, San Francisco, CA

Replication control is fundamental to genomic stability as aberrant re-initiation from replication origins within a single cell cycle can induce high rates of segmental amplification, chromosomal aneuploidy, and possibly other genomic instabilities. Current models for how eukaryotic cells prevent such re-initiation focus on the global cell-wide inhibition of replication proteins involved in loading the Mcm2-7 replicative helicase at origins (e.g. cyclin dependent kinase, CDK, inhibition of ORC, Cdc6, Cdt1, Mcm2-7). By preventing this initial step of initiation from reoccurring once S phase begins, re-initiation can be effectively prevented. Such models, however, treat origins as generic interchangeable elements and cannot account for the diverse efficiencies with which origins re-initiate when global control mechanisms are disrupted. These varied re-initiation efficiencies also cannot be explained by the well-documented diversity in origin timing and efficiency observed during normal S phase initiation. Instead, we now have evidence of a novel mechanism that contributes to the diversity in origin re-initiation efficiency.

Disrupting the regulation of Mcm2-7 and Cdc6 in *Saccharomyces cerevisiae* results in preferential re-initiation at a select group of origins in the genome. We have identified novel genetic elements near two of these origins (ARS317 and ARS1238) that confer preferential re-initiation upon these and other origins. These elements do not confer any detectable change in the replication efficiency or timing of adjacent origins, suggesting that their regulatory effect is specific to origin re-initiation. Hence, we refer to these elements as Re-Initiation Promoters (RIPs). The two RIPs mapped are AT rich sequences 40-50bp in size and exert their effects on adjacent origins in an orientation and distance dependent manner. Analysis of Mcm2-7 association with origins suggests that RIP elements allow local escape from the residual CDK inhibition of helicase loading when global CDK inhibition of Mcm2-7 and Cdc6 is disrupted. We are currently examining whether RIP elements recruit proteins that can antagonize the inhibitory action of CDKs at adjacent origins.

Such local modulation of origin control suggests that there is a complex genomic landscape of re-replication potential, particularly when mechanisms preventing re-replication are partially or sporadically disrupted. Hence, if re-replication does contribute to genomic alterations, as has been speculated for cancer cells, some regions of the genome may be more susceptible to these alterations than others.

2319

**Genomics of Root Architecture.**

*I. D. Rueda<sup>1</sup>, M. Zavala<sup>1</sup>; <sup>1</sup>Department of Biology, California State University of Northridge, Northridge, CA*

In recent years, great strides have been made in understanding the root growth and development of *Arabidopsis Thaliana* but have been mostly focused on a physiological, proteomic or transcription factor network level. Our approach takes a look at root development through a genomic perspective utilizing the tissue specific expression of the reporter gene, Green Florescence Protein (GFP), in a subset of the mutant *Arabidopsis Thaliana* plants known as the GAL4-GFP enhancer trap lines. Given the mostly unknown genomic nature of our selected mutated plants, characterizing the tissue expression organization at the genomic level will expand established models of gene expression spatiotemporal maps and cell fate by gradients. Thermal Asymmetric Interlaced PCR is being used to recover the promoter sites of the T-DNA inserts used to create the tissue specific expression in the GAL4-GFP enhancer trap lines. Following mapping, respective GFP expressing root cell protoplasts will be harvested to examine the retention of the cell identity in relation to the location within the genome. The study looks at how the overall *Arabidopsis* genome is being orchestrated during development for the final tissue specific expression of a select number of enhancer trap lines as a model for understanding root development. (This research was funded by the NIH T34 GM 08395-22 grant.)

**Gene Gap Investigation of Chalcone Synthase in California Tarweeds and The Hawaiian Silverswords.**

*T. L. Myers<sup>1</sup>, C. Rodriguez<sup>1</sup>, V. Vandergon<sup>1</sup>; <sup>1</sup>Biology, California State University Northridge, Northridge, CA*

Complex organisms such as plants have many different metabolic pathways that influence substrate specific reactions. Changes in these lead to phenotypic differences related to speciation events. The anthocyanin biosynthetic pathway (ABP), which is a part of the Phenylpropanoid pathway, controls many internal and external mechanisms that regulate temperature, UV protection, microbial invasion, fruit, seed and flower coloring. Anthocyanin production is important to attract pollinators for the proliferation and evolution of the species. In the ABP, Chalcone synthase (CHS) is an enzyme that is responsible for catalyzing the first condensation reaction and essential for other genes further down the pathway such as, dihydroflavonol-4-reductase (DFR), which is a middle gene, and anthocyanidin synthase (ANS), which is a late gene in the pathway. The Hawaiian Silverswords are of great interest due to the fact that the species under went adaptive radiation and have large phenotypic differences but little genotypic differences from their ancestor, the California Tarweeds. In previous studies copies of CHS in *Dubautia scabra*, *Dubautia linearis*, and *Wilkesia gymnoxiphium* in the Hawaiian Silverswords as well as *Madia elegans*, *Madia gracilis*, and *Holocarpha macradenia*, which are apart of the California tarweeds, have been partially sequenced and analyzed. The gaps that remain are the focus of this study looking at sequence included in exon 1 and 2 of the CHS gene for *Wilkesia gymnoxiphium*, and *Dubautia linearis*. The current strategy will be to use polymerase chain reaction, cloning, sequencing, and further analysis of genotypic differences will be done using bioinformatics.

**Glucocorticoid reduces the gene expression of neuronal PAS domain 4 (Npas4) in the brain.**

Y. Hibi<sup>1</sup>, J. Yun<sup>1</sup>, T. Nagai<sup>1</sup>, K. Yamada<sup>1</sup>; <sup>1</sup>Hospital pharmacy, Nagoya University, Nagoya, Japan

**>Objective:** The expression levels of neuronal PAS domain 4 (NPAS4) mRNA are decreased in the hippocampus of socially-isolated or restricted mice, which is accompanied by impairments of memory and emotional behavior with a reduced hippocampal neurogenesis. The reduction of NPAS4 expression induced by psychosocial stress may play a role in mental disorders, since NPAS4 has recently been shown to regulate the development of GABAergic inhibitory neurons. In this study, to investigate the transcriptional regulation of NPAS4 expression by stress, we focused on the effect of corticosterone (CS) on NPAS4 transcription. **>Methods:** Effect of CS on Npas4 expression in restraint stressed mice was evaluated by using a glucocorticoid receptor (GR) antagonist, RU486. Npas4 expression level in the hippocampus of ICR mice were measured 2 hours after the CS (10mg/kg) injection or 1 week after the adrenalectomy. The effect of GR on the Npas4 promoter activity in Neuro2a cells was determined by a luciferase assay. Interaction of GR and Npas4 promoter was confirmed by a chromatin immunoprecipitation assay. **>Results:** Npas4 mRNA levels were reduced by restraint stress for 3 h, but pretreatment with RU486 prevented this reduction. Restraint stress for 3 h increased serum CS concentration compared with controls, while RU486 had no effect upon CS concentration. Acute CS treatment significantly decreased the expression level of Npas4 mRNA in the hippocampus of mice, while the expression level was increased by adrenalectomy. Reduced NPAS4 expression was also observed in CS-treated Neuro2a cells. Putative GREs were found at -2 kb to -1 kb upstream of the transcription initiation site of Npas4 promoter. The Npas4 promoter activity was increased by deletion of GREs rich sequence or treatment with RU486. Moreover, chromatin immunoprecipitation assay revealed the binding of ligand-bound GR to Npas4 promoter region. **>Conclusion:** These results suggest that psychosocial stress reduces the Npas4 gene expression via the binding of CS/GR complex to GREs located on the promoter region of the gene.

**TATA-Binding Protein (TBP)-Like Protein Is Required for p53-Dependent Transcriptional Activation of an Upstream Promoter of the *p21<sup>Waf1/Cip1</sup>* Gene.**

H. Suzuki<sup>1</sup>, R. Ito<sup>1</sup>, K. Ikeda<sup>1</sup>, T-A. Tamura<sup>1</sup>; <sup>1</sup>Graduate School of Science, Chiba University, Chiba, Japan

TBP-like protein (TLP) is involved in development, checkpoint, and apoptosis through potentiation of gene expression. TLP-overexpressing human cells, especially p53-containing cells, exhibited a decreased growth rate and increased proportion of G1-phase cells. TLP stimulated expression of several growth-related genes including *p21* (*p21<sup>Waf1/Cip1</sup>*). TLP-mediated activation of the *p21* upstream promoter in cells was shown by a luciferase promoter reporter assay. A point mutation at the p53-binding sequence located in the *p21* upstream promoter diminished the TLP-responsivity. In the luciferase promoter reporter assay conducted in p53-null cells, TLP could not activate *p21* promoter. These results showed that the p53-binding sequence located in the *p21* upstream promoter and p53 itself are required for TLP-mediated transcriptional activation. TLP specifically activated transcription from the endogenous upstream promoter, and p53 was required for this activation. We showed that TLP and p53 bound to each other *in vitro/in vivo*, so it is easy to imagine synergistically enhanced activity of the upstream promoter by TLP and p53. Etoposide, a representative cell stress agent, also resulted in activation of the upstream promoter as well as nuclear accumulation of TLP and p53.

Moreover, chromatin immunoprecipitation assay revealed that the upstream promoter was associated with endogenous p53 and TLP, and the p53 recruitment to p53-binding sequence was enhanced by TLP. The results of the present study suggest that TLP mediates p53-governed transcriptional activation of the *p21* upstream promoter.

2323

### **Characterization of the miR-125b1 promoter and its deregulation in breast cancer cell lines.**

*F. Cisneros<sup>1</sup>, E. Soto-Reyes<sup>2</sup>, R. González Barrios<sup>2</sup>, C. Castro<sup>1</sup>, L. Herrera Montalvo<sup>2</sup>; <sup>1</sup>UNAM, México, Mexico, <sup>2</sup>Instituto Nacional de Cancerología, México, Mexico*

In cancer cells, abnormal transcriptional gene silencing has been associated with genetic and epigenetic defects. The disruption of DNA methylation patterns and covalent histone marks has been associated with cancer development. Until recently, microRNA (miRNA) gene silencing was not well understood. In particular, miR-125b1 has been suggested to be a miRNA with tumor suppressor activity, and it has been shown to be deregulated in various human cancers. In this study, we characterized the promoter of the miR-125b1 and the epigenetic deregulation associated with its silencing.

To define miR-125b1 promoter region we analyzed in silico the locus of the gene. Then, we characterized the promoter activity by luciferase assay, cloning a fragment in the 5' extreme close to the transcriptional start site of the miR-125b1 gene. We found that the sequence in the 5' extreme close to the transcriptional start site of the miR-125b1 has promoter activity and it is unidirectional. Subsequently, we analyzed the DNA methylation in the CpG island promoter and found that in breast cancer cell lines, it is methylated compared to the same region in non-transformed breast cell line. Also, we evaluated the covalent histone modifications associated with transcriptional activation (H3K4me2) and repression (H3K9me3 and H3K27me3). In the breast cancer cell lines, there is an enrichment in the H3K9me3 compared with the non-transformed breast cell line. To determine the effect of DNA methylation at the CpG island and the covalent histone repression marks of miR-125b1 on the expression of this gene, we performed a expression assay. We observed a significant reduction on the expression of miR-125b1 in cancer cells lines suggesting that the epigenetic deregulation in the CpG island promoter might reduce miR-125b1 expression.

Our data suggest that the DNA fragment in the 5' extreme close to the transcriptional start site of the miR-125b1 gene is a functional and unidirectional promoter. Also, the CpG island in this region is aberrantly DNA methylated and it has an enrichment in the histone repression marks in breast cancer cell lines. Finally, this epigenetic changes promote the silencing of the miR-125b1 gene. Grants: PAPIIT (IN213311) and CONACYT (83959).

2324

### **DNA-protein interactions around the NPY2R -224 A/G variant in the Neuropeptide Receptor Y2 (NPY2R) Gene in Predisposition to Hypertension.**

*E. Albino-Rodríguez<sup>1</sup>, T. Katsuya<sup>2</sup>, A. Deng<sup>3</sup>, J. Dutil<sup>4</sup>; <sup>1</sup>Biochemistry Department, Ponce School of Medicine & Health Sciences, Ponce, PR, <sup>2</sup>Graduate School of Medicine, Osaka University, Osaka, Japan, <sup>3</sup>Molecular Genetics Laboratory, University of Montreal Research Center, Montreal, QC, Canada, <sup>4</sup>Biochemistry, Ponce School of Medicine & Health Sciences, Ponce, PR*

Essential hypertension (HTN) is a consequence of an interaction between environmental and genetic factors. Previous work in animal models and human populations identified Neuropeptide Y receptor 2 (NPY2R) as a candidate gene for HTN. In two independent Japanese populations, the GG genotype single nucleotide polymorphism (SNP) located 224 bp upstream of the transcription start site was associated with an increased risk of HTN. The aim of this study was

to assess the DNA-nuclear protein interactions surrounding the NPY2R -224 A/G SNP. Human Embryonic Kidney (HEK) 293 cells were transfected with pGL4.10 DNA constructs containing the promoter of NPY2R with either an A or G nucleotide at the -224 position upstream of the luciferase reporter gene. Two versions of double stranded oligonucleotide probes corresponding to the sequence flanking NPY2R -224 A/G were synthesized and incubated with several amounts of nuclear protein fractions for an electrophoretic shift assay (EMSA). The DNA/protein reactions were loaded on a 5% non-denaturing polyacrylamide gel. Interestingly, the luciferase activity induced by the NPY2R promoter with the G allele in position -224 was reduced by 34% compared to the promoter containing an A in that position. Differences in the level of relative Luciferase activity between A and G constructs were statistically significant ( $p < 0.01$ ). The EMSA showed an allele-specific binding with the oligonucleotide containing an A in -224 position. The data provide strong evidence for a functional role of NPY2R in genetic predisposition to HTN.

2325

**Synergy Between Chromatin Remodeling complexes (SWI/SNF) and Splicing.**

S. K. Pradhan<sup>1</sup>, M. A. Hossain<sup>1</sup>, T. L. Johnson<sup>1</sup>; <sup>1</sup>Division of Biological Sciences, University of California, San Diego, La Jolla, CA

Pre-messenger RNA splicing plays a critical role in gene expression. In spite of the considerable progress that has been made in understanding the mechanism of splicing, an important question that remains far less well understood is how splicing is coordinated with RNA synthesis and, more specifically, how changes in the chromatin template affect splicing. Recent studies in mammals show that nucleosome occupancy and specific histone modifications are enriched in the exonic regions of genes, which raise the possibility that specific histone marks may be associated with splicing signals. For example, proteins that bind to methylated histones, facilitate the recruitment of snRNPs to nascent transcript and influence the efficiency of splicing. Recently we have shown that GCN5-dependent histone acetylation is critical for cotranscriptional spliceosome assembly and spliceosomal rearrangements. To gain further mechanistic insights into this observation, we have explored the possibility of “communication” between the chromatin remodeling machinery that interact with acetylated histones and the splicing machinery using both genetic and biochemical approaches. One such chromatin remodeling complex is SWI/SNF complex, which binds to the acetylated histones. Further, previous studies show that SWI/SNF regulates alternative splicing in human. In order to understand the role of SWI/SNF complex in splicing we performed an in vivo copper sensitive splicing assay using ACT1-CUP1 reporter constructs. Interestingly, the assay reveals that deletion of SNF2, the ATPase component of SWI/SNF complex, significantly suppress the growth defects of the 3' splice site mutants. Consistent with the growth assay, the primer extension of ACT1-CUP1 constructs also indicate the improved splicing in SNF2 deleted cells as compared to WT. Furthermore, in vivo interaction studies demonstrate physical interactions between the SWI/SNF complex and the snRNP components. Together, these studies suggest a synergistic relationship between the SWI/SNF complex and the splicing machinery in gene expression.

**Digitor, an Essential Protein with Homology to Mammalian ATMIN, is Involved in Brain Development and Oxidative Stress Pathways in *Drosophila*.**

S. Sengupta<sup>1</sup>, C. Yao<sup>1</sup>, U. Rath<sup>1</sup>, J. Gorton<sup>1</sup>, J. Johansen<sup>1</sup>, K. M. Johansen<sup>1</sup>; <sup>1</sup>Roy J. Carver  
 Department of Biochemistry, Biophysics & Molecular Biology, Iowa State University, Ames, IA

In *Drosophila* we have used yeast two-hybrid interaction assays to identify Digitor (CG14962) a zinc-finger protein with six TQT motifs that interacts with the carboxy-terminus of Skeletor. Skeletor localizes to interband regions of polytene chromosomes during interphase and transient expression studies of GFP-tagged Digitor suggested a nuclear localization for Digitor as well. Furthermore, pulldown assays confirmed a physical interaction with Skeletor as well as with Cut-up, a Dynein light chain protein of 8 kDa. Multiple sequence alignments indicated that Digitor may be the *Drosophila* homolog of the ATM-kinase interacting protein ATMIN, sharing the zinc-finger and SQ/TQ motifs that are hallmarks of DNA damage response proteins. In order to initiate functional studies of Digitor we identified a P-element insertion that based on RT-PCR analysis is a likely null allele. Homozygous mutants for Digitor give rise to late pupal lethality with no escapers. Interestingly, while the size of Digitor mutant larvae are indistinguishable from wild-type larvae their brain size is specifically affected, being significantly smaller. By TUNEL assays we show that this small brain phenotype is associated with increased apoptosis. Furthermore, heterozygous mutant flies have increased susceptibility to acute exposure to paraquat implicating Digitor in signaling pathways combating acute oxidative stress. Supported by NIH grant GM62916 and NSF grant MCB0817107.

**Elucidating the Transcription Networks in the *Drosophila melanogaster* Salivary Gland.**

C. B. Smith<sup>1</sup>, D. Johnson<sup>2</sup>, D. Andrew<sup>2</sup>; <sup>1</sup>Biology, North Carolina A&T State University, Greensboro, NC, <sup>2</sup>Cell Biology, Johns Hopkins University, Baltimore, MD

Various transcription factors contribute to the development of the *Drosophila* salivary gland. To fully understand the formation of this organ, we must know the role of these transcription factors, identify their downstream targets, and learn if target gene regulation is direct. This study focuses on five transcription factors: CrebA, Fork head (Fkh), Hucklebein (Hkb), Senseless (Sens), and Sage, and the identification of all genomic targets to which they bind in the salivary gland of *Drosophila melanogaster*. The transcription factors listed are particularly important due to their functions in the salivary gland, and the finding that, if mutated, significant defects occur. Although previous studies have revealed important functions for these proteins, little is known regarding the genes they bind and regulate within a given tissue. We plan to use "ChIP-Seq" with green fluorescent protein (GFP) tagged versions of each transcription factor to find everything each protein binds to in the genome of the salivary gland. Our goal was to build constructs for expressing GFP-tagged versions of each protein in the fly salivary gland. PCR amplification products of the open reading frame of each protein were first subcloned into the TOPO entry vector and then into a Gateway UAS-GFP fly expression vector. The Gateway constructs were then to be injected into the germ cells of the *Drosophila* embryos to establish lines that will be used for salivary gland-specific expression of each tagged protein. Each transcription factor is at a different stage in this process. CrebA, Fkh, and Hkb open reading frames (ORF) have been PCR amplified. Sens has undergone TOPO cloning and Sage has been injected into embryos and we are in the process of generating and establishing Sage-GFP transgenic lines. Once we have established lines for expressing each of these proteins, we will work with the *Drosophila* ModEncode project to do the ChIP-Seq. Once the binding sites are

identified, we will have genome-wide view of which genes each of these transcription factors regulate.

2328

**Analysis of extra-transcriptional functions of RNA polymerase III bound sites in *Saccharomyces cerevisiae*.**

A. Korde<sup>1</sup>, J. M. Rosselot<sup>1</sup>, D. Donze<sup>1</sup>; <sup>1</sup>Biological Sciences, Louisiana State University, Baton Rouge, LA

RNA polymerase III (Pol III) is primarily responsible for the transcription of transfer RNA (tRNA), 5S ribosomal RNA and several other non-coding RNA molecules. Moreover, Pol III transcription complex (TFIIIC, TFIIIB and Pol III) assembled on eukaryotic chromosomes can exert extra-transcriptional effects on chromosome function. Previous findings point out that bound Pol III complexes or even partial complexes can exert significant effects on expression levels of neighboring genes. These bound complexes can also influence other chromosomal processes like directing integration of Ty elements, acting as pause sites for replication fork progression, overriding of nucleosome positioning sequences, transcriptional repression of neighboring RNA Polymerase II (Pol II) genes and conversely the protection of neighboring pol II genes from repressive chromatin spreading. Transfer RNA genes (tDNAs) have also been shown to act as insulator-like enhancer blockers in yeast.

In *Saccharomyces cerevisiae*, a tDNA [*tV(UAC)*] lies between divergently transcribed *CIS1* and *SES1* genes. Microarray analyses indicated that *SES1* is transcribed at ~70-fold higher levels than *CIS1* under normal growth conditions. We speculated that tDNA [*tV(UAC)D*] acts as an insulator that prevents inappropriate activation of *CIS1* promoter by regulatory elements responsible for high transcription of *SES1*. In addition to increased *CIS1* transcript levels, we observed that deletion of this tDNA resulted in an extended *CIS1* transcript. Further investigation of the extended transcript illuminated that this longer transcript is due to readthrough from an untranslated transcript *SUT467* originating near the *SES1* upstream activating sequence (UAS). It appears that *tV(UAC)D* blocks the progression of this intergenic transcript, to allow the normal *CIS1* promoter to escape transcriptional interference. This suggests a unique barrier function of *tV(UAC)D* that prevents advancement of Pol II.

Previous studies on tDNA heterochromatin barrier function identified that in addition to the Pol III complex genes *TFC3* and *BRF1*, the chromatin proteins Nhp6, Htz1, Bdf1, Rpd3, the chromosome assembly proteins condensin and cohesin, and genes coding for components of Sas, Rsc and Isw remodeling complexes also participate in heterochromatin barrier activity. Likewise, our Northern analysis on individually mutated yeast strains in *TFC3*, *BRF1*, *NHP6*, and *SAS2* showed the longer *CIS1* transcript. Whereas, mutation in *HTZ1*, *BDF1*, *RPD3*, *RSC* and *ISW2* failed to show the extended transcript. Subtle appearance of this longer transcript was observed in condensin and cohesin mutants.

Our results indicate that bound Pol III (partial or complete) complexes along with other chromatin proteins at the tDNA can also function as barriers to Pol II progression, which could be important in protecting gene promoters from deleterious effects due to cryptic intergenic transcription.

**Intricate regulation of Gcr1 expression drives metabolic flux in response to glucose starvation in *S. cerevisiae*.***J. M. Claggett<sup>1</sup>, M. A. Hossain<sup>1</sup>, T. L. Johnson<sup>1</sup>; <sup>1</sup>Division of Biological Sciences, Molecular Biology Section, University of California, San Diego, La Jolla, CA*

In a dynamic environment, cells must undergo precise metabolic changes that are determined by a series of tightly regulated gene expression reactions. Since the transcription factor Gcr1 is extensively involved in the expression of cyclins, ribosomal protein genes, and glycolytic genes, we hypothesized that regulation of Gcr1 might play a critical role in determining the metabolic changes required for the cellular response to glucose starvation. Here we show that total Gcr1 levels are regulated in a manner that is glucose-dependent and that contributes to metabolic flux. Unexpectedly, we also discovered that *GCR1* generates multiple protein isoforms when cells are grown in a glucose-rich environment and that the expression of each isoform is minimally dependent on regulation at the level of transcription, splicing and decay. Remarkably, exclusive expression of each isoform causes overlapping and distinct effects on genome-wide RNA expression by RNA-seq analyses suggesting that changing the ratio of Gcr1 isoforms provides a means by which the cell can elicit highly specific changes in gene expression. Since we find that the Gcr1 isoforms are differentially regulated in response to glucose depletion, our data support a model whereby the cell alters the Gcr1 isoform ratio to enable gradual metabolic adjustment when exposed to a fluctuating glucose environment.

**Regulation of VWF expression in response to hypoxia.***A. Mojiri<sup>1</sup>, M. Nakhaii-Nejad<sup>1</sup>, S. Kulak<sup>1</sup>, W. Phan<sup>1</sup>, E. Michelakis<sup>1</sup>, N. Jahroudi<sup>1</sup>; <sup>1</sup>Medicine, University of Alberta, Edmonton, AB, Canada*

Background: Von Willebrand factor (VWF) is a procoagulant molecule, exclusively expressed in endothelial cells and megakaryocytes. In lung VWF expression is primarily restricted to larger vessels with low or non-detectable levels in capillaries. In response to injury, such as pulmonary hypertension (PH), elevated levels of VWF in lung are detected while the mechanism is not known. VWF transcription is regulated by a complex mechanism including distinct regions that are necessary for VWF promoter activation in brain and lung. Transacting factors YY1 and NF-IB, functioning as activator and repressor respectively, participate in lung specific expression of the VWF gene. We investigated the mechanism of VWF activation in response to lung injury using a hypoxia induced model of pulmonary hypertension in mice.

Method: Transgenic mice expressing LacZ transgene under the regulation of brain-lung specific VWF regulatory sequences were exposed to hypoxia and levels, as well as expression patterns of endogenous VWF and LacZ transgene were determined using RT-PCR and immunofluorescent microscopy analyses. Additionally cultured lung microvascular endothelial cells were exposed to hypoxia and levels of VWF transcript, transacting factors NF-IB and YY1 levels, as well as their nuclear distribution and chromatin binding were determined. YY1 inhibition through siRNA transfection was used to determine its role on VWF expression in response to hypoxia. Furthermore, platelet activity was measured under shear stress in both control and hypoxia exposed cells.

Results: VWF and LacZ transgene expression in hypoxia treated mice were significantly upregulated and specifically there was de novo activation of VWF transcription in lung microvascular endothelial cells. Hypoxia-induced increase in VWF transcription was

concomitant with decreased NF-IB and increased YY1 interaction with their respective binding regions on the VWF regulatory sequences. Additionally, increased nuclear localization of YY1 in hypoxia exposed endothelial cells in vivo as well as in vitro was demonstrated. Increased levels of VWF were accompanied with a significant increase in platelet binding as was shown in real time experiment. Inhibition of YY1 expression has abolished hypoxia-induced increase of VWF.

Conclusion: Hypoxia results in upregulation and specifically microvascular directed de novo activation of VWF transcription in lung endothelial cells leading to increased platelet binding. This process is associated with modulation of functions of specific transacting factors namely NF-IB and YY1 that participate in VWF transcription regulation in lung.

**Efficient chromosomal integration in avian cells by a transposon-based approach, in which helper-independent *piggyBac* plasmid was transfected by lipofection, electroporation, sonoporation, and a combination of electroporation and sonoporation.**

K. Shinozuka<sup>1</sup>, Y. Kase<sup>1</sup>, S. Baba<sup>1</sup>, A. Inoue<sup>1</sup>, S. Moisyad<sup>2</sup>, K. Maruyama<sup>1</sup>; <sup>1</sup>Meiji University, Kawasaki, Japan, <sup>2</sup>Anatomy, Biochemistry, and Physiology, John A. Burns School of Medicine, University of Hawaii, Honolulu, HI

The chromosomal integration of genes in avian cells by a transposon vector was evaluated. The *piggyBac* transposase was obtained from the moth *Trichoplusia ni*. Helper-independent *piggyBac* plasmid containing EGFP nucleotide sequence, *pmhyGENIE-3* was used to determine the efficiency in QT6 cells, a quail fibroblast cell line. As a reference, a plasmid containing EGFP nucleotide sequence, *pCX* was used.

The QT6 cells were cultured in DMEM/F12 and approximately  $3.5 \times 10^5$  cells in a culture dish with a 35-mm diameter were transfected with *pmhyGENIE-3* using four different transfection techniques: lipofection, electroporation, sonoporation, and a combination of electroporation and sonoporation. The number of replicates was six for the experiment. At 2 days and 14 days after transfection, cells were fixed in 10% formalin and nuclei were stained with Hoechst33342. The number of cells emitting EGFP green fluorescence and the number of cells emitting Hoechst33342 blue fluorescence were determined to calculate the relative transfection efficiency. From the relative transfection efficiencies at Day 2 and at Day 14, the efficiency of chromosomal integration was calculated.

With *pmhyGENIE-3*, the relative transfection efficiency by lipofection was 6.3% at Day 2 and 4.0% at Day 14 to yield the integration efficiency of 63.4%. With *pCX*, it was 19.3% at Day 2 and 0.5% at Day 14 to yield the integration efficiency of 2.7%. Overall, the integration efficiency by *piggyBac* transposon ranged from 63.4% by lipofection to 48.9% by the combination of electroporation and sonoporation with the average of 54.9%. However, no statistically significant difference was observed among four transfection techniques.

2332

**Position-specific impact of small RNAs on alternative pre-mRNA splicing.**

N. N. Singh<sup>1</sup>, M. Lawler<sup>1</sup>, D. Upreti<sup>1</sup>, J. Kaczynski<sup>1</sup>, J. Seo<sup>1</sup>, E. W. Ottesen<sup>1</sup>, R. N. Singh<sup>1</sup>; <sup>1</sup>Department of Biomedical Sciences, Iowa State University, Ames, IA

Modulation of aberrant pre-mRNA splicing using antisense oligonucleotides (ASOs) is a fast developing technology with a tremendous therapeutic potential. In addition, an ASO-based approach could be employed to define "splicing cis-regulators" that are otherwise difficult to uncover using conventional methods. Employing ASO-based approaches, we have reported position-specific role of intronic residues downstream of the 5' splice site of *SMN2* exon 7,

skipping of which is associated with spinal muscular atrophy (SMA), one of the leading genetic causes of infant mortality. Our study revealed intronic splicing silencer N1 (ISS-N1) and an overlapping GC-rich sequence as the possible therapeutic targets for splicing correction in SMA. ISS-N1 and GC-rich sequences occupy 10<sup>th</sup>-24<sup>th</sup> and 8<sup>th</sup>-15<sup>th</sup> positions of *SMN2* intron 7, respectively. Our finding that an 8-mer ASO targeting GC-rich sequence is able to fully correct aberrant splicing in SMA represents the first such report of therapeutic efficacy of a short ASO. Our subsequent study revealed that an unpaired cytosine residue at the 10<sup>th</sup> intronic position (<sup>10</sup>C) serves as a negative regulator of splicing in the context of the structural changes brought about by an ASO targeting immediately downstream sequences. Our results underscore the utility of an ASO-based approach as an immensely powerful tool to capture unique long-distance interactions that play critical role during dynamic process of pre-mRNA splicing.

**An embryonic stem cell factor essential for maintenance of self-renewal regulates PRC2 target genes.**

*H-J. Han<sup>1</sup>, F. Yang<sup>2</sup>, D. G. Camp<sup>2</sup>, R. D. Smith<sup>2</sup>, T. Kohwi-Shigematsu<sup>1</sup>; <sup>1</sup>Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, <sup>2</sup>Biological Sciences Division, Pacific Northwest National Laboratory, Richland, WA*

Mammalian genomic DNA is functionally packaged in the nucleus so that a large number of genes are dynamically regulated in a temporal and cell type-specific manner. How this is accomplished is a fundamentally important question that has wide implications in biology from stem cell function to disease. We focused on specialized genomic sequences characterized by a high propensity to become unpaired, termed base-unpairing regions (BURs). BURs can be found throughout the mammalian genome. SATB1 was previously identified as a protein which binds specifically to BURs. SATB1 functions as a genome organizer by regulating three-dimensional folding of chromatin through binding BURs, recruiting chromatin remodeling and transcriptional factors to its target genes, and establishing region-specific epigenetic modifications. Through such function, SATB1 is capable of reprogramming the expression profiles of genes. We searched for other BUR-binding proteins in mouse embryonic stem cell (ESC) using BUR affinity chromatography and protein mass spectrometry. Our study led to identification of a number of nuclear proteins that bind to BURs in the ESC genome, one of which associates with Suz12, a component of the Polycomb repressive complex 2 (PRC2). This factor is located adjacent to heterochromatin and regulates gene expression to prevent ESC differentiation. When expression of this particular protein was knocked down, ESC spontaneously differentiated, activating genes that are normally repressed by the PRC2 complex. Chromatin immunoprecipitation followed by quantitative PCR and deep sequencing showed that the genomic occupancy of Suz12 was greatly reduced at the target gene loci when this protein was knocked down. These studies suggest an important mechanism, at the level of higher-order chromatin architecture, which is crucial for the maintenance of ESC self-renewal and pluripotency.

**Enhancers of transcription active in mouse embryonic stem cells.**

*J. A. Mitchell<sup>1</sup>, H. Zhou<sup>1</sup>, M. Schwartz<sup>1</sup>, F. Collura<sup>1</sup>, S. Davidson<sup>1</sup>; <sup>1</sup>Cell and Systems Biology, University of Toronto, Toronto, ON, Canada*

Identifying regulatory regions that regulate cell-type specific and developmentally regulated gene expression programs in mammalian genomes remains a challenge as these regions can be located at great distances from the genes they regulate. Understanding how these regulatory regions function in regulating specific genes is critical in understanding how the

genome directs the process of cellular differentiation and cell fate restriction that occurs during development. We identified enhancer regions and used chromosome conformation capture (3C) data to investigate which genes these enhancers regulate. Initially we used ChIP-Seq and genomic feature data from mouse embryonic stem (mES) cells to predict enhancers active in this cell type. Using features that were most predictive of enhancers (EP300, H3K4me1, MED12, NIPBL) We identified 1277 high probability enhancer regions ( $\geq 0.8$ ) in the mouse genome that are linked with increased transcriptional output of surrounding genes in mES cells (Chen et al. 2012). Interestingly some of these enhancer regions are clustered in the genome at enhancer hubs similar to the well characterized  $\beta$ -globin locus control region. While increased sequence conservation compared to promoter regions was not predictive of individual enhancers the enhancer hubs show conservation of sequence and epigenetic features marking the human genome in hES cells. Furthermore, these epigenetic features are specific to undifferentiated ES cells and lost upon differentiation. In addition, investigation of HiC data, which identifies chromatin-chromatin interactions genome wide, revealed that enhancer clusters contact transcribed genes within about 250 kb of surrounding chromatin with some examples of contact extending beyond this local region. Further investigation using 3C into an enhancer hub 70-100 kb downstream of *Sox2*, a transcription factor critical for pluripotency maintenance in ES cells, revealed that this cluster region contacts the *Sox2* promoter in mES cells but not in fibroblast cells that do not express *Sox2*. Taken together these data suggest a critical role for this distal enhancer hub downstream of *Sox2* in maintaining the increased expression of *Sox2* in ES cells. Furthermore, enhancer hubs throughout the genome, which are bound by several transcription factors critical in maintaining pluripotency (OCT4, SOX2, NANOG, KLF4), likely have a central role in regulating the gene expression program in ES cells.

#### **Covalent and non-covalent SUMO interactions regulate Maf1 function.**

A. Rohira<sup>1</sup>, J. Allen<sup>1</sup>, D. Johnson<sup>1</sup>; <sup>1</sup>*Department of Biochemistry and Molecular Biology and the Norris Comprehensive Cancer Center, Keck School of Medicine, University of Southern California, Los Angeles, CA*

Maf1 is a novel transcription repressor that directly represses the transcription of RNA polymerase (pol) III- and select RNA pol II-dependent promoters. Importantly, Maf1 negatively regulates the expression of genes that promote oncogenic transformation and increased Maf1 expression inhibits anchorage independent growth. Recent studies have identified the PI3 kinase signaling pathway as a negative regulator of Maf1. Our current studies have identified an important new role for sumoylation in mediating the ability of Maf1 to repress RNA pol III-dependent transcription. As increased expression of either SUMO1 or SUMO2 repressed the expression of tRNA and 7SL RNA genes, we further examined whether Maf1 might be regulated by sumoylation. We find that Maf1 is covalently modified by both SUMO1 and SUMO2. Mutation of each of the eleven lysine residues to arginine revealed that K35 is the major site of sumoylation on Maf1. Compared to Maf1 wild type (WT), Maf1K35R is impaired in its ability to repress RNA pol III-dependent transcription and to suppress colony growth. While sumoylation does not alter Maf1 subcellular localization, Maf1K35R is defective in its ability to associate with RNA Pol III. This impairs the recruitment of Maf1 to promoters in vivo and the subsequent dissociation of RNA pol III. In addition to its covalent interaction with Maf1, SUMO1 and SUMO2 non-covalently associate with Maf1. However, covalent modification of Maf1 at K35 is not required for non-covalent SUMO interactions. Further mutational analysis identified S123 as a critical residue that controls non-covalent interactions of Maf1 with SUMO. Compared with Maf1WT, Maf1S123A displays an enhanced ability to interact with SUMO, and to repress transcription and colony growth. In contrast to Maf1S123A, Maf1S123D exhibits functions that

are comparable to that observed with Maf1WT. Furthermore, Maf1S123A displays an increase in its association with RNA pol III that is dependent upon enhanced SUMO expression. Together, our results demonstrate that both covalent and non-covalent interactions of SUMO with Maf1 positively regulate its interaction with RNA pol III and its ability to repress RNA pol III-dependent transcription and cell growth. Given that emerging evidence is revealing that desumoylases are aberrantly up-regulated in cancer, it is likely that the deregulation and desumoylation of Maf1 plays an important role in oncogenic transformation.

### **Brain isoform of Glycogen Phosphorylase being a marker of undifferentiated hepatic progenitor cells and affecting progenitor cell differentiation.**

*Y-W. Huang<sup>1,2</sup>, H-S. Lee<sup>1,3</sup>; <sup>1</sup>Institute of Biotechnology, National Taiwan University, Taipei, Taiwan, <sup>2</sup>Taiwan Food and Drug Administration, Department of Health, Taipei, Taiwan, <sup>3</sup>Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan*

The liver progenitor cell (Lig-8 cell line)-derived monoclonal antibody has been proved specifically responding to liver progenitor cells. We used the monoclonal antibody to immunoprecipitate its target protein and we identified the brain isoform glycogen phosphorylase (GPBB) through liquid chromatography combined tandem mass spectrometry (LC-MS/MS) analysis. GPBB is known as the first present isozyme of glycogen phosphorylase during fetal development. In adult rat liver, liver isozyme of glycogen phosphorylase is the major predominant isotype, which catalyzes glycogen degradation. GPBB has never been detected in adult rat liver. In this study, our results demonstrate GPBB exists in identified liver progenitor cells, both Lig-8 and well known WB-F344 cell lines at RNA and protein level but both liver progenitor cell lines do not express liver form or muscle form of glycogen phosphorylase. More interestingly, expression of GPBB in liver progenitor cells declined as the cells were induced differentiation by sodium butyrate induction. When the GPBB gene of WB-F344 cells is silenced by short hairpin RNA (shRNA) interferences, the mature biliary epithelial marker CK19 decreases about 40% during sodium butyrate-induction model. We suspect that GPBB can not only be a novel marker of undifferentiated hepatic progenitor cells but also affect liver progenitor cells differentiation, which possibly provides energy to support hepatic progenitor cells differentiation to biliary cells. Furthermore GPBB facilitates identifying human liver stem cells.

### **Cellular Stress and Protein Folding in Vascular Epigenetics: Chance and Necessity [Algorithms] in Adaption and Disease Reactions.**

*J. H. Wissler<sup>1</sup>; <sup>1</sup>Arcons Institute for Applied Research & Didactics, Postfach 1327, D-61231 Bad Nauheim, Germany*

**Objective:** From same genotype, different vascular phenotypes result by coded genetic [Mendelian] and epigenetic [non-Mendelian] reactions: Normal hierarchically organized, functionally efficient and abnormal, inefficient, leaky, mess-chaotic [tumor] blood and lymphatic vessel patterns may be formed by [hem-]angiogenesis, arteriogenesis and lymphangiogenesis. The folding of vascular epigenetic regulator proteins was investigated for regulatory principles on interaction with nascently transcribed RNA from cells subject to environmental chemical [metabolic, immunological] and physical [shear] stress chance [stochastic] and coded necessity [algorithm] reactions. **Methods:** Ann. N. Y. Acad. Sci. **1022:** 163-184, 2004; **1137:** 316-342,

2008; Biophys. J. **102** [3], 639a[3245], 2012. **Results:** In reticuloendothelial cells, environmental chance reactions induce proteins and regulatory RNAs [ $<200n$ ] of defined sequences, like angiomorphogens [angiotropins]. These are RNPs formed by folding of a Mendelian-coded protein [S100-A12] upon interaction with non-Mendelian functional non-coding RNA bioaptamers and metal [Ca, Cu, Na, K] ions. A metal ion-structured  $5'CUG^3$ -hairpin loop of RNA fits to a folded protein groove. Modified nucleosides essential for interaction are e.g. isoguanosine / crotonoside, adenosine-N1-oxide of 151Da base families. Biosynthetically, these result from Fenton-type redox-OH<sup>\*</sup>-radical RNA modification induced by environmental chance factors [stress, hypoxia, metal ions, nutrition reductones/vitamins]. These intimately participate in coded processes resulting defined novel sequences: The non-Mendelian RNA are genomic DNA derivatives, but not anymore base-complementary and, therefore, not to retranslate completely to genomic sequences. Chemically, by a general search, a novel common structural relation could be disclosed for factors involved in angio-, arterio- and lymphangiogenesis. It suggested that RNA regulate phenotypic adaptation to environmental needs by complementary interaction with defined conserved homologous helix-nucleating Mendelian consensus domains shared in vascular epigenetic regulator proteins.

**Conclusions:** The results suggest epigenetic phenotyping being not just only stochastic [chance] and heuristic [trial/error] regulatory processes. But coded [algorithmic] necessity pathways include sequences of finite instructions in which probabilistic randomness may be incorporated by chance and heuristic reactions. Different associated intrinsic and extrinsic interactive complementary biomolecular imprints and factors are implied: **[1]** Non-Mendelian nucleic acid 3D-episcritps in helix-nucleating complementary interaction with **[2]:** Conserved Mendelian homologous domains in epigenetic regulator protein and other matrices which are genotype-derived, **comprising** variant, mutational, infectious [viral] and heritable disease implications. **[3]** Extrinsic and intrinsic factors upon which formation of [1] and interaction of [1] with [2] depends [e.g. splicing, redox- and metalloregulation]. Thus, epigenetic codes comprise more complexity, diversity and plasticity repertoires than genetic codes.

2338

#### Potential Contribution of SRY in Sexual Dimorphisms in Neurodevelopment.

Z. Sun<sup>1</sup>, Y. Li<sup>1</sup>, N. Pilon<sup>2</sup>, D. Silversides<sup>3</sup>, C. Lau<sup>1</sup>; <sup>1</sup>VA Medical center, UCSF, San Francisco, CA, <sup>2</sup>UQAM, Montreal, Canada, <sup>3</sup>university of Montreal, Montreal, Canada

Genes on the Y chromosome are usually expressed in the testis and are tightly regulated during embryonic development and adult. Since the Y chromosome is present only in males, ectopic expression of Y-encoded genes could have significant male-specific effects on the affected tissues, thereby resulting in sexual dimorphisms in the development, physiology and diseases. The Y-encoded SRY is the founder of a family of transcription factors; called SRY-box (SOX) proteins harboring a conserved HMG box capable of binding to similar consensus sequences. SRY and SOX proteins are cell-fate determinants, involved in the development of numerous organs and tissues. The HMG boxes of SRY and SOX proteins are functionally interchangeable, but could differ in their gene regulation functions. SRY could be abnormally expressed in various non-gonadal tissues, thereby exerting a male-specific effect(s) on the development of the affected tissues. To address the issue on where and when SRY could be ectopically expressed, we have examined two transgenic mouse lines harboring an YFP reporter gene directed by the promoter of either the pig or human SRY promoter. We have focused our study on embryonic day 9.5 (e9.5) and embryonic day 11.5 (e11.5). Immunofluorescence and confocal microscopy analysis showed that the YFP transgene was primarily expressed in the developing neural tube, neural crest cells, dorsal root ganglia, neocortex, and enteric ganglia. Parallel analyses of various neural crest and neural markers, such as SOX9, SOX10, NeuN and p75, showed that the SRY promoters were capable of directing the expression of the YFP

transgene in cells expressing these same markers at these two developmental stages. In particular, SRY and SOX9/SOX10 harbor the highly conserved HMG box, the co-expression of SRY in the same cells as SOX9 and SOX10 raises the possibility that SRY could competitively bind to the same target genes for SOX9/SOX10 in the neural cells, thereby altering their gene regulatory programs and exerting a male-specific effect(s) on the neural development. Our results suggest that if ectopically expressed, SRY could be a male-specific genetic modifier and induce sexual dimorphisms in neural development and associated disorders.

2339

**Nov/CCN3 is a novel prostaglandin E<sub>2</sub>-induced secreted protein of the ductus arteriosus.**

I. Kenji<sup>1</sup>, K. Nagasawa<sup>2</sup>, T. Kato<sup>2</sup>, S. Minamisawa<sup>1,3</sup>; <sup>1</sup>Department of Life Science and Medical Bioscience, Waseda University, Tokyo, Japan, <sup>2</sup>Graduate School of Science and Engineering, Bioscience and Biomedical Engineering, Waseda University, Tokyo, Japan, <sup>3</sup>Cell Physiology Research Institute, The Jikei University School of Medicine, Tokyo, Japan

**[Objective]** The ductus arteriosus (DA) is a fetal shunt that connects the pulmonary trunk and the descending aorta, and it closes immediately after birth. Not only functional closure (vascular contraction), but also anatomical closure (vascular remodeling such as neointima formation) is essential for permanent DA closure. Our previous study has demonstrated that prostaglandin E<sub>2</sub> (PGE<sub>2</sub>)-EP4 signaling plays a critical role in neointima formation of DA closure by promoting migration of smooth muscle cells via secretion of hyaluronan. We aspired to comprehensively identify other secreted proteins of the DA induced by PGE<sub>2</sub>. **[Methods and results]** In order to comprehensively detect secreted proteins, we performed liquid chromatography mass spectrometry (LC/MS/MS) analysis for the supernatant of cultured rat DA smooth muscle cells (DASMCs) stimulated with PGE<sub>2</sub>. LC/MS/MS analysis revealed that the amount of four proteins, Nov/CCN3, biglycan, fibronectin, and follistatin-like 1 was increased when compared with the control supernatant. In order to confirm the result of LC/MS/MS analysis, enzyme linked immunosorbent assay (ELISA) revealed that concentration of Nov/CCN3 was increased in the supernatant of DASMCs stimulated with PGE<sub>2</sub> in a dose-dependent manner. Quantitative RT-PCR (qRT-PCR) analysis revealed that the expression levels of Nov/CCN3 mRNA were increased in DASMCs stimulated with PGE<sub>2</sub> and an EP4 agonist and that the expression levels of Nov/CCN3 mRNA were the highest in the rat DA tissue at embryonic day 21<sup>st</sup> among the samples from fetuses at embryonic day 19<sup>th</sup> and 21<sup>st</sup>, and neonates just after birth. Furthermore, we found that Nov/CCN3 significantly inhibited PGE<sub>2</sub>-induced neointima formation in the ex vivo DA tissues. We also revealed that the amount of hyaluronan was significantly decreased in the supernatant of DASMCs by Nov/CCN3 stimulation. **[Conclusions]** Nov/CCN3 was detected as a novel secreted protein of the DA induced by PGE<sub>2</sub>, and suppressed neointima formation of the DA at least in part via inhibiting hyaluronan production.

2340

**Basal cell protrusive activity is a primary determinant of planar cell polarity in the *Drosophila* egg chamber.**

M. Cetera<sup>1</sup>, L. Lewellyn<sup>1</sup>, M. J. Fairchild<sup>2</sup>, G. Tanentzapf<sup>2</sup>, S. Horne-Badovinac<sup>1</sup>; <sup>1</sup>Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, <sup>2</sup>Department of Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada

Coordinated cell behaviors are critical to form complex structures in a developing organism. We are using the *Drosophila* egg chamber as a highly tractable model for the study of morphogenetic mechanisms. The egg chamber is composed of germ cells encapsulated by an epithelial layer of follicle cells (FCs). The initially spherical egg chamber elongates along its anterior-posterior (AP) axis to form an elliptical egg. This morphogenesis requires an unusual

form of planar polarity at the basal FC surface in which cortical actin filaments, filopodial protrusions and fibril-like structures in the ECM all align perpendicular to the elongating axis. These structures are then thought to serve as a molecular corset to restrict growth to the AP axis. Recent work has shown that, during this same period, the FCs also undergo a dramatic form of collective cell migration, which causes the entire egg chamber to rotate within the ECM. We hypothesize that this global migration is possible because each FC actively migrates and contributes equally to net forward movement. Factors that provide the motile force for migration would thus be planar polarized at the basal epithelial surface, such that they are enriched at the leading edge of each migrating FC. We have found that the filopodia mark the front of the migrating FCs and their formation is dependent on Ena/VASP. Reducing Ena levels eliminates filopodia but does not influence FC migration, suggesting another actin network could be polarized at the front of the cell. The Arp2/3 activator Scar/WAVE fulfills this role by being planar polarized both in the presence and absence of Ena suggesting a branched actin network moves the FCs forward. Arp2/3 activity is cell autonomously required for protrusion formation. Reduction of Arp2/3 activity across the entire epithelium, though, results in global loss of FC planar polarity and migration. We have also identified Dystrophin as the earliest known marker of planar polarity in this tissue. Interestingly, Dystrophin polarization is never established when Arp2/3 activity is reduced. However, inhibiting Arp2/3 activity after migration begins blocks motility while leaving planar polarity intact. These data suggest that, in addition to driving FC migration, Arp2/3-dependent cell protrusive activity plays a primary role in establishing FC planar polarity, but that other factors stabilize this state once migration commences.

2341

**Patterned cellular behaviors coordinating tissue morphogenesis in the developing *Drosophila* wing.**

R. Etournay<sup>1</sup>, M. Merke<sup>2</sup>, B. Aigouy<sup>3</sup>, A. Sagner<sup>1</sup>, S. Grill<sup>1</sup>, F. Julicher<sup>2</sup>, S. Eaton<sup>1</sup>; <sup>1</sup>Max Planck Institute MPI-CBG, Dresden, Germany, <sup>2</sup>Max Planck Institute MPI-PKS, Dresden, Germany, <sup>3</sup>Epithelial Growth and Morphogenesis, C.N.R.S 6247 I.N.S.E.R.M U931, Clermont-Ferrand, France

How collective cellular behavior specifies the size, shape and polarity of an entire tissue is poorly understood. We address this question *in vivo* using the *Drosophila* wing. During pupal development, the wing epithelium undergoes significant reshaping: one part of the tissue – the hinge – undergoes a large scale contraction that determines tissue shape and global planar polarity in the wing blade. We have previously shown that pupal wing morphogenesis is characterized by a specific pattern of tissue deformation, referred to as shear, which results from an inhomogeneous flow of cells within the epithelium (Aigouy *et al.* Cell. 2010). While we know that the tissue shear pattern arises from coordinated cellular behaviors, including contraction of hinge cells, oriented cell divisions and oriented neighbor exchanges, the contribution of cellular behaviors to the shear pattern is not well understood. Understanding this process would require comprehensive quantitative data on the cellular behaviors that occur throughout the entire tissue during its development. Thus, we developed a method to image the entire wing (400x800 microns) at cellular resolution for 24 hours and built custom image processing tools to quantify cell shape, divisions, rearrangements, and extrusions to be able to correlate cellular behaviors with the shear pattern that shapes the wing. The resulting dataset includes all tracked cells and cell bonds of the tissue, and their description in term of size, shape, and destiny, totalizing around 650 millions of entries in our database for a single movie. We discovered that in the hinge, cell extrusions only play a minor role in the reduction of tissue size. Cells continue dividing but reduce their apical cross-section by half, resulting in a densely packed section of the tissue. Using laser ablation, we found that hinge contraction is likely to be internally driven by cell contractility, so that the hinge literally pulls on the wing blade to generate

cell flow in the neighboring tissue. Additionally, using "Particle Image Velocimetry" to compute the shear pattern in our high resolution movies, we found that tissue shear is constrained regionally by the wing veins and the hinge-blade interface. We are currently addressing how oriented cell divisions and oriented cell neighbor exchanges affect the shear pattern in these specific regions. Our approach bridges the cellular and tissue scales in the study of tissue morphogenesis and should ultimately provide important insight into how tissues acquire their final shape and size.

### **The Atypical Cadherin Fat3 Conveys Retinal Ganglion Cell Signals Regulating Amacrine Cell Migration.**

A. Viegas Tomas<sup>1</sup>, M. R. Deans<sup>1</sup>; <sup>1</sup>Neuroscience and Otolaryngology/HNS, Johns Hopkins University School of Medicine, Baltimore, MD

In the vertebrate retina, neurons are organized by function into separate layers that communicate through precisely organized synaptic contacts. This laminar development and synaptic organization requires neuronal migration into the appropriate nuclear layer followed by dendrite extension into the correct plexiform layer. Previously it was shown that an important role for the atypical cadherin Fat3 is to control amacrine cell (AC) dendrite formation and AC distribution between the inner nuclear layer (INL) and ganglion cell layer (GCL). Fat3 is expressed by ACs and retinal ganglion cells (RGCs) and likely functions by regulating developmental interactions between these cell types. In the absence of *fat3*, the mouse retina is altered by the formation of two additional plexiform layers that are the result of changes in AC distribution between the INL and GCL, and the formation of ectopic AC dendrites. When *fat3* is selectively removed from ACs by *ptf1a*-Cre mutant ACs are faithfully retained in the INL but still form ectopic dendrites. Thus we propose that AC migration and dendrite formation are dependent upon separate Fat3 functions in RGCs and ACs respectively. Specifically a non-autonomous function of Fat3 in RGCs creates a "boundary" that prevents ACs from migrating across the inner plexiform layer (IPL) and into the GCL. This hypothesis was tested by generating RGC-specific CKOs using *brn3b*-Cre transgenic mice in which Cre is expressed in ~80% of RGCs. The effect of Fat3 signaling between RGCs and ACs was determined by measuring the distribution of the BHLHB5-positive class of ACs between the INL and GCL. When *fat3* is removed from RGCs there is a measurable increase in the number of BHLHB5-positive ACs located in the GCL. These findings are similar to the aberrant AC migration phenotype that occurs in *fat3* KOs. Together these results support a model in which Fat3 regulates AC development by acting autonomously in ACs to determine dendrite number and non-autonomously in RGCs to control AC movement. This unexpected commitment from a classical planar cell polarity signaling molecule in the control of cell migration likely reflects functional adaptations of this protein class that are unique to vertebrates.

### **Wntless is required for cell survival in the developing chick spinal cord.**

S. D. Allen<sup>1</sup>, L. M. Galli<sup>1</sup>, N. Zebarjadi<sup>1</sup>, L. W. Burrus<sup>1</sup>; <sup>1</sup>Biology, San Francisco State University, San Francisco, CA

The Wnt signaling pathway contributes to the regulation of important developmental and cellular events, such as cell survival, proliferation, and specification. Within vertebrates, one of the best-characterized examples of a Wnt gradient is found in the developing spinal cord. There, dorsally expressed Wnts form a dorsal to ventral gradient of proliferation and neuronal specification. For Wnts to function properly, they must first be secreted from Wnt-producing cells. Wntless (Wls), a

transmembrane protein, is necessary for the secretion of all known Wnt family members in vertebrates. Knockout of Wls in the mouse model system causes early embryonic lethality that coincides with the timing of the first known requirement for Wnt signaling. The goal of this project was to determine the role of Wls in Wnt gradient formation in the chick spinal cord.

We hypothesized that loss of Wls would disrupt the Wnt gradient and thereby cause defects in survival, proliferation, and patterning. To test this hypothesis, electroporation was used to achieve a transient siRNA-mediated knockdown of Wls. Transverse sections were analyzed for morphological changes, the most noticeable of which was a significant loss of cells on the electroporated side of the spinal cord accompanied by a significant delamination of cells. With respect to the patterning of the spinal cord, we stained for N-tubulin, a marker for mature neurons located in the mantle zone of the spinal cord. The electroporated side of the spinal cord showed a significant decrease in the number of mature neurons. However, upon normalizing this loss to the loss of cells in general, there was no significant change between the control and electroporated sides of the spinal cord, suggesting that the loss of cells is affecting progenitor cells. Current data suggests that this loss of cells is due to inappropriate apoptosis - as assayed by TUNEL. Though knockdown of Wls also decreased the total number of proliferative cells - as assayed by phosphohistone H3, the percentage of proliferative cells was not significantly diminished. Thus, this study suggests that Wls-dependent Wnt signaling is necessary for cell survival in the developing neural tube.

**Jak2 is essential for mouse ectoderm development and plays a critical role in neural function.**

*S. O. Park<sup>1</sup>, K-U. Wagner<sup>2</sup>, P. P. Sayeski<sup>1</sup>; <sup>1</sup>Department of Physiology and Functional Genomics, University of Florida College of medicine, Gainesville, FL, <sup>2</sup>Department of Pathology and Microbiology, University of Nebraska Medical Center, Omaha, NE*

Janus tyrosine kinase 2 (Jak2) is known to play a critical role in hematopoiesis. However, its role in neural function is poorly understood. We hypothesized that ectodermal deletion of Jak2 would result in neural dysfunction. To test this, we generated an ectoderm-specific Jak2 conditional knockout (cKO) mouse. In this model, a Jak2 flox/flox mouse was crossed with a transgenic mouse expressing Cre recombinase under the control of the Msx2 promoter. An R26R LacZ-reporter was used to monitor Cre activity. We found that Jak2 was deleted in ectoderm derived organs such as the nervous system, sensory organs, epidermis, and epidermal tissues of the fingernails, hair, and skin. Accordingly, this Jak2 cKO mouse presented with digital abnormalities including hyper-dactyly and hypo-dactyly. In addition, the Jak2 cKO mice were extremely hyperactive when compared to their littermate controls. The hyper-active phenotype began around weaning and lasted until 18 months of age. Lastly, the Jak2 cKO mice exhibited extreme alopecia and pre-mature aging. These data demonstrate that Jak2 is critical for ectodermic organ development and thus may provide additional insights into the role of Jak2 signaling in neural disorders.

**Jitterbug(jbug)/Filamin and Protein Tyrosine Phosphatase 69D (PTP69D) are required for tendon cell orientation and axon targeting in *Drosophila*.**

P. Olguin<sup>1</sup>, C. Molina<sup>1</sup>, J. Sierralta<sup>2</sup>, E. Lopez<sup>2</sup>, C. Oliva<sup>3</sup>; <sup>1</sup>Programa de Genética Humana, ICBM, Facultad de Medicina, Universidad de Chile, Santiago, Chile, <sup>2</sup>Biomedical Neuroscience Institute, ICBM, Facultad de Medicina, Universidad de Chile, Santiago, Chile, <sup>3</sup>VIB Center for the biology of disease, Katholieke Universiteit Leuven, Leuven, Belgium

Mechanical stress generated by the interaction of cells/tissues during development regulates cell differentiation, growth and morphogenesis. Gain or loss of function (LOF) of genes that maintain the isometric tension of cells results in alterations of shape and polarity. Using *Drosophila* as a model system we found that LOF of chascon- jitterbug(jbug)/Filamin system, the protein tyrosine phosphatase 69D (PTP69D) and non muscular Myosin-II (MyoII), display similar shape and cell orientation phenotypes in tendon like cells. These cells differentiate from a monolayer epithelium and serve as bridge between the muscle and the exoskeleton of the fly. During metamorphosis, the dorsal flight muscles attach to the thoracic epithelium, and shorten pulling the differentiating tendon cells, which extend an axon like process that follows the muscle. Interestingly, we found that *jbug/Filamin* is required in photoreceptor cells for axonal growth and targeting, similarly to *PTP69D*, which is expressed both in tendon and photoreceptor cells. *jbug/Filamin* is expressed in photoreceptors under the control of the transcriptional regulator Hindsight and localizes at the membrane from apical to the axonal terminal. We propose that Jbug/Filamin, PTP69D and MyoII are components of an adaptation mechanism that maintains the isometric tension of tendon and photoreceptor cells during its interaction with other tissues during development.

**N-Cadherin regulates the proliferation and differentiation of ventral midbrain progenitors to dopaminergic neurons.**

F. Sakane<sup>1</sup>, M. Tang<sup>2</sup>, E. J. Huang<sup>2</sup>, Y. Miyamoto<sup>1</sup>; <sup>1</sup>Graduate School of Humanities and Sciences, Ochanomizu University, Tokyo, Japan, <sup>2</sup>Department of Pathology, University of California, San Francisco, San Francisco, CA

Adherens junction between dopaminergic (DA) progenitors maintains the structure of ventricular zone and polarity of radial glia cells in the ventral midbrain (vMB) during embryonic development. We have previously shown that removal of  $\beta$ -catenin, which is an essential component of adherens junction and canonical Wnt signaling pathway, controls multiple steps in the neurogenesis of DA neurons in vMB. In addition, our results also indicate that N-cadherin and  $\beta$ -catenin show extensive colocalization in the neural progenitors in the ventricular zone of vMB. However, it is unclear how loss of N-cadherin might influence the integrity of the adherens junction and the process of DA neurogenesis.

Here, we use conditional gene targeting approaches to perform region-specific removal of N-cadherin in the neurogenic niche of DA neurons in the vMB. Similar to the conditional  $\beta$ -catenin mutants, removal of N-cadherin in vMB using Shh-Cre disrupts the adherens junctions of DA progenitors and radial glia processes in vMB. Surprisingly, in contrast to the  $\beta$ -catenin mutants, loss of N-cadherin in vMB leads to a significant expansion of DA progenitors, including those expressing Sox2, Ngn2, Otx2, and Lmx1a. Cell cycle analyses reveal that the cell cycle exit in the progenitor cells was decreased in the mutants from E11.5 to E12.5. The efficiency of progenitors to differentiate into DA neurons is decreased from E10.5 to E12.5, leading to a marked reduction in the number of DA neurons at E11.5, E12.5, and E17.5. The loss of N-cadherin leads to a diffuse distribution of  $\beta$ -catenin proteins from the adherens junction to the

entire cytoplasm in the neuroepithelial cells, suggesting that the canonical Wnt signaling might be activated in the progenitors in the vMB. Consistent with this notion, the expression of canonical Wnt target genes, *Otx2*, *Lmx1a*, and *cyclin D1*, show a significant increase in the N-cadherin conditional mutants.

Taken together, these results support the notion that N-cadherin regulates the proliferation of DA progenitor cells and the differentiation of DA neurons via the canonical Wnt- $\beta$ -catenin signaling in the vMB.

2347

### **Rbfox3-regulated Alternative Splicing of Numb Promotes Neuronal Differentiation during Development.**

*K. Kim<sup>1</sup>, J. Nam<sup>1</sup>, Y-S. Mukouyama<sup>1</sup>, S. Kawamoto<sup>1</sup>; <sup>1</sup>National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD*

Alternative pre-mRNA splicing is a major mechanism to generate diversity of gene products. However, the biological roles of alternative splicing during development remain elusive. Here we focus on a neuron-specific RNA binding protein, *Rbfox3*, recently identified as the antigen of the widely used anti-NeuN antibody. SiRNA-mediated loss-of-function studies using the developing chicken spinal cord revealed that *Rbfox3* is required to promote neuronal differentiation of post-mitotic neurons. *Numb* pre-mRNA encoding a signaling adaptor protein was found to be a target of *Rbfox3* action and *Rbfox3* represses the inclusion of an alternative exon via binding to the conserved UGCAUG element in the upstream intron. Depleting a specific *Numb* splice isoform reproduces similar neuronal differentiation defects. Forced expression of the relevant *Numb* splice isoform is sufficient to rescue, in an isoform-specific manner, post-mitotic neurons from defects in differentiation caused by *Rbfox3* depletion. This study provides a novel mechanism by which *Rbfox3*-dependent *Numb* alternative splicing regulates progression of neuronal differentiation during vertebrate development.

2348

### **Nodal signaling regulates endodermal cell motility and actin dynamics via Rac1 and Prex1**

*S. Woo<sup>1</sup>, M. Housley<sup>1</sup>, O. Weiner<sup>1</sup>, D. Stainier<sup>1</sup>; <sup>1</sup>University of California San Francisco, San Francisco, CA*

During organ morphogenesis, fate specification and differentiation decisions are translated into dynamic cell behaviors in order to form the three-dimensional shape of the organ. In the zebrafish embryo, endodermal cells are specified prior to gastrulation and subsequently undergo a series of complex movements to bring initially dispersed cells into a coherent epithelium that will ultimately line gastrointestinal tract. In order to investigate the molecular mechanisms underlying these early morphogenetic movements, we generated a novel transgenic line that labels the endodermal actin cytoskeleton, which allowed us to track actin dynamics and cell motility at high resolution in vivo. We observed that during early gastrulation, endodermal cells first migrated in a random, non-persistent manner and exhibited a high degree of actin dynamics. However, at late gastrulation, actin protrusions were more persistent and migration became more oriented as endodermal cells converged on the dorsal side of the embryo. We show that the dynamic actin and random motility characteristic of early gastrulation are dependent on Nodal signaling, and that Nodal signaling regulates activity of the Rho GTPase Rac1. Furthermore, we identified the Rac exchange factor Prex1 as a Nodal target and found that Prex1 is also required for random motility. Reducing Rac1 activity in endodermal cells caused them to bypass the random migration phase and resulted in cells aberrantly

contributing to mesodermal tissues. Together our results reveal a novel role for Nodal signaling in regulating actin dynamics and migration behavior, which are crucial for endodermal morphogenesis and cell fate decisions.

**Quantitative analysis of cytokinesis *in situ* using the *C. elegans* vulval precursor cells.**

K. Bourdages<sup>1</sup>; <sup>1</sup>Molecular Biology, University of Montreal, Montreal, QC, Canada

Single cell and tissue-level morphogenetic events involve remodeling of the cytoskeleton and cellular junctions. Cytokinesis, the final step of cell division, is executed by an actomyosin ring, which constricts to physically separate a cell into two. The molecules that regulate cytokinesis have been well established using various model organisms including yeast, cultured cells and invertebrate embryos, such as that of *Caenorhabditis elegans*. However, it is unknown whether molecular requirements are the same in an intact developing organism, and how the tissue setting affects cytokinesis.

We developed a novel model to characterize cytokinesis *in situ*, using *C. elegans*. Specifically, we study the vulval precursor cells (VPCs). These cells undergo three rounds of division and several morphogenetic changes to form the worm's egg-laying organ. Using high-resolution 3D time-lapse imaging and computational analysis, we first determined the kinetics and geometry of cytokinesis in the VPCs. As we have observed in human and fly cultured cells and the *C. elegans* zygote, contractile ring closure in the VPCs accelerates during the first half of cytokinesis, before decelerating until closure. The maximum speed of furrowing is 15% per minute, similar to that of human and fly cultured cells. The progressive cell size decrease during VPC development allowed us to determine that contractile ring dimensions scale with cell size. The contractile ring closes asymmetrically, towards the apical membrane of VPCs, as seen in mammalian epithelial cells. We hypothesized that apical junctions cause this asymmetry by inhibiting furrowing of the apical cortex. Depleting E-cadherin did not perturb the kinetics and geometry of cytokinesis, most likely due to redundancy from the AJM-1 based junctions for maintaining epithelial integrity. We will next test the effects of disrupting both types of apical junctions. In investigating the roles of conserved cytokinesis proteins in the VPCs, we find that amongst those, ZEN-4 and Anillin are needed for proper vulval morphogenesis. Notably, depletion of Anillin results in slower contractile ring closure as was seen in mammalian cultured cells injected with an anti-anillin antibody.

Currently available anti-mitotic cancer therapies have unexplained tissue specificity. We are optimistic that our novel model for studying cell division *in situ* will help address this difficulty. Furthermore, cytokinesis could serve as a target for novel cancer chemotherapies. Since cytokinesis requires remodeling of the cell cortex, characterizing it in the context of an intact tissue should aid the development of future therapies and predict their effectiveness in various tissue contexts.

**Roles of Dlg5, a Crohn's disease associated protein, as a regulator of TGF- $\beta$  signals and epithelial to mesenchymal transition.**

T. Sezaki<sup>1</sup>, K. Inada<sup>1</sup>, L. Tomiyama<sup>1,2</sup>, K. Ueda<sup>1,2</sup>, N. Kioka<sup>1</sup>; <sup>1</sup>Div. Appl., Grad. Sch. Of Agri., Kyoto Univ., Kyoto, Japan, <sup>2</sup>iCeMS, Kyoto Univ., Kyoto, Japan

Crohn's disease (CD), which is one of the two major forms of inflammatory bowel disease, is characterized by chronic inflammation of the gastrointestinal tract. Dlg5 polymorphism is one of

the risk factors for CD. Dlg5 is a member of MAGUK (membrane associated guanylate kinase) adaptor family proteins. Dlg5 localizes at cell-cell adhesion sites in epithelial cells, and Dlg5 gene knockout mice showed defects in the kidney and brain. However, these functions cannot explain the association with CD. Thus, it is important to clarify Dlg5 functions to develop therapeutic strategy and understand the pathogenic mechanism of CD.

Using LLC-PK1 epithelial cells, in which Dlg5 expresses at high level, we have found that TGF- $\beta$ -induced epithelial to mesenchymal transition (EMT) suppressed Dlg5 expression in LLC-PK1 epithelial cells. Depletion of Dlg5 expression by knockdown promoted the expression of the mesenchymal marker proteins, fibronectin and  $\alpha$ -smooth muscle actin (SMA), and suppressed the expression of E-cadherin, suggesting that Dlg5 suppresses EMT of LLC-Pk1 cells. Furthermore, we found that induction of fibronectin and SMA expression by Dlg5 depletion was inhibited by pharmacological T $\beta$ RI inhibitor (ALK5 inhibitor II) and physiological T $\beta$ R inhibitor, Smad7. These observations suggest that Dlg5 suppresses T $\beta$ R-dependent signals, resulting in suppression of EMT.

We next examined the mechanism of Dlg5 regulation of T $\beta$ R-dependent signals. Immunoprecipitation assay showed that Dlg5 was co-immunoprecipitated with both T $\beta$ RI and T $\beta$ RII in 293T cells. Dlg5 and T $\beta$ RI were co-localized at plasma membrane. In addition Dlg5 overexpression promoted T $\beta$ RI degradation. These findings suggest that Dlg5 forms a complex with T $\beta$ Rs and enhances their degradation. This mechanism may explain how Dlg5 suppresses T $\beta$ R-dependent signals and EMT.

**The maternal-zygotic transition reinforces the actin cytoskeleton to make morphogenesis robust.**

*L. Zheng<sup>1</sup>, A. M. Sokac<sup>1</sup>; <sup>1</sup>Baylor College of Medicine, Houston, TX*

Robustness is a property built in to biological systems to ensure normal function, even in the face of internal and environmental fluctuations. During development, robustness safeguards embryos against mistakes that underlie miscarriage, shortened gestation, and structural and functional birth defects. Yet the mechanisms that make development robust are poorly defined, and are completely unknown on the cell biological scale. Our goal for this study is to understand how morphogenesis is made more robust during cellularization, the first tissue-building event in *Drosophila* development. We have identified Spitting Image (Spt; CG8247) and its homolog Serendipity- $\alpha$  (Sry- $\alpha$ ) as novel actin regulators that share a redundant actin building function during cellularization. We find that Spt is maternally loaded into embryos, while Sry- $\alpha$  is zygotically expressed in a pulse just before cellularization. Spt activity alone is sufficient for development at an optimum temperature, but Spt and two copies of Sry- $\alpha$  are required for cellularization at extreme temperatures and when the actin cytoskeleton is genetically compromised by a reduced dose of profilin. Thus, zygotic Sry- $\alpha$  augments maternal Spt, to ensure that actin accumulates to a level required for reliable cellularization over a range of conditions. This work has two significant implications: First, our data reveals a new paradigm whereby zygotic proteins are not necessarily instructive, but instead add to the maternal contribution to make development more robust. Second, to our knowledge, we provide the first demonstration that the complex spatiotemporal dynamics of morphogenesis can be made more robust by reinforcing the actin cytoskeleton.

2352

**Non catalytic domains of membrane type-1 matrix metalloproteinase (Mmp14) are involved in mammary gland branching morphogenesis.**

H. Mori<sup>1</sup>, C. M. Nelson<sup>2</sup>, J. Alcaraz<sup>3</sup>, C. M. Ghajar<sup>1</sup>, M. Seiki<sup>4</sup>, M. J. Bissell<sup>1</sup>; <sup>1</sup>Lawrence Berkeley National Laboratory, Berkeley, CA, <sup>2</sup>Chemical & Biological Engineering and Molecular Biology, Princeton University, Princeton, NJ, <sup>3</sup>Universitat de Barcelona, Barcelona, Spain, <sup>4</sup>Cancer Cell Research, Institute of Medical Science, The University of Tokyo, Tokyo, Japan

Invasion of epithelial cells through the surrounding stromal extracellular matrix (ECM) is a key event in branching morphogenesis. Whereas epithelial invasion (penetration) during glandular development is well-controlled, the invasive properties of cancer cells in tissues are aggressive and disorganized. To understand how the malignant behavior usurps the signaling pathways from the normal tissues, it is important to understand the regulatory pathways in the normal gland. Elucidating the mechanism by which mammary epithelial cells (MECs) invade the fat pad to bring about exquisite branching morphogenesis may provide valuable clues to target mammary cancer cell invasion and metastasis.

Mmp14 is known to have a crucial role in allowing cancer cells to invade by degrading ECMs, activating other proteases and shedding cell surface molecules. We hypothesized that Mmp14 is also a key player in normal mammary gland branching morphogenesis. Mmp14 profiling in different developmental stages of mammary gland indicated that it was highly expressed during mammary branching morphogenesis in nulliparous mice; the expression was particularly intense in MECs at the tip of the growing branches. To investigate the function of Mmp14 in this context, we used three dimensional cultures of mammary organoids and genetically manipulated MECs, as well as Mmp14 transgenic mice. We discovered that MECs employ both proteolytic activity-dependent and -independent cellular invasion in collagen-1 (CL-1) gels. The cells utilize an association between Mmp14 and an ECM receptor as part of the non-proteolytic activity during the invasion/branching. We have identified the non-catalytic domains that are responsible for signaling in less dense CL-1 and will discuss the different mechanisms Mmp14 utilizes in different modes of cellular invasion during mammary branching morphogenesis.

2353

**The Role of Slit Signaling in Asymmetric Self-Renewal of Mammary Stem Cells.**

M. Ballard<sup>1</sup>, N. Iwai<sup>1</sup>, L. Hinck<sup>1</sup>; <sup>1</sup>University of California, Santa Cruz, Santa Cruz, CA

Mammary gland regeneration following each estrus cycle and pregnancy relies on the self-renewal of a population of multipotent mammary stem cells (MaSCs). Despite their importance in maintaining tissue homeostasis, how MaSCs generate progenitors and self-renew remains poorly understood. Recent work in the developing mouse retina and epidermis suggest that stem cells balance self-renewal with expansion through closely regulated asymmetric and symmetric divisions, and I have recently identified both of these divisions in the gland. SLITs are a family of extracellular guidance cues that signal through the Roundabout (ROBO) receptors. During pubertal outgrowth, ROBO1 is expressed exclusively in the basal cell population, which is thought to contain the stem cells. Loss of *Robo1* at this stage of development leads to increased expression of the ACD regulator *Inscuteable* (mINSC), and we find that this increase in mINSC is associated with a decrease in ACDs in MaSCs and dividing cells in the end buds. However, in basal cells along the ducts, the increased mINSC expression leads to an increase in apico-basal divisions. As the effects are context-dependent, these results suggest that loss of SLIT signaling may deregulate the spindle machinery and cause randomized cell divisions. Given these collective data, I hypothesize that SLIT signaling regulates the renewal and development of the mammary gland by controlling the plane of cell division in stem and progenitor cells through mINSC. Furthermore, our results suggest a mechanism by which

extracellular cues, such as SLITs, regulate the process of MaSC/progenitor cell self-renewal. As the effects of loss of SLIT signaling depend on the biological context of the dividing cell, our results also emphasize the importance of the stem cell niche in governing the growth and regeneration of epithelial tissues.

2354

**Revealing the consequences of cell-to-cell variability in Ras activity on the collective behavior of mammary epithelial cells.**

*J. S. Liu<sup>1</sup>, J. T. Farlow<sup>1</sup>, A. K. Paulson<sup>1</sup>, M. A. Labarge<sup>2</sup>, Z. J. Gartner<sup>1</sup>; <sup>1</sup>Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA, <sup>2</sup>Life Science Division, Lawrence Berkeley National Lab, Berkeley, CA*

To study the consequences of cell-to-cell variability on multicellular processes such as morphogenesis, we used DNA-programmed assembly to construct three-dimensional mammary epithelial microtissues that are mosaic for low-level expression of activated H-Ras. We found two emergent behaviors in mosaic microtissues: cells with activated H-Ras are basally extruded or lead motile multicellular protrusions that direct the collective motility of their wild-type (WT) neighbors. Remarkably, these behaviors were not observed in homogeneous microtissues where all cells expressed the activated Ras protein, indicating that heterogeneity in Ras activity, rather than the total amount of Ras activity, is critical for these processes. Our results directly demonstrate that cell-to-cell variability in pathway activation can drive emergent behaviors during epithelial morphogenesis.

2355

**Perturbation of Cellular Clock Affects Breast Acinar Morphogenesis.**

*S. Rossetti<sup>1</sup>, F. Corlazzoli<sup>1</sup>, A. Gregorski<sup>1</sup>, N. A. Azmi<sup>1</sup>, N. Sacchi<sup>1</sup>; <sup>1</sup>Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY*

Most physiological and biological processes are regulated in a circadian fashion through an endogenous clock that acts both at the organism level and the cellular level. The cellular clock consists of a set of core clock genes that oscillate with a 24-hour period and eventually control non-clock genes involved in fundamental cellular processes. Both disruption of circadian rhythm and altered clock gene expression have been associated with breast cancer. By using a method to induce circadian oscillations in cultured cells, we found that the expression of key clock genes, such as PER2 and BMAL1, oscillate in a circadian fashion in breast epithelial cells (HME1), but not in breast cancer cells. HME1 cells can form mammary gland-like acinar structures in three-dimensional (3D) culture. Thus, we exploited the HME1 model to test whether decreasing the circadian expression of PER2, one of the clock genes found affected in breast cancer that perturbs the cellular clock, can impair 3D acinar development. By using a mechanistic approach, we demonstrated that PER2 knock down, by negatively affecting the level of expression/amplitude of BMAL1 transcript oscillation, which in turn exacerbates PER2 downregulation, severely hampers the development of HME1 acini. This study provides the first evidence of clock gene-mediated regulation of the breast acinar morphogenetic process.

### Prostaglandin E<sub>2</sub>-EP4 Signaling Inhibits Vascular Elastic Fiber Formation in the Rodent Ductus Arteriosus.

S. Minamisawa<sup>1</sup>, U. Yokoyama<sup>2</sup>, R. Ishiwata<sup>2</sup>, Y. Sugimoto<sup>3</sup>, H. Aoki<sup>4</sup>, T. Nakamura<sup>5</sup>, Y. Ishikawa<sup>2</sup>; <sup>1</sup>Cell Physiology, the Jikei University School of Medicine, Tokyo, Japan, <sup>2</sup>Yokohama City University, Yokohama, Japan, <sup>3</sup>Kumamoto University, Kumamoto, Japan, <sup>4</sup>Kurume University, Kurume, Japan, <sup>5</sup>Kansai Medical University, Osaka, Japan

**Background** Elastic fiber formation in the arterial wall developmentally begins mid-gestation and increases rapidly during the last trimester, just as blood pressure and cardiac output increase steeply. The ductus arteriosus (DA), a fetal arterial bypass artery between the aorta and the pulmonary artery, exhibits poor elastic fiber formation compared to the neighboring elastic arteries. However, the DA and its connecting elastic arteries are exposed to essentially the same mechanical forces and hemodynamics. The molecular mechanism regarding poor elastic fiber formation in the DA remains unknown. **Methods and Results** We found that the prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) specific receptor EP4-disrupted DA exhibited aorta-like elastic fiber formation and then resulted in persistent patent DA after birth. On the other hand, the wild-type DA exhibited poor elastogenesis and normally closed after birth. PGE<sub>2</sub> and a selective EP4 agonist significantly attenuated elastic fiber formation in rat DA smooth muscle cells (SMCs). Because lysyl oxidase (Lox) catalyzes cross-links in elastin assembly, we examined the expression of Lox. PGE<sub>2</sub>-EP4 stimulation significantly down-regulated Lox protein, but not mRNA in DA SMCs. We further analyzed the downstream signals responsible for the EP4-mediated decrease in Lox protein. The c-Src-PLC $\gamma$  signal pathway, but not cAMP pathway played a primary role in the PGE<sub>2</sub>-EP4-induced degradation of Lox protein in lysosomes. **Conclusion** The present data suggest a new signal pathway in which PGE<sub>2</sub>-EP4-c-Src-PLC $\gamma$  stimulation promotes the degradation of Lox protein, thereby impairing elastogenesis in the rodent DA. The findings regarding the regulation of elastogenesis by PGE<sub>2</sub>-EP4 stimulation may provide new insight into elastic fiber formation and strategies against related elastin deficiency diseases.

2357

### Connective Tissue Growth Factor is a Key Regulator of Oxygen-Induced Retinopathy.

H. Chintala<sup>1</sup>, H. Liu<sup>1</sup>, R. Parmar<sup>1</sup>, M. Kamalska<sup>1</sup>, Y. Kim<sup>1</sup>, D. Lovett<sup>2</sup>, M. Grant<sup>3</sup>, B. Chaqour<sup>1</sup>; <sup>1</sup>SUNY Downstate Medical Center, Brooklyn, NY, <sup>2</sup>University of California, San Francisco, CA, <sup>3</sup>University of Florida, Gainesville, FL

Connective tissue growth factor (CTGF/CCN2) is an inducible matricellular protein that plays a major role in connective tissue remodeling during development and diseases. We found that CTGF/CCN2 was dynamically expressed in the developing murine retinal vasculature and was abnormally increased and localized within neovascular tufts in the mouse eye with oxygen-induced retinopathy (OIR). Ectopic expression of the CTGF/CCN2 gene through lentivirus-mediated gene transfer further accelerated neovascularization while lentivirus-mediated loss-of-function or -expression of CTGF/CCN2

significantly reduced ischemia-induced neovessel growth in OIR mice. The neovascular effects of CTGF/CCN2 were mediated, at least in part, through increased expression and activity of matrix metalloproteinase (MMP)-2. In cultured cells, CTGF/CCN2 activated MMP-2 promoter through increased expression and tethering of the p53 transcription factor to a highly conserved p53 binding sequence within the MMP-2 promoter. Concordantly, the neovascular effects of CTGF/CCN2 were suppressed by p53 inhibition which culminated in reduced enrichment of the MMP-2 promoter with p53 and decreased MMP-2 gene expression. Our data identified new

gene targets and downstream effectors of CTGF/CCN2 and provided the rationale basis for targeting the p53 pathway to curtail the effects of CTGF/CCN2 on neovessel formation associated with ischemic retinopathy.

2358

**PI3K/Akt1 plays an essential role in retinal angiogenesis.**

*J. Ha<sup>1</sup>; <sup>1</sup>pharmacology, Pusan National University school of medicine, Yangsan-si, Korea*

Phosphoinositide 3-kinase (PI3K) and Akt, downstream target molecule of PI3K, regulate multiple cellular functions including cell proliferation, cell cycle progression, tumor growth, and angiogenesis. In this study, we investigated the role of Akt during retinal angiogenesis. Vascular endothelial growth factor (VEGF)-induced capillary-like tube formation was significantly abolished in Akt1 knock-down Human Umbilical Vein Endothelial Cells (HUVECs), whereas Akt2 knock-down cells were not affected. In addition, VEGF-stimulated corneal angiogenesis was completely inhibited by lacking Akt1. Retinas from WT or Akt1 deficient mice were stained with endothelial cell marker, isolectin B4. Interestingly, retinas from Akt1 knock-out mice showed tortuous, irregular and clustering retinal vessels and delayed vessel development compared to that of WT mice. In addition, retinas from both EC and SMC-specific Akt1 knock-out were shown delayed vascular development compared to retinas from control or EC or SMC-specific Akt2 knock-out mice. It represented that loss of Akt1 caused vascular morphological alterations. Given these results, we suggest that Akt1 requires for vessel development and vascular morphological alterations during retinal angiogenesis.

2359

**How to make and eye: Non-apical progenitors substantially contribute to retinal neurogenesis.**

*I. P. Weber<sup>1</sup>, A. P. Ramos<sup>1</sup>, C. Norden<sup>1</sup>; <sup>1</sup>MPI of Molecular Cell Biology and Genetics, Dresden, Germany*

The retina as an outpocketing of the central nervous system (CNS) has proven to be an excellent model for studying brain development. Understanding general developmental programs in the retina generates important insights in understanding other, less accessible parts of the CNS.

In this study, we present a new pool of progenitor cells occurring at late stages of zebrafish retinal development. Until recently it was believed that all retinal neurons derive from apical division of multipotent progenitors. A couple of years ago however, non-apical divisions (a phenomenon so far mainly explored in the rodent neocortex) were observed in the outer plexiform layer (OPL) and shown to give rise to the horizontal cell (HC) layer (Godhino et al. 2007). Our lab has extended on this finding by showing that these precursors can a) divide at multiple locations between the OPL and the inner plexiform layer (IPL) and b) seem to have the potential to divide more than once before differentiating into HCs. We also show that HCs are not the only cells in the retina arising from subapically dividing precursors but that also a subset of bipolar cells (BCs) does so. These BC precursor divisions occur more apically than the ones of HCs. Both precursor pools are unipotent and give rise to one cell type only. Careful statistics on fixed samples elucidated the birth order of cells arising from this new class of progenitors: BC progenitors are the first cells to divide at sub-apical locations followed by divisions of HC progenitors. This analysis sheds new light onto the general birth order of retinal neurons and expands on the findings merely based on apically dividing cells.

To understand the need for these additional progenitor types we take tissue and cell morphology into account. One reason for the emergence of retinal basal progenitors could be

space constraints within the tissue. The zebrafish retina, unlike the neocortex, is not generated in an “inside-out” fashion, as the most apically located photoreceptors are born rather early in development. Therefore, BC progenitors might divide subapically mainly because they cannot reach the apical surface anymore. Our current data substantiates this assumption.

To understand the morphological basis of the more basally dividing HC precursors we take a different approach: knock down of the transcription factor Ath5 leads to a depletion of retinal ganglion cells, the most basally located cell population, whose space is then taken up by amacrine cells (ACs) (Kay et al. 2005). Interestingly, upon Ath5 knock down we observe an increase of divisions in more basal locations than ever detected in the wild type scenario. We now investigate if these divisions give rise to ACs a cell type that is usually born exclusively at the apical side.

### **RFX transcription factors and their direct target genes (in ciliogenesis).**

*P. Swoboda<sup>1</sup>; <sup>1</sup>Biosciences and Nutrition, Karolinska Institute, Stockholm-Huddinge, Sweden*

Evolutionarily RFX transcription factors (TFs) are present only in the unikonts: animals, fungi, choanozoa and amoebozoa. RFX TFs have a unique DNA binding domain with which they bind to the X-box promoter motif (RFX = Regulatory Factor binding to the X-box). Thereby they directly regulate their target genes. It has been shown experimentally that in fungi RFX TFs regulate genes involved in cell cycle control, while in animals RFX TFs regulate genes involved in the immune response and in cilia formation and development. We have carried out searches for X-box promoter motifs in several animal genomes (*C. elegans*, *Drosophila*, mouse and humans) and have successfully identified direct RFX TF target genes, many of which we confirmed to be involved in ciliogenesis, for example by using GFP assays in transgenic *C. elegans* worms or luciferase assays in transfected mammalian cell lines. Accordingly we were able to assign some of these ciliary genes – upon malfunction – to being at the root of a human disease class termed ciliopathies. We are presently working on cell biological aspects of human brain-related, suspected ciliopathies. We are also trying to tie together the different biological functions (in ciliogenesis) of direct RFX TF target genes by cross-comparing a large number of candidate X-box regulated genes in a variety of different genomes. With these approaches we will be able to track the RFX TF target gene module from basic biological function to disease states in humans.

### **LIM kinase-mediated regulation of cytoskeletal dynamics in mouse submandibular salivary gland branching morphogenesis.**

*S. Ray<sup>1</sup>, J. A. Fanti<sup>1</sup>, N. Dhulekar<sup>2</sup>, D. A. Nelson<sup>1</sup>, B. Oztañ<sup>2</sup>, B. Yener<sup>2</sup>, M. Larsen<sup>1</sup>;  
<sup>1</sup>Department of Biological Sciences, University at Albany, SUNY, Albany, NY, <sup>2</sup>Computer Science, Rensselaer Polytechnic Institute, Troy, NY*

Branching morphogenesis in the mouse submandibular gland is a complex and dynamic process involving several structural changes in the epithelium, including dynamic regulation of cytoskeletal stability, cell migration, and cell-cell adhesions to control formation of clefts, or indentations in the epithelial buds. In this study, we report that LIM kinase (LIMK), a dual-specificity serine/threonine kinase that is regulated by Cdc42 and Rac GTPase in early embryonic salivary glands, is required for branching morphogenesis and is a master regulator of these structural changes. We utilized LIMK I/II siRNA and pharmacological LIMK inhibitors – BMS-3 and BMS-5 - to show that LIMK I/II functions in a myosin-independent pathway to increase cofilin phosphorylation thereby inactivating it, and hence stabilize F-actin filaments in

embryonic day 13 salivary glands. LIMK I/II inhibition was previously reported to stabilize microtubules through interaction with p25/tubulin polymerization promoting protein (TPPP). Accordingly, use of TPPP siRNA caused a decrease in branching and a similar increase in stabilized microtubules. Interestingly, 24 hours of incubation with LIMK I/II siRNAs caused destabilization of clefts. Cleft destabilization was also observed in mesenchyme-free epithelial cultures treated with a LIMK inhibitor (BMS-3) that negatively impacts both the actin- and microtubule-dependent effects of LIMK, whereas an inhibitor that only affects only F-actin organization (BMS-5) prevented initiation of new clefts, as detected by time-lapse microscopy. Whereas BMS-3 drastically reduced cell-cell adhesions and cell proliferation, BMS-5 did not affect cell-cell adhesions or cell proliferation. We utilized computational analysis to determine that BMS-5 significantly reduced cell area relative to control while BMS-3 did not. Using time-lapse confocal microscopy to track movement of nuclei in BMS-5 inhibitor-treated, mesenchyme-free epithelial rudiments, we found that LIMK also inhibited epithelial migration in an actin-dependent manner. We propose a mechanism whereby LIMK regulates actin polymerization and microtubule stability to control epithelial cell-cell adhesion and cell migration to affect both cleft formation and cleft stability in developing salivary glands. Supported by NIH/NIDCR RO1 DE019244.

## Stem Cells and Pluripotency II

2363

### The Nuclear Dynamics of Pluripotency Gene Loci During Embryonic Stem Cell Differentiation.

M. S. Bodnar<sup>1</sup>, D. L. Spector<sup>1</sup>; <sup>1</sup>Cold Spring Harbor Laboratory, Cold Spring Harbor, NY

Mammalian embryonic development proceeds in a highly organized fashion, orchestrating the creation of a complex multi-cellular organism from just one cell. Embryonic Stem (ES) cells, which are derived from the inner cell mass (ICM) of a blastocyst stage embryo, are an excellent *in vitro* model for the study of pre-implantation mammalian development. During the process of differentiation, ES cells undergo dramatic changes in gene expression/repression, chromatin structure, and histone modifications. Little is known about how such drastic changes are coordinated in time and space in the complex nuclear environment. Chromosomal movements/interactions may be an integral event in the transition from the ES cell transcriptional program to cell-type specific gene expression. In addition, gene interactions with nuclear bodies may mediate the observed changes in chromatin organization and gene expression. We were therefore interested in investigating the nuclear position of critical ES cell genes during the transition of ES cells from a pluripotent to differentiated state.

Murine ES cells were differentiated by withdrawal of leukemia inhibitory factor (LIF) or with retinoic acid (RA) and harvested at 12-24 hour intervals following the onset of differentiation, utilizing methods to preserve the 3-D structure of the nucleus. Fluorescence *in situ* hybridization (FISH) was used to examine the 3-D nuclear position of genes including Nanog, Sox2, and Oct4 in pluripotent and differentiating ES cells. Interestingly, we observed transient colocalization of the Oct4 gene alleles during early ES cell differentiation. The timing of Oct4 allelic associations coincides with the repression of the Oct4 gene, suggesting a role for Oct4 gene movements in Oct4 gene repression. Further, we have identified a 3.4kb DNA element at the Oct4 locus, which is able to mediate pairing of a transgenic locus with endogenous Oct4 loci during ES cell differentiation. Ongoing experiments seek to identify proteins that bind to this critical 3.4kb

genomic region, thereby elucidating mechanisms that initiate and/or mediate transient pairing of Oct4 alleles and subsequent gene repression.

**Identification and Applications of a Genome Locus with High Homologous Recombination Frequency in Mouse Embryonic Stem cells.**

A. Wang<sup>1</sup>, Y. Zhang<sup>1</sup>, C. Liu<sup>2</sup>, R. Adelstein<sup>1</sup>; <sup>1</sup>Laboratory of Molecular Cardiology, NHLBI/NIH, Bethesda, MD, <sup>2</sup>Transgenic Mouse Core Facility, NHLBI/NIH, Bethesda, MD

Gene targeting by homologous recombination (HR) provides a powerful means for studying gene function by a reverse genetic approach. This technology also offers a potential tool for gene therapy. However, gene targeting frequencies are very variable for reasons that largely remain unclear. In the course of generating genetic replacement mouse models we found for the first time that the gene targeting locus, a 6 kb sequence in the region of exon 2 of the Myh9 gene, displays an extremely high and repeatable frequency of HR in mouse embryonic stem (ES) cells (95% in this case vs 1-10% in most cases; Wang A, et al. Proc Natl Acad Sci 2010, 107:14645-50). To our knowledge this is the highest rate that has been reported to date. Interestingly, there is no evidence for a specific DNA sequence that is responsible for this high targeting efficiency since a gradual shortening of the homologous arms results in a corresponding reduction of targeting frequency. This finding provides a useful entry point for studying the mechanisms of HR in mammalian cells, and further it may have important applications. One benefit of the Myh9 locus is that it can provide a safe harbor for transgene insertions in the absence of the influence of the integration site, allowing multiple transgenic lines to be more accurately compared. In our current study we took advantage of the high frequency of HR at the Myh9 locus and carried out a series of site-specific transgenic projects including: I) generating genetic replacement mouse models to study the isoform and domain specificity of nonmuscle myosin IIs (Ibid.; Zhang Y et al., see poster this meeting ). So far, at least 5 mouse models have been produced for these purposes. II) Creating Myh9 related disease (Myh9-RD) mouse models. Further investigation confirmed that these mouse models successfully mimic the Myh9-RD phenotype found in humans (Zhang Y, Blood. 2012, 119: 238-50). III) Obtaining high purity cardiomyocytes derived from mouse embryonic stem cells. To this end, a construct of Puromycin controlled by a cardiac-specific promoter was integrated into the Myh9 locus. In each case, the high HR frequency facilitated isolation of the desired ES cell clones. Currently, we are expanding the applications of this useful targeting site.

**Gene expression analyses of a heart injury model system in *Ciona intestinalis*.**

C. Manning<sup>1</sup>, P. M. Pardhanani<sup>1</sup>, J. Barth<sup>2</sup>, H. Evans-Anderson<sup>1</sup>; <sup>1</sup>Biology, Winthrop, Rock Hill, SC, <sup>2</sup>Medical University of South Carolina, Charleston, SC

*Ciona intestinalis* is a useful animal model system for studying developmental processes. It is particularly helpful in studies of heart development since many of the developmental steps and genes are conserved in *Ciona* and replicate early heart development in other Chordates, such as vertebrates. However, in contrast to most vertebrates, *Ciona* hearts have the capacity for regeneration. In order to identify important regeneration factors in the *Ciona* heart, microarray analysis was conducted on RNA from adult *Ciona* hearts with normal or damaged myocardium using custom Affymetrix GeneChips. Hearts were injured via ligation or cryoinjury to stimulate regeneration. After a 24 or 48 hour recovery period, total RNA was isolated from damaged and control hearts. Initial results indicate significant changes in gene expression in hearts damaged by ligation in comparison to cryoinjured or control hearts. Ligation injury shows differential expression of 223 genes as compared to control (fold change >2, p<0.01, Student's t-test) with

limited false discovery (5.8%). Among these 223 genes, 117 have known orthologs of which 68 were up-regulated and 49 were down-regulated. Altered orthologous genes that were discovered via microarray analysis were validated by RT-PCR. Currently, gene expression patterns in the *Ciona* hearts are being identified via in situ hybridization, including FGF 9/16/20, Foxo, and a non-orthologous heart-specific gene. In combination, these studies will help to elucidate the regulatory mechanisms of cardiac myocyte proliferation by the identification of orthologous genes involved in the development and regeneration of the *Ciona* myocardium.

#### **Ultrastructure and Immunohistochemical Analyses of a Regenerative Myocardium.**

*L. Washburn*<sup>1</sup>, *S. Stokes-Cox*<sup>1</sup>, *P. M. Pardhanani*<sup>1</sup>, *R. Price*<sup>2</sup>, *H. Evans-Anderson*<sup>1</sup>; <sup>1</sup>*Biology, Winthrop, Rock Hill, SC,* <sup>2</sup>*Instrumentation Resource Facility, University of South Carolina School of Medicine, Columbia, SC*

*Ciona intestinalis* is an invertebrate animal model system that is well characterized and has many advantages for the study of cardiovascular biology. A striking difference between most vertebrates and *Ciona* is that the *Ciona* myocardium is capable of regenerating cardiac myocytes throughout its lifespan, which makes the mechanisms of cardiac myocyte proliferation in *Ciona* intriguing. In order to stimulate regeneration, hearts were injured via ligation around the middle of the heart. After a 24 or 48 hour recovery period, damaged and control hearts were fixed for immunohistochemical or ultrastructure analyses. Preliminary TEM studies show degradation of the myofibrils and changes in the organization of mitochondria in cardiac myocytes. Interestingly, in addition to damaged myocytes, dividing myocytes are also evident and undifferentiated cells populate the damaged myocardium. Furthermore, thickening of the extracellular matrix is apparent, particularly within the lumen of the heart. Histological studies using Mayer's Hematoxylin and Eosin as well as Movat pentachrome stains show basic organization of the matrix components within the *Ciona* heart. Specific labeling of the myocardium using the MF20 antibody (Iowa Hybridoma Bank) shows organization of the cardiac myocytes. Studies using immunohistochemistry to identify proliferation and apoptosis in cardiac myocytes of damaged hearts are currently underway. Taken together, these studies will coordinate differences in cellular organization to ultrastructural changes in cardiac myocytes within the regenerative myocardium of *Ciona*, which will help to elucidate the basic mechanisms of cardiac myocyte proliferation.

#### **FXR, a Novel Receptor in Bone Cell Differentiation and Function.**

*F. M. Moussa*<sup>1</sup>, *S. L. Lababidi*<sup>1</sup>, *A. S. Sanyurah*<sup>2</sup>, *L. N. El-Shaar*<sup>1</sup>, *K. M. Novak*<sup>1</sup>, *S. Abdelmagid*<sup>1</sup>, *Y. Zhang*<sup>1</sup>, *F. F. Safadi*<sup>1</sup>; <sup>1</sup>*Northeast Ohio Medical University, Rootstown, OH,* <sup>2</sup>*Kent State University, Kent, OH*

Farnesoid X receptor (FXR), also known as NR1H4 (nuclear receptor subfamily 1, group H, member 4) is a bile acid receptor key in maintaining bile acids and cholesterol homeostasis. FXR is highly expressed in liver and small intestine, where bile acids are synthesized and secreted, respectively. As such, FXR plays an important role in fat metabolism. It has also been found that FXR is an upstream regulator of Fibroblast Growth Factor 21 (FGF-21), which has recently been shown to contribute to bone loss through the inhibition of osteoblastogenesis and stimulation of adipogenesis. While it has long been known that FXR is expressed in liver, intestine, kidney, and adipose tissue, its expression and function in bone are not well understood. In this study, we examined the expression of FXR in bone and demonstrate its key regulatory role in osteoblast and osteoclast differentiation and function. We performed qPCR on

mRNA collected from long bone and calvaria of WT mice, demonstrating the expression of FXR in normal bone development. Next, we examined the skeletal phenotype of FXR KO mice. Micro-CT analysis showed a significant increase in bone volume and trabecular thickness in FXR KO compared to WT mice. Cell survival and proliferation assays in primary osteoblasts collected from FXR KO and WT mice showed significantly less proliferation and survival in the FXR KO compared to WT. In contrast, when MC3T3-E1 osteoblast-like cells were differentiated in the presence of an FXR agonist (GW4064), they demonstrated significantly less matrix mineralization staining by day 21 compared to untreated culture. Osteoclast differentiation (in the presence of M-CSF and RANKL) of hematopoietic stem cells harvested from FXR KO and WT mice showed significantly fewer number of osteoclasts coupled with less TRAP staining and activity in the FXR KO compared to the WT. These results suggest that FXR is a negative regulator of osteoblasts and positive regulator of osteoclasts, and therefore a novel protein in bone cell differentiation and function. Taken together, further studies are warranted to demonstrate the mechanism of FXR in bone cell differentiation and function in vivo.

#### **Normal migratory epithelial stem cells express vimentin.**

*C. A. Velez-delValle<sup>1</sup>, M. Marsch-Moreno<sup>1</sup>, F. Castro-Muñozledo<sup>1</sup>, M. Hernández-Quintero<sup>1</sup>, A. Beltran-Langarica<sup>1</sup>, I. J. Galván-Mendoza<sup>2</sup>, W. Kuri-Harcuch<sup>1</sup>; <sup>1</sup>Cell Biology, Centro de Investigación y de Estudios Avanzados del IPN, México D.F., Mexico, <sup>2</sup>Laboratorios Centrales, Unidad de microscopía confocal y multifotónica, Centro de Investigación y de Estudios Avanzados del IPN, México D.F., Mexico*

Keratins, the largest group in the intermediate filament (IF) family, are broadly expressed in epithelial cells, while vimentin (Vim), which belongs to the type-III IF proteins, is found primarily in mesenchymal cells. However, Vim it is also found in epithelial cells during development, and in keratinocytes grown under low-calcium conditions, in the outgrowths of epidermal explants, and in some metastatic tumor cells. These results lead to consider Vim as a possible marker of oncogenic progression, but little is understood about its role in normal epithelial cells.

We describe, the coexistence, organization and function of Vim IFs and keratin IFs in diploid, non-transformed human epidermal keratinocytes cultured under conditions with normal  $\text{Ca}^{2++}$  levels that support proliferation, stratification and terminal differentiation. These conditions enabled us to identify and localize the epidermal stem and transient amplifying cells, either in the growing colonies and in confluent stratified epithelia.  $\text{Vim}^+$  keratinocytes in confluent cultures were about  $3.7\% \pm 0.15$  of total cells as determined by flow-cytometry analyses. We also show that the  $\text{Vim}^+$  migratory keratinocytes correspond to the stem and/or transit amplifying cells of the epidermis; since they expressed epithelial stem cell markers such as cytokeratin14, p63, basonuclin and  $\alpha 5\beta 1$ -integrin. Functional experiments designed to analyze the effect of EGF on the growth rate and the migration of keratinocytes showed that EGF promotes an increase in number of  $\text{Vim}^+$  keratinocytes and augmented colony growth as compared to control cultures. The ratio between the number of  $\text{Vim}^+$  cells and colony radius remained constant during time in EGF-treated cultures, suggesting a direct correlation between the number of  $\text{Vim}^+$  keratinocytes and the rate of colony expansion. The results also show that after wounding a confluent cultured epithelium, the number of  $\text{Vim}^+$  cells increases at the wounded edge in less than 20-24 hours, before proliferation would take place.

There are several conditions in human skin that could involve Vim expression in basal keratinocytes, amongst them morphogenetic movements. Cultured HEK form confluent layers, undergo pattern formation producing ridges that form complex structures resembling the primate dermatoglyphs. By 39 days post-confluence, Vim<sup>+</sup> keratinocytes oriented in curves and swirls suggesting that they undergo extensive cell movements and migration.

Our results suggest that in the proliferative epidermal keratinocytes a subset of the stem and/or transit amplifying cells would become migratory through the presence and organization of Vim IFs, integrating the mechanical functions of the cytoskeletal elements for keratinocyte migration, proliferation and re-epithelization.

### **Temporally-Regulated Mechanotransduction Controls Stem Cell Cardiomyogenesis.**

*J. L. Young<sup>1</sup>, K. Kretchmer<sup>1</sup>, J. Schaefer<sup>1</sup>, A. J. Engler<sup>1</sup>; <sup>1</sup>Bioengineering, University of California, San Diego, La Jolla, CA*

As cells migrate and differentiate throughout development, they secrete and assemble extracellular matrix (ECM), giving rise to time-dependent, tissue-specific stiffness, i.e. cardiac muscle originates from soft mesoderm, <500 Pa (Pascal; a unit of stiffness), and stiffens ~10-fold as the myocardium matures. When mimicked in vitro with a hyaluronic acid (HA) hydrogel, myocardial matrix stiffening enhanced cardiac specific gene expression and myofibril organization in immature, isolated pre-cardiac mesoderm. With less specified mouse embryonic stem cells (mESCs), mechanical cues alone were insufficient to induce cardiogenesis, but a combination of precisely-timed developmentally-relevant chemical cues (e.g. BMP4, Activin A, DKK-1) and presentation of dynamic matrix mechanical cues at the cardiac mesoderm induction stage enhanced maturation of mESC-derived cardiomyocytes versus growth factors alone. Measurement of sarcomere length shows mESC-derived cardiomyocytes plated on dynamic HA hydrogels exhibited greater than 30% more mature myofibrils compared to cells plated on static, stiffer matrices. While active mechanotransduction aided maturation, the specific proteins responsible for responding to time-dependent stiffness remain unknown. In order to assess matrix-mediated mechanotransduction across cells of varying myocardial commitment, we examined the expression and phosphorylation state of 800+ protein kinases, as well as organization of mechanosensitive proteins, e.g. focal adhesion kinase (FAK) and vinculin, of pre-cardiac mesoderm or mESC-derived cardiomyocytes plated on matrices with either dynamic or static cardiac tissue-specific stiffness. Microarray analysis of protein kinases showed differential expression as a function of mechanics, confirmed by ratiometric western blotting. Many focal adhesion proteins exhibited time-dependent upregulation on dynamic versus static matrices, including CAS, FAK, Paxillin and Src. These data indicate that mechanically driven maturation is at least partially achieved via active mechanosensing at focal adhesions. Identifying mechanosensitive pathways that are active in cardiomyogenesis can lead to a better understanding of how stem cell differentiation and development are mediated by extracellular matrix properties.

**Regulated subnuclear gene positioning restricts neural stem cell competence in *Drosophila*.**M. Kohwi<sup>1</sup>, J. Lupton<sup>1</sup>, S-L. Lai<sup>1</sup>, M. Miller<sup>1</sup>, C. Q. Doe<sup>1</sup>; <sup>1</sup>Institute of Neuroscience, University of Oregon, Eugene, OR

Progressive loss of stem/progenitor competence to specify earlier-born cell fate is a fundamental process of development whose mechanisms are little understood. Using a combination of DNA fluorescent *in situ* hybridization (FISH) and immunostaining in intact *Drosophila* embryos, we visualized changes in genome architecture *in vivo* as neuroblasts (neural stem cells) undergo rapid (~1hr) transcriptional transitions within the developing central nervous system. We tracked the subnuclear position of the gene locus encoding the transcription factor Hunchback (Hb), which specifies early-born temporal identity. We found that the *hb* gene progresses through three states: transcriptionally active, transcriptionally inactive but inducible, and finally, permanently silenced. We found that when the *hb* gene is transcriptionally active or inducible, the *hb* gene locus is positioned in the nuclear interior, and the neuroblast is competent to specify early-born identity. In contrast, when the *hb* gene is permanently silenced, we found its locus is positioned at the nuclear lamina, a highly repressive domain. Strikingly, the timing of this repositioning correlates precisely with the time neuroblast competence is lost. When the nuclear lamina is disrupted, the *hb* locus is positioned away from the nuclear envelope, and the competence window, as defined by the duration *hb* is transcriptionally inducible, is extended. Furthermore, we identified a neuroblast nuclear factor, Distal antenna (Dan) whose expression perfectly matches the neuroblast competence window. Prolonging Dan expression prevented repositioning of the *hb* locus to the nuclear lamina and extended neuroblast competence, suggesting it may play a role in regulating gene architecture in neuroblasts. We propose that gene reorganization is a mechanism by which stem cell competence to specify particular fates becomes restricted during development. These data may provide insight into mechanisms that can be harnessed to reverse loss of stem cell competence for tissue replacement therapies.

**Escargot blocks niche cell-stem cell conversion in the *Drosophila* testis.**S. L. Sandall<sup>1</sup>, J. Voog<sup>2</sup>, G. Hime<sup>3</sup>, M. T. Fuller<sup>4</sup>, L. Jones<sup>1</sup>; <sup>1</sup>The Salk Institute for Biological Studies, La Jolla, CA, <sup>2</sup>Medicine, University of California, San Diego, La Jolla, CA, <sup>3</sup>Anatomy and Neuroscience, University of Melbourne, Melbourne, Australia, <sup>4</sup>Dept of Developmental Biology & Genetics, Stanford University, Stanford, CA

Stem cells are the building blocks during development and serve as a reservoir of cells for maintaining tissues throughout life. They reside within specialized microenvironments, or niches, that control many aspects of stem cell behavior. Our lab utilizes the *Drosophila* testis and intestine as models to explore the molecular mechanisms regulating adult stem cell behavior. Quiescent somatic hub cells reside at the apical tip of the *Drosophila* testis and regulate the behavior of two populations of stem cells, the germline stem cells (GSCs) and somatic cyst stem cells (CySCs). As such, hub cells are a critical component of the stem cell niche in the testis.

The transcriptional repressor Escargot (Esg) is expressed in GSCs, CySCs, and hub cells. *Drosophila* males homozygous for a hypomorphic allele of *esg*, *shutoff* (*shof*), begin to lose hub cells during development, followed by subsequent loss of both stem cell populations. Cell type-specific reduction of *esg* function revealed that hub cells lacking *esg* acquire CySC

characteristics and undergo differentiation as cyst cells, eventually resulting in testis that lose all hub cells and eventually CySCs and GSCs. We have identified Esg-interacting proteins and confirmed an interaction between Esg and the co-repressor C-terminal binding protein (CtBP), which is also required for maintenance of hub cell identity. Our results indicate that differentiated niche cells can acquire stem cell properties upon removal of a single transcription factor *in vivo*, revealing the importance of defining networks that maintain the balance of cell fates within the stem cell niche. Esg is also expressed in other *Drosophila* stem cells; therefore, we propose that investigating Esg will reveal conserved mechanisms utilized to regulate stem cell behavior in multiple tissues.

**Gap Junction Communication in the Adult Neural Stem Cell Niche.**

J. Goldberg<sup>1</sup>, T. Vadakkan<sup>2</sup>, M. Dickinson<sup>2</sup>, K. Hirschi<sup>1</sup>; <sup>1</sup>Yale University School of Medicine, New Haven, CT, <sup>2</sup>Baylor College of Medicine, Houston, TX

Only recently has the discovery of adult neurogenesis been able to overturn the long-standing dogma describing the adult mammalian brain as a static organ. The subventricular zone (SVZ) represents the largest documented neurogenic region within the adult brain. This bone fide neural stem cell (NSC) niche provides a specialized microenvironment that integrates both local and systemic signals to potentiate endogenous NSC activity. The vasculature and associated extracellular matrix are among key components that not only comprise niche architecture, but serve to support and regulate its homeostasis and regeneration. In fact, putative NSC and their most immediate progenitor progeny, transit-amplifying cells, are intimately associated with the vascular plexus within the SVZ. Furthermore, this vascular association is exaggerated during niche regeneration in experimental models. Although some evidence points to secreted factors mediating cross-talk between and among SVZ cells, the role of direct contact in stem cell signaling, maintenance and differentiation has yet to be determined. Gap junction intercellular communication (GJIC) represents a direct means for cell-cell communication normally mediated through physical contact. However, the connexin family of proteins that comprises gap junctions has evolved beyond their traditional role of allowing small molecules, ions and metabolites to pass between adjoining cells. Recent studies have implicated unpaired connexins in intracellular cascades that regulate cell growth, survival, and migration. To address the potential role that gap junctions play in modulating the phenotype and function of NSC, we have developed a novel computational method to detect and quantify connexin expression in specific subsets of stem and progenitor cells in the SVZ. Furthermore, combining confocal microscopy with this image analysis platform has allowed us to correlate connexin expression patterns to blood vessel distance measurements within the niche. Using these systematic tools and methods of analysis, we have characterized the cell specific distribution of connexins among neural stem and progenitor cells (NSPC) as well as the vascular endothelium in the SVZ.

**Effects of Heavy Metals on a Mouse Embryonic Stem Cell Model of Developmental Neurotoxicity.***C. E. McDonald<sup>1</sup>, M. Zagzoog<sup>1</sup>, M. El Majdoubi<sup>1</sup>; <sup>1</sup>Dominican University of California, San Rafael, CA*

Neurotoxic effects of heavy metals on the developing brain (developmental neurotoxicity) are a major public health concern. Because of the limitations of animal-based models and traditional cell culture models of neuronal development, the mechanisms of developmental neurotoxicity are poorly understood. In recent years, embryonic stem cell (ESC)-derived neuronal models have been developed and offer distinct advantages over traditional in vivo and in vitro model systems for investigating the effects of neurotoxins directly on the developing neuron. ESCs are undifferentiated cells that can proliferate indefinitely and also be induced to differentiate into functional adult neurons in culture. This in vitro neuronal differentiation recapitulates several critical processes involved in the development of the nervous system such as proliferation, migration, differentiation, and synaptogenesis. In the present study, we cultured feeder-independent mouse embryonic stem cells (ES14 stem cell line) and directed their differentiation into neurons using retinoic acid, a powerful induction factor of stem cell neuronal differentiation. Using this model of developing neurons, we assessed developmental neurotoxicity of four heavy metal compounds found in the environment: mercury, cadmium, lead, and manganese. Changes in cell viability, replication rates and migration were monitored at different steps of the developmental process of ESCs. The efficiency of neuronal differentiation was determined by calculating the proportions of cells that are immuno-positive for MAP-2, a cytoskeleton protein unique to neurons. Undifferentiated ESCs were generally more sensitive to higher physiological doses of all four compounds, which inhibited cell proliferation and induced apoptosis. In contrast, lower physiological doses of these compounds did not impact ESCs proliferation but significantly decreased neuronal migration and differentiation. These results are consistent with findings in animal-based models and show that the directed neuronal differentiation of ESCs is a useful model system for investigating the effects of heavy metals and endocrine disruptors as well as their mechanism of action directly on developing neurons.

**Fast formation of neurodiscs from adherent rat neural stem cell culture via multi-parametric microenvironment control.***B. Miller<sup>1</sup>, A. Zayac<sup>1</sup>, T. Gaige<sup>1</sup>, P. Hung<sup>1</sup>, C. Chen<sup>1</sup>; <sup>1</sup>R&D, CellASIC/EMD Millipore, Hayward, CA*

It is known that neural stem cells are sensitive to their respective microenvironment including cell-cell contact, cell-ECM interaction, nutrient and waste transport, and oxygen microenvironment. However, how these parameters in the microenvironment affect the stem cells' morphology, proliferation, and pluripotency remains unknown.

In this study, we adopted a commercially available live cell imaging microfluidic platform capable of multi-parametric microenvironment control on an adult rat hippocampus neural stem cell line. For cell-ECM interaction, protocols were developed to coat the #1.5 coverglass substrate with polyornithine/laminin, poly-D-lysine or poly-L-lysine. For nutrient and waste transport, a pneumatically driven mechanism was applied to provide low-shear steady-state perfusion through the neural stem cell cultures. Since the device is made of gas-permeable materials, by inoculating the culture with different mixtures of gases, the oxygen microenvironment can be designated ranging from severe anoxia to hyperoxia. To achieve different cell-cell contact scenarios, seeding densities were optimized to allow the culture to start growing from low to

high cell concentrations. By attempting various combinations of these microenvironment parameters, we found that the rat neural stem cells exhibited different morphologies and proliferated best under physiologic mild hypoxia conditions as reported by other groups. Through the combination of high seeding density at 200,000/mL, polyornithine/laminin coating, continuous perfusion at 5 $\mu$ L/hour, and 3% oxygen mild hypoxia gas microenvironment, the rat neural stem cells formed a 3mm x 3mm x 0.1mm neurodisc (neurosphere-like tight structures) in 72 hours. Through live cell imaging on a fluorescent microscope, we further discovered that while the peripheral cells around the neurodisc were successfully immunostained for two pluripotency markers, Nestin and Sox2, the image of the neurodisc itself showed condensed bright spots of Sox2 but no Nestin. The ability to form these neurosphere-like tight structures quickly in non-suspension culture as well as the ability to image them with fluorescent microscopy could facilitate assay development for neural stem cells as well as provide a model system for neurogenesis and neural development research.

**The role of Smad4 mediated signaling in mouse trophoblast lineage development.**

Y. Chen<sup>1</sup>, J. Guo<sup>1</sup>, P. Yuvaraj<sup>1</sup>; <sup>1</sup>Kent State University, Kent, OH

The maintenance and differentiation of trophoblast lineages is essential for implantation, embryonic patterning, fetal growth and nutrition. Mouse trophoblast stem (TS) cells established from the outgrowth of the polar trophoblast of blastocysts or the extraembryonic ectoderm of post-implantation embryos are the precursors of trophoblasts and can contribute to all trophoblast lineage derivatives in vivo, providing a powerful in vitro system for the study of trophoblast stem cell self-renewal and differentiation. Although it is known that Transforming Growth Factor (TGF- $\beta$ )/Nodal-related signaling together with FGF4 signaling is critical for TS self-renewal, the function of Smad4, the central mediator of the TGF- $\beta$  related signaling pathways, in TS cells has not been fully investigated, partially due to the early lethality of Smad4 null embryos. To investigate the role of Smad4-dependent signaling in trophoblast development, we derived smad4 null TS cells. Although loss of Smad4 does not overtly affect cell proliferation, Smad4 null TS cells display enhanced motility and invasiveness and undergo epithelial-mesenchymal transition. Consistent with the changes in cellular properties, transcriptome profiling reveals misregulation of genes associated with tumorigenesis and cancer progression in Smad4 null TS cells. Moreover, Smad4 deficiency also alters the differentiation kinetics and trophoblast lineage distribution of the mutant TS cells. We will present in vitro and in vivo evidence linking the differentiation defects seen in the Smad4 null TS cells to alterations in several signaling pathways, including the Wnt pathway, whose role in TS cell biology has not been appreciated previously. Taken together, our studies revealed a novel requirement for Smad4 in maintaining the morphology and homeostasis of TS cells through Smad4-dependent signaling and cross-talks with other developmentally important signaling pathways. Our analysis will provide insights into the molecular mechanisms that regulate trophoblast lineage development in vivo.

**Proapoptotic effect of valproic acid on progenitors of ES-derived glutamatergic neurons.**

R. Fujiki<sup>1</sup>, T. Yamashita<sup>1</sup>; <sup>1</sup>Department of Molecular Neuroscience, Graduate School of Medicine, Osaka University, Suita, Japan

We improved and established the culture system involving the generation of essentially pure (more than 97%) populations of glutamatergic neurons from mouse embryonic stem (ES) cells. Although we first tried establishing this culture system in our laboratory according to the previous report, these ES-derived neurons did not survive as long as reported previously under

the same conditions that were originally described. We mainly arranged the medium condition without decreasing the purity of glutamatergic neurons, and finally established the efficient and reproducible method.

Valproic acid (VPA) is a branched-chain saturated fatty acid with a long history of clinical use as an antiepileptic drug (AED). It is well known that VPA is also a powerful histone deacetylase inhibitor (HDACi) and relieves HDAC-dependent transcriptional repression by hyperacetylating histones. There are many contradictory reports that show VPA's neuroprotective or neurodestructive effects on neuronal progenitor cells and neurons. And the mechanisms underlying those effects are explained by the function of VPA either as an AED or an HDACi. There is no report examining the VPA's effect on homogeneous neurons and their progenitors.

Here, we report that VPA has a proapoptotic effect not on glutamatergic neurons but on their progenitors at the therapeutically employed concentrations through its function as an HDACi, not as an AED. We treated ES-derived glutamatergic neurons and their progenitors with two famous HDACis including trichostatin A (TSA) and sodium butyrate (NaB), VPA, and VPM (a structural analogue of VPA which has the same antiepileptic effect as VPA, but lack the HDAC inhibitory activity), and examined the apoptosis ratio and acetylated histone levels. TSA, NaB, and VPA showed remarkably similar levels of acetylating and proapoptotic effects on progenitors, but not on neurons. In contrast, VPM showed neither acetylating nor proapoptotic effect regardless of cell types. These findings indicate that inhibition of HDACs may be the mechanism underlying progenitors' apoptosis induced by VPA. Taken together with the fact HDACis prevent proliferation and induce apoptosis of malignancies, the cell specificity of HDACis' proapoptotic effect may be due to the division potential. Fetal exposure of animals and humans to VPA is reported to produce congenital malformations and cognitive impairment. VPA's inhibition of HDACs which play an important role during the embryogenesis of numerous organisms can be the mechanism underlying such phenomena.

### **ES-specific proteins are degraded via autophagy in hESCs.**

*Y-H. Cho<sup>1</sup>, K. Han<sup>1</sup>, D. Kim<sup>1</sup>, S-H. Lee<sup>2</sup>, Y-M. Han<sup>1</sup>; <sup>1</sup>Department of Biological Sciences, KAIST, Daejeon, Korea, <sup>2</sup>BioMedical Research Center, KAIST, Daejeon, Korea*

Human embryonic stem cell (hESC) pluripotency is regulated by several ES-specific proteins such as OCT4, SOX2, and NANOG and pluripotency-related proteins. However, the mechanisms underlying the control of protein homeostasis in hESCs remain elusive. Here, we demonstrate that autophagy acts to modulate the levels of ES-specific proteins critical for hESC pluripotency. Autophagy inhibition reduced hESC pluripotency despite the upregulation of ES-specific proteins. In cells cultured under starvation conditions, autophagy inhibition significantly increased the levels of ES-specific proteins and LC3 II. The colocalization of OCT4 with an ubiquitin-binding receptor for autophagy (SQSTM1) in the cytoplasm indicated a direct interaction of ES-specific proteins with autophagosomes. Autophagy was involved in the degradation of cytoplasmic and nuclear ES-specific proteins. The present results suggest that autophagy regulates homeostasis of ES-specific proteins.

**The role of a voltage-gated calcium channel in controlling stem cells in a non-excitabile tissue like skin**

G. Yucel<sup>1</sup>, B. Altindag<sup>1</sup>, N. Gomezospina<sup>1</sup>, A. Rana<sup>2</sup>, G. Panagiotakos<sup>2</sup>, R. Dolmetsch<sup>2</sup>, A. Oro<sup>1</sup>;  
<sup>1</sup>Dermatology, Stanford University, Stanford, CA, <sup>2</sup>Department of Neurobiology, Stanford University, Stanford, CA

Adult stem cells are multipotent cells that possess the capacity for programmed organ replacement and carry the promise of induced organ repair in response to injury or damage. Voltage gated calcium channels (VGCC) are found in excitable cells such as neurons and cardiomyocytes and they respond to electrical signals and work as pacemakers. Although VGCCs are expressed, the role for VGCCs in non-excitabile cells such as adult stem cells is poorly understood.

Murine hair follicle is a great system to study stem cells due to its short, genetically controlled, repeated cycles of growth (anagen), regression (catagen) and quiescence (telogen). Intense recent focus has come to elucidate the controls of stem cell quiescence and the timing of re-entering the proliferative anagen stage.

In this study, we find that Cav 1.2 is an L-type VGCC that is expressed highly in hair follicle stem cells. According to calcium imaging and patch clamping experiments, hair follicle stem cells lack voltage dependent calcium currents. To understand the role of this calcium channel that works independently of calcium, we looked at different mutants and small molecule inhibitors that mimic the different stages of the channel. Gain of function mutation in this channel (mimicking the open state of the channel) causes Timothy Syndrome (TS) in humans associated with baldness in the first two years of life. Expression of Cav1.2<sup>TS</sup> in hair follicle stem cells causes late entry to anagen consistent with the TS phenotype. Loss of function mutation removing the pore region of the channel (mimicking the closed state of the channel) in hair follicle stem cells also causes late entry to anagen. Treatment of mice with various L type channel blockers (mimicking the inactive state of the channel) causes early entry to anagen. In conclusion, we find that Cav1.2 does not act as a classical voltage gated calcium channel but it provides a voltage-independent, two-state signal (open and inactive) in hair follicle stem cells that inhibits quiescence and promotes tissue regeneration and may be a target for inducing regeneration in other non-excitabile tissues.

**Biophysical regulation of pluripotency and embryonic development.**

K. Chalut<sup>1,2</sup>, M. Hoepfler<sup>2</sup>, J. Nichols<sup>1</sup>, J. Guck<sup>3</sup>; <sup>1</sup>Wellcome Trust/Medical Research Council Centre for Stem Cell Research, University of Cambridge, Cambridge, United Kingdom, <sup>2</sup>Cavendish Laboratory, Cambridge, United Kingdom, <sup>3</sup>Technische Universität Dresden, Dresden, Germany

We are studying how cell and nuclear mechanics regulate the exit from pluripotency in mouse embryonic stem cells, and how these same biophysical factors manifest similarly in controlling the development of the early mouse embryo. Towards these ends, we have developed several techniques to study stem and progenitor cells both in vitro and in vivo (i.e. in the embryo); these techniques are physics-based and include optical trapping, microrheology and microfluidics for studying cell and nuclear mechanics. Moreover, we are also studying the connection between chromatin structure and nuclear mechanics with quantitative microscopy and temporal spectroscopy. We found first, using optical stretching and microfluidics, that embryonic stem

cells and their nuclei become significantly softer when they make their first fate decision towards a lineage specification. Second, we applied quantitative microscopy techniques to show that the reason the nuclei of these cells become softer as they exit pluripotency is a global decondensation of chromatin. This chromatin decondensation changes the viscoelastic properties of the nucleus. It is noteworthy that our results, at first sight, seem to contradict previous results showing that, as stem cells differentiate, the nucleus becomes stiffer and chromatin condenses. However, we emphasize that we are studying the very first stages of embryonic stem cell differentiation, i.e. when the stem cell first exits the pluripotent state. Finally, we are applying microrheology to study the mechanics and structure of the cytoskeleton and the nucleus within cells in the very first stages of embryonic development. It is in these very first stages that pluripotency is established in the mouse embryo, and the dynamics of this embryonic stage have profound implications on how pluripotency is programmed in development. What we have found is that the same considerations of how biophysics regulates pluripotency in embryonic stem cells have similar consequences in the embryo. Cell and nuclear mechanics are modulated when cells are internalized in the embryo to form the inner cell mass. The inner cell mass then segregates, according to the specific mechanical properties of the cells within the mass, into extraembryonic tissue and the pluripotent epiblast from which embryonic stem cells are harvested. As an outlook, we will explore how the biophysical mechanisms we are observing may play a significant role in feedback loops between transcription and intracellular forces. Our findings could have significant implications for understanding how differentiation and reprogramming are regulated in stem cell biology.

**Identification of non-platelet RNA-containing particles in human umbilical cord blood.**

*W. Kong<sup>1</sup>, M. Nuo<sup>1</sup>, X. Zhu<sup>1</sup>, L. Luo<sup>2</sup>, X. Wang<sup>3</sup>; <sup>1</sup>R&D, Khasar medical technology, Beijing, China, <sup>2</sup>Beijing Hospital, Beijing, China, <sup>3</sup>Beijing University, Beijing, China*

For many years, platelet-rich plasma (PRP) has been considered to have regenerative function. In addition, evidences indicate that exosomes released by stem cells are therapeutic for cardiovascular disease. To clarify the mechanism of the true factors that function on tissue regeneration or repair, we have studies PRP in human umbilical cord blood and mouse blood. In the cultural condition, a group of small particles in PRP can grow from less than 500 nm to 5  $\mu$ m. Under electron microscopy, at least 5 varieties of small non-platelet RNA-containing particles (NPRCPs) were identified. Unlike platelets, these particles do not contain  $\alpha$ -granules, cell organelles or glycogen granules. Most NPRCPs are between 1  $\mu$ m to 5  $\mu$ m, composed of nuclear granules and proteins that locate in a thin bi-layer membrane. Analyses of the contents of the nuclear granules indicate that NPRCPs contain only small RNAs with sizes less than 250 nt; about 30% of them are microRNAs, which is similar to that described to stem cell released exosomes. MicroRNA array analyses indicate that about 40 microRNAs are significantly up-regulated in NPRCPs. Immunofluorescent studies confirm that NPRCPs contain Oct4, sox2, integrin  $\beta$ 1, DDX4, tubulin, and actin. We also have found that GFP-transgenic mouse (GFP was constructed downstream to actin promoter)-derived NPRCPs express GFP. When co-culturing with nucleated cells, the number of NPRCPs decreased, while the number of the new stem cells increased. Immunofluorescent studies indicate that these small new cells express oct4 and sox2. Our data provide strong evidences that NPRCPs are the regenerative factor in PRP. NPRCPs can grow in cultural condition and possibly are from the stem cell exosomes. In addition, NPRCPs are rich in umbilical cord blood and fetal blood, which could explain the better regenerative function of using umbilical cord blood than using adult peripheral blood.

## Ubiquitin and Proteasome Function

2381

### A Temperature-sensitive Mutation in the Ubiquitin-activating Enzyme E1 and its Relation to the Maintenance of Chromosome Integrity.

K. Sugaya<sup>1</sup>, Y. Ishihara<sup>1</sup>, S. Inoue<sup>1</sup>, H. Tsujii<sup>2</sup>; <sup>1</sup>Research Center for Radiation Protection, National Institute of Radiological Sciences, Chiba, Japan, <sup>2</sup>Fukushima Project Headquarters, National Institute of Radiological Sciences, Chiba, Japan

A temperature-sensitive (ts) CHO-K1 mutant tsTM3 exhibits chromosomal instability and cell cycle arrest in S to G<sub>2</sub> phases with decreased DNA synthesis at the nonpermissive temperature, 39°C. Complementation tests with other mutants characterized previously showed that the tsTM3 did not complement with DNA replication-defective ts mutant ts-131b and the ubiquitin-activating enzyme E1 (Uba1) defective ts mutant ts85, suggesting that these mutants harbor same genetic defect. Uba1 catalyze the first step in ubiquitin conjugation to mark cellular proteins for degradation. In addition to regulating protein stability, ubiquitination also participates in a variety of non-proteolytic function including DNA replication and DNA damage repair. To identify the causative mutation, we cloned and sequenced the *Uba1* gene from wild-type and mutant cells. Comparison of these sequences revealed that the mutant phenotype is caused by a G-to-A transition that yields a Met-to-Ile substitution at position 256 in hamster Uba1. The temperature-sensitive defects in tsTM3 were complemented by the expression of the wild-type of Uba1 tagged with green fluorescent protein. We conclude that a ts-mutation of *Uba1* found in tsTM3 cells appears to be a novel mutation which affects the maintenance of chromosome integrity, reflecting the important roles of Uba1 in cellular function.

### Novel small molecule inhibitors of p97 as potential cancer therapeutics.

D. Anderson<sup>1</sup>, E. Emberley<sup>1</sup>, V. Pickering<sup>1</sup>, J. Rice<sup>1</sup>, M. Rolfe<sup>1</sup>, E. Valle<sup>1</sup>, J. Wang<sup>1</sup>, D. Wustrow<sup>1</sup>, B. Yao<sup>1</sup>, H-J. Zhou<sup>1</sup>; <sup>1</sup>Cleave Biosciences, Burlingame, CA

The ubiquitin-proteasome system (UPS) sustains cancer cell viability by regulating proteins that enable pro-survival mechanisms and by alleviating proteo-toxic stress, caused by an imbalance of protein synthesis and degradation. Bortezomib, a proteasome inhibitor approved for the treatment of multiple myeloma and mantle cell lymphoma, has validated the UPS as a target for pharmaceutical intervention. Because of Bortezomib's limited use in the cancer setting, the discovery of novel drugs that target non-proteasomal targets within the UPS will provide novel approaches to exploit cancer cells addiction to protein homeostatic mechanisms.

The AAA-ATPase p97 functions to reshape the proteome by converting chemical energy into mechanical force. p97 oversees several facets of protein homeostasis, including ubiquitin-dependent protein degradation, endoplasmic reticulum-associated degradation (ERAD), protein secretion and autophagy. In pre-clinical cancer model systems, increased autophagic flux has been described as a potential escape mechanism from proteasome inhibition<sup>1</sup>. Moreover, the dependency of certain late-stage tumors on autophagy highlights the importance of this pathway as a pro-survival mechanism<sup>2</sup>. p97's role in the UPS and autophagy suggests that pharmacologically targeting p97 may provide another means to inhibit tumor growth.

N2,N4-dibenzylquinazoline-2,4-diamine (DBeQ) was recently identified from a high-throughput screen as a selective and moderately potent inhibitor of p97<sup>3</sup>. Through structure-activity relationship-based efforts, we have discovered several analogues of DBeQ with increased

potency to 20nM. These compounds also show anti-tumor activity in myeloma and non-small cell lung carcinoma cells. To verify on target activity of this class of inhibitors, we have implemented several cellular reporter assays that readout out specific functions of p97, including ubiquitin-dependent degradation, ERAD, protein secretion and autophagy. Surprisingly, when our DBeQ analogues were tested in this suite of cellular assays, differential inhibition amongst these reporter assays was observed. These findings suggest that chemical inhibition can preferentially block distinct functions of p97, possibly due to separate affinities for p97 in complex with different cofactors. We are currently undertaking biochemical and cellular approaches to further characterize these specific inhibitor effects. Additionally, we are testing these molecules in vivo to determine which cellular activities p97 are most critical for inhibiting tumor growth.

**The organisation and evolution of the Muskelein/RanBPM/CTLH complex.**

*F. Han<sup>1</sup>, O. Francis<sup>1</sup>, J. C. Adams<sup>1</sup>; <sup>1</sup>Biochemistry, University of Bristol, Bristol, United Kingdom*

Ubiquitination is a major form of post-translational modification that regulates protein stability, trafficking and signalling processes in eukaryotes. Substrate specificity is governed by E3 ubiquitin ligases of which there are several hundred in the human genome. Some ubiquitin ligases act as single proteins, others are participants in multi-protein complexes. The goal of our investigations has been to understand the organisation and evolution of a little-studied, multiprotein RING E3 ligase complex, the muskelein/RanBPM/CTLH complex. This complex is conserved between mammals and budding yeast, and five of the components (Rmnd5, Maea, TWA1, RanBPM and muskelein) have a related domain organisation, all containing LisH and CTLH domains. Rmnd5 contains a RING domain and confers E3 ligase activity. However, functions of the complex in yeast and mammals appear distinct. In yeast, the complex acts to degrade fructose 1, 6, bisphosphatase to switch cells to glycolytic metabolism. In mammalian cells, over-expression or knockdown of several components impacts cell morphology and actin organisation. To understand this complex in more depth, we undertook co-immunoprecipitation and protein localisation studies with wild-type or domain deletion forms of the five proteins, in mammalian cells under high, normal, or low glucose conditions. These data have enabled an initial map of organisation of the mammalian complex, in which TWA1 appears central to complex assembly. We also examined the molecular phylogeny of the five components to understand their evolutionary relationships. Muskelein is specific to the opisthokont lineage, whereas RanBPM, Rmnd5, Maea and TWA1 are present in all eukaryotic supergroups. Sequence similarities between the LisH/CTLH domains of Rmnd5 and Maea, and RanBPM and TWA1, respectively, support a model that the encoding genes evolved through a series of gene duplications on the eukaryotic stem lineage, indicating the ancient origin and likely central roles of these proteins in complex organisation and function. These data add to knowledge of the complexity of the ancestral eukaryote.

Supported by the Wellcome Trust and a BBSRC DTG studentship.

**The MARCH8 E3 ubiquitin ligase N-terminus plays an important role in CD44 specificity.**

*C. D. Williamson<sup>1</sup>, C. Eyster<sup>1</sup>, N. Cole<sup>1</sup>, J. Donaldson<sup>1</sup>; <sup>1</sup>NHLBI, National Institute of Health, Bethesda, MD*

Ubiquitination of plasma membrane (PM) proteins can signal changes to their internalization, recycling, or degradation rates and thus plays a critical role in regulating cell surface composition and turnover of PM proteins. E3 ubiquitin ligases are primarily responsible for conferring substrate specificity to ubiquitination reactions. Eleven membrane-associated RING-CH (MARCH) E3 ligases have been identified in humans that ubiquitinate and down-regulate a number of PM proteins. MARCH1 and MARCH8 are closely related multi-pass membrane proteins with similar subcellular distributions at the PM and in endosomes. MARCH1 and MARCH8 can ubiquitinate multiple PM proteins, although little is understood about what dictates their substrate specificities. Here we consider two substrates, CD98 and CD44, which occupy the same subcellular compartments but diverge in their ability to be ubiquitinated by MARCH1 and MARCH8. CD98 and CD44 are PM proteins that are internalized by clathrin-independent endocytosis (CIE) and recycled back to the PM via CIE recycling tubules. In HeLa cells, CD44 and CD98 are long-lived PM proteins. Over-expression of either MARCH1 or MARCH8 elicits the loss of cell surface CD98 through ubiquitination, and its rapid lysosomal degradation. In contrast, while both MARCH1 and MARCH8 co-localize with CD44 in HeLa cells, only MARCH8 causes its degradation. MARCH1 and MARCH8 have U-shaped membrane topologies, with a short ectodomain confined by two transmembrane domains (TMDs) and both N- and C- terminal tails extending into the cytosol. The N-terminus contains a highly conserved catalytic RING domain just upstream of the first TMD. These proteins share ~55% amino acid sequence homology, with the highest variance in the most distal N- and C- terminal sequences. The N-terminus, TMDs, and C-terminal tail have separately been implicated in determining MARCH substrate specificities. To determine the region of MARCH8 responsible for CD44 specificity, we made chimeric MARCH proteins, exchanging portions of the N-terminus, TMDs, and C-terminus of MARCH8 with MARCH1. For all chimeras, CD98 degradation served as a positive control for ubiquitin ligase activity. Surprisingly, the MARCH8 C-terminus was not involved in CD44 recognition. Instead, we found that the N-terminal cytosolic juxta-membrane region of MARCH8, including its RING domain, was important for regulating CD44 degradation. Differing in only 8 amino acids between MARCH1 and MARCH8, this region appears to be involved in conferring CD44 substrate specificity.

**Obscure links and cullin(g) ends.**

*S. Lange<sup>1</sup>, S. Perera<sup>2</sup>, P. Teh<sup>1</sup>, B. Udd<sup>3</sup>, J. Chen<sup>1</sup>; <sup>1</sup>School of Medicine, UC San Diego, La Jolla, CA, <sup>2</sup>Centre of Research Excellence, Randall Division for Cell and Molecular Biophysics and Cardiovascular Division, King's College London, London, United Kingdom, <sup>3</sup>Folkhalsan Institute of Genetics, University of Helsinki, Helsinki, Finland*

The sarcomere, one of the most regular macromolecular assemblies in nature, is the force-generating apparatus in all cross-striated muscles. Despite the seemingly static nature of the sarcomere, its myofibrillar components undergo constant turnover. Sarcomeric proteins like titin or  $\alpha$ -actinin have been known to interact with muscle specific E3-ubiquitin ligases for their subsequent degradation through the ubiquitin-proteasome system. We observed that cullin-RING proteins, ubiquitously expressed E3-ligases that may have distinct properties in cross-striated muscles, also exhibit a sarcomeric localization that is altered in models of cardiac and skeletal myopathy. Recent reports and evidence from experiments on knockout mouse models

indicate that several cullin E3-ligases, their substrate adaptors and regulators, may be linked to obscurin proteins, a family of large sarcomeric proteins that include obscurin, and its close homologue Obsl1.

Using the obscurin knockout mouse model we were able to elucidate the protein turnover mechanism of sAnk1.5, a muscle specific isoform of ankyrin 1.

sAnk1.5 ubiquitylation is tightly regulated by posttranslational modifications, its interaction with the BTB/POZ-domain containing protein KCTD6, and its subcellular compartmentalization by obscurin. KCTD6 represents a novel substrate adaptor for the Z-disc associated cullin-3 E3-ubiquitin ligase. Lack of obscurin reduced sAnk1.5 levels and lead to mislocalization of the sAnk1.5/KCTD6 complex within the sarcomere. Scaffolding functions of obscurin may therefore prevent activation of the cullin-mediated protein degradation machinery and ubiquitylation of sAnk1.5, through sequestration of sAnk1.5/KCTD6 at the sarcomeric M-band, away from the Z-disc associated cullin-3. Regulatory functions of obscurin proteins on cullin-dependent protein turnover may not be restricted to sAnk1.5, as cullin proteins, their substrate adaptors and regulators are altered in muscles of obscurin knockout mouse models.

### Ubiquitination regulates the turnover of Parkinson disease-linked UCH-L1 protein

J. E. McKeon<sup>1</sup>, L-S. Chin<sup>1</sup>, L. Li<sup>1</sup>;

<sup>1</sup>Dept. of Pharmacology, Emory University, Atlanta, GA

Ubiquitin carboxyl-terminal hydrolase L1 (UCH-L1/PARK5) is a neuronally expressed deubiquitinase that has been implicated in familial and sporadic Parkinson disease (PD). UCH-L1 cleaves C-terminal adducts of ubiquitin and has been shown to play an important role in neuronal survival and in maintaining the monomeric ubiquitin pool. Indeed, loss of UCH-L1 expression in mice results in progressive axonal degeneration, learning and motor defects, shortened life span, and reduced monomeric ubiquitin level. However, little is currently known about UCH-L1 function or regulation within the nervous system. Here we report that UCH-L1 is post-translationally modified by ubiquitination. We observed UCH-L1 ubiquitination in cultured cells, mouse brain tissue, and in a cell free *in vitro* system. Our studies have also identified a novel interactor of UCH-L1, an E3 ubiquitin-protein ligase, dubbed UCH-L1 interacting protein (UCHIP), which mediates, at least in part, the ubiquitination of UCH-L1. We found that neither the PD-associated UCH-L1 mutation (I93M) nor the reportedly neuroprotective polymorphism (S18Y) alter interaction between UCH-L1 and UCHIP. Additionally, western blotting analysis of brain tissue from mice lacking UCHIP expression revealed an elevation in the total UCH-L1 protein level, suggesting that UCHIP-mediated ubiquitination may regulate UCH-L1 protein turnover. Our studies have important implications for understanding the role of UCH-L1 in normal neuronal physiology as well as in neurodegenerative disease states.

2387

### SUMO-dependent regulation of the yeast transcription factor Cin5.

S. Park<sup>1</sup>, A. Kitazono<sup>2</sup>; <sup>1</sup>University of Tennessee, Knoxville, Knoxville, TN, <sup>2</sup>Chemistry, Universidad Nacional Agraria La Molina, La Molina, Peru

Cin5/Yap4/Hal6 has crucial roles in the responses to presence of oxidative agents, hyperosmolarity, metals, DNA damage, etc. Yet, *CIN5* was originally isolated in a genetic screen for mutants that exhibit chromosome loss and sensitivity to microtubule inhibitors, phenotypes that are frequently associated with deficient regulation of mitosis. As expected from its many roles, Cin5 functions within an intricate and dynamic network of interactions with

several other transcription factors, regulating expression of hundreds of genes. However, very little is known about how this transcription factor itself is regulated. Expression of Cin5 is induced early in the stress response and phosphorylation by the PKA and GSK3 kinases has been proposed to positively influence its protein stability. However, non-phosphorylatable *cin5* mutants grow as well as wild type in the presence of high salt, suggesting there are other regulatory mechanisms.

In order to learn more about its functions and regulation, we undertook a two-hybrid screen designed to identify proteins that interact with Cin5. Among the proteins identified, several harbored SUMO-interacting motifs and bind to proteins that carry that modification. Thus, these results suggest that Cin5 might be regulated by sumoylation and we have identified two lysine residues as putative targets. These residues were mutated to prevent sumoylation of Cin5 and the mutants have been characterized for changes in localization, protein stability and other phenotypes.

2388

#### **Plant CULLIN3-based E3 ligases and their function in transcriptional processes.**

*L. Chen<sup>1</sup>, H. Hellmann<sup>1</sup>, J. Lee<sup>1</sup>, H. Weber<sup>2</sup>; <sup>1</sup>School of Biological Sciences, Washington State University, Pullman, WA, <sup>2</sup>Department Applied Genetics, Freie University Berlin, Berlin, Germany*

E3 ubiquitin protein ligases play important regulatory roles in cell division, cell cycle control and general development in eukaryotic organisms. Cullin3 (CUL3) and MATH-BTB/POZ domain (BPM) proteins form Cullin3-based ubiquitin E3 ligase (CRL3s) complexes that facilitate ubiquitylation of proteins, which can lead to their degradation via the 26S proteasome. The plant *Arabidopsis thaliana* encodes for six BPM proteins (BPM1 to 6) and two CUL3 proteins (CUL3a and 3b). Here we show that the MATH domain mediates the interaction of BPMs with members of the ERF/AP2 (ethylene-responsive factors/ APETALA2) transcription factors, a large protein family with more than 140 members in *Arabidopsis*. ERF/AP2 proteins are widely involved in developmental processes as well as tolerance towards abiotic stress conditions such as cold, drought, or salt stress. We hypothesized that in plants BPM proteins target a large number of these transcription factors, and that this interaction leads to their ubiquitylation and proteolytic degradation. This hypothesis is supported by our findings that selected members are highly unstable in a 26S proteasome-dependent manner. By using detailed biochemical and genetic analysis, we demonstrate that the observed instability depends on the activity of CUL3-based E3 ligase complexes that employ BPM proteins as their respective substrate adaptors. These results define CUL3-based E3 ligase as central and novel regulators in controlling transcriptional processes in plants.

2389

#### **Identification and characterization of an ENU-induced mutation in *Usp14*.**

*A. Marshall<sup>1</sup>, J. Watson<sup>1</sup>, P-C. Chen<sup>1</sup>, J. Wilson<sup>1</sup>, S. Wilson<sup>1</sup>; <sup>1</sup>University of Alabama Birmingham, Birmingham, AL*

The Ubiquitin Proteasome System (UPS) plays a critical role in many aspects of neurodevelopment, including neurite outgrowth, axon guidance, and synaptogenesis. Work from our laboratory has demonstrated that mutation of the proteasomal deubiquitinating enzyme (DUB) *Usp14* is responsible for the neurodevelopmental defects observed in the *ataxia (ax<sup>1</sup>)* mice. The *ax<sup>1</sup>* mice present with reduced muscle development, motor-end plate disease, loss of synaptic function and premature death. **Therefore, we hypothesize that study of *Usp14***

**deficient mice allows for the discovery of new pathways required for proper structural and functional NMJ development and possible identification of new drug targets for the treatment of motor neuron diseases.** In this study we identified and characterized a new mouse line with an ENU-induced mutation in *Usp14* (*nmf375*). Positional cloning and genetic complementation assays established that the causative mutation in the *nmf375* mice resides in *Usp14*. Sequence analysis of *Usp14* transcripts and genomic DNA revealed a point mutation in the splice site donor region of exon 9 of the *Usp14* gene. Using quantitative PCR and western blot analysis, we determined that the *nmf375* mutation causes mRNA splicing defects leading to a reduction in both the mRNA and protein for Usp14. Instead of exhibiting the NMJ developmental deficits observed in the *ax<sup>l</sup>* mice, the *nmf375* mutant mice display adult onset neuromuscular disease. To determine possible differences between the phenotypes of these two Usp14 mutant mice, we examined genetic background as a contributing factor. While the *ax<sup>l</sup>* mice are maintained on a C57BL/6J background, the *nmf375* arose on BALB/c. C57BL/6J mice containing the *nmf375* mutation are dead at birth and indicate that the *nmf375* mutation is likely to result in a greater reduction in Usp14 levels than *ax<sup>l</sup>* and that the effects of the loss of Usp14 are sensitive to genetic background. Interestingly, we found age dependent differences in proteasomal activity in BALB/c versus C57BL/6J mice that do not appear to be coupled with differences in proteasomal protein levels. These results demonstrate that Usp14 is required for the development and maintenance of the NMJ and that differences in proteasome activity may be responsible for the structural and functional changes seen in the Usp14 deficient mice.

**The deubiquitinating enzyme Ataxin-3 regulates the activity of the ubiquitin ligase Hrd1 in Endoplasmic Reticulum-Associated Degradation.**

A. A. Burr<sup>1</sup>, W-L. Tsou<sup>2,3</sup>, S. V. Todt<sup>2,3</sup>; <sup>1</sup>Oncology, Wayne State University School of Medicine, Detroit, MI, <sup>2</sup>Pharmacology, Wayne State University School of Medicine, Detroit, MI, <sup>3</sup>Neurology, Wayne State University School of Medicine, Detroit, MI

Protein Quality Control (PQC) comprises cellular pathways that regulate the turnover of short-lived, misfolded proteins. Aberrations in PQC have been linked to various malignancies and neurological diseases. A main component of PQC is Endoplasmic Reticulum-Associated Degradation (ERAD), which controls the turnover of proteins synthesized in the Endoplasmic Reticulum. During ERAD, misfolded proteins are recognized, ubiquitinated, extracted into the cytosol and degraded by the proteasome. While significant progress has been made in understanding ERAD, it is not entirely clear how substrate ubiquitination and degradation are regulated. Two proteins associated with ERAD are the E3 ubiquitin ligase HRD1 and the deubiquitinating enzyme (DUB) ataxin-3. Ataxin-3 is of particular interest because mutations in it cause the dominantly inherited neurodegenerative disease Spinocerebellar Ataxia Type 3, one of at least nine polyglutamine-related diseases that include Huntington's Disease and several SCAs. Normal ataxin-3 suppresses neurodegeneration in several *Drosophila* models of polyglutamine disease and protects mammalian cells from proteotoxic stress. The cellular functions of ataxin-3 or how it causes disease are unclear. Here, we present evidence that ataxin-3 and HRD1 functionally interact in ERAD. Ataxin-3 and HRD1 co-immunoprecipitate from mammalian cells and co-localize at the Endoplasmic Reticulum. Ataxin-3 counteracts the positive effect of HRD1 on ERAD substrate degradation in cells. HRD1 makes different types of poly-ubiquitin chains in reconstituted systems *in vitro*, depending on the molecular complex with which it associates. Recombinant ataxin-3 opposes poly-ubiquitin chain formation by HRD1 in a manner that depends on its DUB activity. Ataxin-3 with mutated ubiquitin-interacting motifs does not counteract HRD1 as well as wild type ataxin-3. Also, this DUB can cleave ubiquitin chains formed by HRD1 after their synthesis. These data support a model where ataxin-3 binds ubiquitin chains formed by HRD1 to cleave them, instead of inhibiting the ability of HRD1 to

synthesize poly-ubiquitin *in vitro*. Our work suggests that ataxin-3 balances HRD1 activity, providing clues into the decision between substrate degradation or rescue in ERAD.

**Protein phosphatase PP6 modulates the phosphorylation status of beta-catenin.**

*P. Wang<sup>1</sup>, J. Zhong<sup>1</sup>, X. Xu<sup>1</sup>; <sup>1</sup>Beijing Key Laboratory of DNA Damage Response, Capital Normal University, Beijing, China*

Phosphorylation status of beta-catenin is a key determinant to the Wnt/beta-catenin signaling pathway. It was reported that protein phosphatase PP2A, a member of the type 2A serine/threonine phosphatase family, promotes the Wnt/beta-catenin signaling through dephosphorylation of beta-catenin. In this study, we found that another type 2A phosphatase PP6C physically interacted with beta-catenin and this interaction was enhanced upon activation of the Wnt signal. A PP6C-containing holoenzyme dephosphorylated phosphorylated forms of beta-catenin. Overexpression of PP6C enhanced the Wnt/beta-catenin signaling to a similar degree when PP2A was overexpressed. Taken together, our data suggested that PP6 is involved in the Wnt/beta-catenin signaling pathway through modulation of the phosphorylation status of beta-catenin.

**Brazilin induces p62-mediated autophagy by ubiquitin-proteasome inhibition in rheumatoid fibroblast-like synoviocytes.**

*H. Lee<sup>1</sup>, I. Yoo<sup>2</sup>, S. Song<sup>2</sup>, J. Kim<sup>2</sup>, S. Kang<sup>2</sup>; <sup>1</sup>Rheumatology, Chungnam National University, Daejeon, Korea, <sup>2</sup>Rheumatology, Chungnam Univ. Hospital, Daejeon, Korea*

Brazilin (7, 11b-dihydrobenz[b]indeno[1,2-d]pyran-3,6a,9,10 (6H)-tetrol) isolated from *Caesalpinia sappan*, which possesses chemotherapeutic potential through its ability to suppress inflammation. The objective of this study was to investigate the effect or mechanism of brazilin in fibroblast-like synoviocytes derived from patients with RA.

RA FLS were isolated from fresh synovial tissue biopsy samples obtained from RA patients at total knee arthroplasty. The underlying molecular mechanism for autophagy formation, NF- $\kappa$ B signaling was examined by analyzing transmission electron microscope and immunoblotting.

Treatment with brazilin resulted in non-apoptotic cell death in a caspase-independent manner. In contrast, brazilin in RA FLS robustly elicited accumulation of autophagosome and upregulated p62 expression in RA FLS. Interestingly, such activation of autophagy pathway by brazilin was mediated by enhanced production of ubiquitinated proteins, which mainly accumulated in insoluble fractions. Furthermore, treatment of brazilin drastically suppressed IL-1 $\beta$  and LPS-induced NF- $\kappa$ B activation under the condition of autophagy formation.

The results suggest that brazilin activates p62-mediated autophagy pathway, which in turn results in controls inflammatory process through suppressing NF- $\kappa$ B activation.

**Autophagy and Ubiquitin-Proteasome Pathway are the Keystones of Sperm Mitochondrial Degradation following Mammalian Fertilization.**

*W-H. Song<sup>1</sup>, Y-J. Yi<sup>1</sup>, P. Sutovsky<sup>1</sup>; <sup>1</sup>Division of Animal Sciences, University of Missouri, Columbia, MO*

Autophagy and the ubiquitin-proteasome system (UPS) are the major protein degradation pathways responsible for the removal of outlived proteins, protein-aggregates, and organelles, including mitochondria. Autophagy comprises several processes which ensure selective

degradation of various cellular structures by sequestering them in autophagosomes. In almost all eukaryotes, mitochondria and mitochondrial DNA (mtDNA) are inherited from the maternal parent. This phenomenon cannot be explained solely through dilution of paternal mtDNA. The UPS has long been considered a degradation mechanism for the sperm-contributed paternal mitochondria. Recent studies in *C. elegans* suggest an interplay between proteasome-dependent degradation and mitophagy, but little is known about these events in mammals. Autophagy of sperm mitochondria could occur along three distinct degradation routes leading to autophagic clearance: 1) Autophagy-associated ubiquitin-receptor p62/SQSTM1 recognizes ubiquitinated cargo and interacts with autophagosome-binding ubiquitin-like modifiers, such as LC3 or GABARAP; 2) Ubiquitinated proteins are extracted from mitochondria and from aggresomes, the protein aggregates induced by ubiquitin-binding adaptor protein HDAC6 that transports them along the microtubules; 3) Mitophagy receptor BNIP3L binds to sperm mitochondria inside the fertilized oocyte and targets them toward autophagosome. We hypothesized that boar sperm mitochondria are recognized by the above ubiquitin-binding receptors and specifically degraded by autophagic machinery inside the fertilized porcine oocyte. Oocytes were inseminated with the MitoTracker tagged boar spermatozoa for 6 hrs and cultured with/without the addition of a specific proteasomal inhibitor MG132 for an additional 24 hrs. The GABARAP-positive autophagosomes formed a halo around the sperm nucleus and mitochondrial sheath at 30 hrs post insemination; treatment with MG132 slowed down the degradation of sperm mitochondria and caused the accumulation of the GABARAP in the vicinity of the sperm mitochondria. A change in GABARAP protein band density was observed by Western blotting of MG132-treated oocytes. Other components of the autophagy/mitophagy pathways, including LC3, HDAC6, and BNIP3L, were detected and immunolocalized in the boar spermatozoa and porcine zygotes by immunofluorescence and Western blotting. Immunoprecipitation of GABARAP from porcine zygotes identified two potential co-precipitating proteins, FABP3 and Profilin-1. These preliminary results indicate that autophagy-associated ubiquitin-like protein modifiers could cooperate with ubiquitin-proteasome system during the degradation of boar sperm mitochondria after fertilization.

#### **Impairment in neuronal development with disruption of polyubiquitin gene *Ubb*.**

H-W. Ryu<sup>1</sup>, K-Y. Ryu<sup>1</sup>; <sup>1</sup>Department of Life Science, University of Seoul, Seoul, Korea

Disruption of polyubiquitin gene *Ubb* leads to hypothalamic neurodegeneration and metabolic disorders including obesity and sleep abnormalities in mice. However, it has yet to be identified why the reduced Ub levels due to loss of *Ubb* lead to these neuronal phenotypes and whether these phenotypes are due to the neuronal cell autonomous defects to maintain ubiquitin (Ub) levels. To determine whether the reduced Ub levels in neurons *per se*, but not their cellular microenvironment, are the cause of the neuronal phenotypes observed in *Ubb* knockout mice, we investigated the characteristics of cultured neurons isolated from *Ubb* knockout mouse embryonic brains, particularly on neuronal development and the formation of synapse. We first found that, during the culture of neurons, although wild-type neurons maintained their cell numbers up to 13 days *in vitro*, they were reduced in *Ubb* knockout neurons due to increased apoptosis, with concomitant increase of pro-inflammatory cytokines, such as IL-1 $\beta$  and TNF- $\alpha$ . By immunofluorescence analysis using various neuronal markers, such as  $\beta$  III-tubulin,  $\alpha$ -internexin, and microtubule-associated protein 2, we found that neuronal morphology, neurite outgrowth and axonal development were significantly impaired in *Ubb* knockout neurons. Furthermore, we demonstrated that, although an early neuronal marker ( $\alpha$ -internexin) levels decreased during development in wild-type neurons, they remained similar in *Ubb* knockout neurons, suggesting the delayed or impaired neuronal maturation. In addition, we found that  $\beta$  III-tubulin levels were reduced and the synaptogenesis was impaired in *Ubb* knockout neurons

with decreased synapsin I levels. Intriguingly, we found that Ub conjugates and total Ub levels were significantly reduced in *Ubb* knockout neurons, but not the free Ub levels, which were similar between wild-type and *Ubb* knockout neurons. Despite the upregulation of *Ubc* in *Ubb* knockout neurons, due to the most significant contribution of *Ubb* toward total Ub levels, compensation by the other polyubiquitin gene *Ubc* was not sufficient to bring up total levels of cellular Ub to those of wild-type neurons. However, we were able to restore Ub conjugates and total Ub levels in *Ubb* knockout neurons to those of wild-type neurons by providing extra Ub using lentivirus-mediated delivery. When *Ubb* knockout neurons restored their cellular Ub levels, their behaviors were comparable to wild-type neurons. Combined together, these results suggest that reduced Ub levels in neurons are the intrinsic cause of neuronal phenotypes observed in *Ubb* knockout mice.

**Effect of cellular ubiquitin levels on the oxidative stress response system regulated by the Nrf2-Keap1 pathway.**

M-N. Kim<sup>1</sup>, H-W. Ryu<sup>1</sup>, K-Y. Ryu<sup>1</sup>; <sup>1</sup>Department of Life Science, University of Seoul, Seoul, Korea

Upon exposure to oxidative stress, cellular stress response pathway is activated and the cytoprotective genes are upregulated to increase the likelihood of survival. Among these are polyubiquitin genes *Ubb* and *Ubc*, which were shown to be upregulated by treatment with NaAsO<sub>2</sub>. Here, we found that ubiquitin (Ub)-deficient cells (mouse embryonic fibroblasts and cultured neurons), in which cellular Ub levels were reduced due to disruption of *Ubb* or *Ubc* exhibited reduced viability under oxidative stress induced by NaAsO<sub>2</sub>. Therefore, we hypothesized that the maintenance of cellular Ub levels is important for oxidative stress response and we tested our hypothesis by investigating whether the activation of Nrf2-Keap1 pathway, which is the major oxidative stress responsive pathway in cells, is dependent on cellular Ub levels. We first confirmed that *Ubb* and *Ubc* were indeed upregulated upon treatment with tert-butylhydroquinone (tBHQ), a well-known activator of Nrf2, in a dose-dependent manner. We then found that the levels of Nrf2 were significantly increased in wild-type cells with tBHQ treatment for 5-10 h, but their levels were much lower in Ub-deficient cells. Furthermore, upon treatment with emetine to block the protein synthesis, we demonstrated that Nrf2 was degraded in a time-dependent manner in wild-type cells, which was completely abolished by co-treatment with tBHQ. However, in Ub-deficient cells, this stabilization of Nrf2 was hardly observed. Reduced Nrf2 levels upon tBHQ treatment in Ub-deficient cells were also confirmed by immunofluorescence analysis. When Nrf2 was stabilized, we found that Nrf2 was almost exclusively localized to the nucleus of wild-type cells, however, the Nrf2 immunoreactivity in the nucleus and the percentage of cells with nuclear Nrf2 were reduced in Ub-deficient cells. Furthermore, we found that, although target gene expression levels, such as *Gstp1* and *Nqo1*, were increased upon activation of Nrf2 in wild-type cells, this increase was less significant in Ub-deficient cells. We believe that, although degradation or stabilization of Nrf2 is tightly regulated in wild-type cells in the absence or presence of stress, this tight regulation seems to be weakened when ubiquitin-proteasome system is impaired due to the reduced cellular Ub levels. In sum, these results suggest that reduced viability of Ub-deficient cells under oxidative stress could, at least in part, be due to impaired activation of Nrf2, which results in the diminished cytoprotective response of cells.

2396

**The essential role played by FAT10 promoter in the pathogenesis of Mallory-Denk bodies (MDBs) formation.**

S. W. French<sup>1</sup>, B. A. French<sup>1</sup>, B. Tillman<sup>1</sup>, F. Bardag-Gorce<sup>2</sup>, J. Li<sup>2</sup>, J. Oliva<sup>2</sup>, A. Canaan<sup>3</sup>;  
<sup>1</sup>Pathology, Harbor ucla med center, torrance, CA, <sup>2</sup>Pathology, Harbor ucla med center, Torrance, CA, <sup>3</sup>Genetics, Yale University Med School, New Haven, CT

Mallory-Denk bodies (MDBs) are aggresomes composed of undigested ubiquitinated short lived proteins which have accumulated because of a decrease in the rate of their degradation by the 26s proteasome. The decrease in the activity of the proteasome is due to a shift in the activity of the 26s proteasome to the immunoproteasome triggered by an increase in expression of the catalytic subunits of the immunoproteasome which replaces the catalytic subunits of the 26s proteasome. This switch in the type of proteasome in liver cells is triggered by the binding of IFN $\gamma$  to the IFN $\gamma$  sequence response element (ISRE) located on the FAT10 promoter. To determine if either FAT10 or IFN $\gamma$  are essential for the formation of MDBs we fed both IFN $\gamma$  and FAT10 knock out (KO) mice DDC added to the control diet for 10 weeks in order to induce MDBs. Mice fed the control diet and Wild type mice fed the DDC or control diet were compared. MDBs were located by immunofluorescent double stains using antibodies to ubiquitin to stain MDBs and FAT10 to localize the increased expression of FAT10 in MDB forming hepatocytes. We found that MDB formation occurred in the IFN $\gamma$  KO mice but not in the FAT10 KO mice. Western blots showed an increase in the FAT10 and ubiquitin smears in the Wild type mice fed DDC but not in the FAT10 KO mice. To conclude we have demonstrated that FAT10 over expression is essential to the induction of MDB formation in the DDC fed mice.

**Cdc48 and its adaptor Ubx4 promote mitotic progression by properly localizing the proteasome in the nucleus.**

C-Y. Chien<sup>1</sup>, R-H. Chen<sup>1</sup>; <sup>1</sup>Institute of Molecular Biology, Academia Sinica, Taipei, Taiwan

Cdc48 is a member of the AAA-ATPase family and has diverse functions in membrane fusion, protein degradation, and cell cycle. These functions are mediated by specific adaptors of Cdc48. We found that the adaptor Ubx4 was not essential for cell viability in the budding yeast *Saccharomyces cerevisiae*, but its deletion was synthetic-lethal with *cdc48-3* temperature-sensitive mutant. Repressing Ubx4 expression through the GAL promoter in combination with *cdc48-3* mutation caused mitotic arrest with sustained mitotic regulators Clb2 and Cdc20 that are normally degraded in anaphase through the E3 ubiquitin ligase Anaphase Promoting Complex (APC). The mitotic arrest was independent of spindle checkpoint and any defect in APC. Interestingly, the cell growth and proteolytic defects of *ubx4 cdc48-3* can be partially rescued by overexpression of Rpn4, the transcriptional activator for proteasome subunits, indicating that the proteasome function is compromised. Indeed, the proteasome visualized by GFP-tagged subunit Pre6 forms a nuclear aggregate in *ubx4 cdc48-3*, instead of its normal distribution in the nucleus. Furthermore, Ubx4 associates with the proteasome through its amino-terminal UBL domain. Our study reveals that mitotic progression requires properly localized proteasome that is mediated by the chaperone Cdc48-Ubx4.

**ZBTB20 interacts with the SUMO-conjugating enzyme UBC9 and is a novel target for SUMOylation.**

R. Koul<sup>1</sup>, A. K. Srivastava<sup>1</sup>; <sup>1</sup>Genetics and Biochemistry, Clemson University / J.C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC

Autism spectrum disorder (ASD) and intellectual disability (ID) are the two most frequently reported, often co-morbid, neurodevelopmental disorders that affect children all over the world. Recently, we identified mutations in the ZBTB20 gene which were associated with susceptibility to ASD and ID. The gene is highly expressed in developing brain and encodes a protein of a BTB (broad complex, tramtrack, bric-a-brac) – zinc finger family of transcription factors. The ASD and ID-associated ZBTB20 missense mutations affected dendritic and synaptic structure of pyramidal neurons.

To elucidate the potential molecular links and pathways by which the ZBTB20 protein functions in neuronal cells, we looked for brain-expressed proteins that interact with ZBTB20. Using a yeast-two-hybrid screen, we identified several proteins that interact with ZBTB20 including the E2 SUMO conjugating enzyme UBC9, suggesting that ZBTB20 likely undergoes SUMOylation. The interaction of ZBTB20 and UBC9 was confirmed by co-immunoprecipitation and co-localization analyses of both proteins expressed in transfected HEK293H cells. Subsequently, we confirmed that ZBTB20 contains two putative conserved SUMOylation (ΨKXE) motifs. We further showed that ZBTB20 undergoes SUMOylation in transfected cells, binds SUMO-1, and the N-terminal region of ZBTB20 is critical for its interaction with UBC9. Mutations altering either of the two putative SUMO motifs had no effects on the subcellular localization of ZBTB20 in mammalian cells. However, deleting the conserved lysine residue (K330) in motif 1, but not the conserved lysine residue (K371) in motif 2, adversely affected SUMO-1 binding to ZBTB20. These findings suggest that residue K330 is the primary target for *in vivo* SUMOylation. The post-translational modification SUMOylation is a major regulator of functional properties of many proteins implicated in human neurological disorders and plays a key role in neuronal function. Further studies will help understand the effect of SUMOylation in the regulation of ZBTB20 physiological functions in neuronal cells and its potential role in ASD and ID.

**Nuclear transport of cell surface EGF receptor and ErbB-2 is regulated through integral membrane-bound trafficking.**

Y-N. Wang<sup>1,2</sup>, H-H. Lee<sup>1,3</sup>, H-J. Lee<sup>1,3</sup>, Y. Du<sup>1</sup>, H. Yamaguchi<sup>1</sup>, M-C. Hung<sup>1,2,3</sup>; <sup>1</sup>Department of Molecular and Cellular Oncology, The University of Texas MD Anderson Cancer Center, Houston, TX, <sup>2</sup>Center for Molecular Medicine and Graduate Institute of Cancer Biology, China Medical University, Taichung, Taiwan, <sup>3</sup>Cancer Biology Program, The University of Texas Graduate School of Biomedical Sciences at Houston, Houston, TX

Multiple cell surface receptor tyrosine kinases (RTKs), such as FGF receptor-1 (FGFR-1), IGF receptor, cMet, VEGF receptor, and the four members of EGF receptor (EGFR) family, have been reported to localize in the nucleus. Among these, both full-length nuclear EGFR and ErbB-2 have been shown to be involved in transcriptional regulation, cell proliferation, DNA repair, DNA replication, and chemo- and radio-resistance. Recent studies have demonstrated that

endocytosis and importin  $\beta$  are involved in the nuclear transport of cell surface RTKs, including EGFR, ErbB-2, and FGFR-1. We previously showed that cell surface EGFR is translocated to the nucleus via a retrograde route from the Golgi to the endoplasmic reticulum (ER) and then EGFR is targeted to the inner nuclear membrane (INM) through the INTERNET (integral trafficking from the ER to the nuclear envelope transport) pathway. Nevertheless, the nuclear trafficking mechanisms of other membrane RTKs, apart from EGFR, remain unclear, which dampened progress of this important area that has been overlooked for decades. To expand our knowledge of the trafficking mechanisms of various nuclear RTKs, we compared the nuclear transport of EGFR family proteins with that of FGFR-1, since FGFR-1 has an atypical transmembrane domain, which is different from EGFR. In this study, we used the digitonin permeabilization system and sub-nuclear fractionation assays to investigate the difference between the two pathways of nuclear trafficking in EGFR/ErbB-2 and FGFR-1. We interestingly found that the membrane-bound INTERNET mechanism regulates the nuclear trafficking of EGFR/ErbB-2 but not that of FGFR-1. We further demonstrated that the ER translocon Sec61 $\beta$  localized in the INM is involved in releasing ErbB-2 from the INM to the nucleoplasm, which is similar to the nuclear trafficking of EGFR. This novel discovery as location and function of translocon Sec61 in the INM may serve as a general mechanism for nuclear translocation of other cell surface receptors. Together with previous studies, our proposed model timely provides a comprehensive membrane-bound trafficking pathway for the nuclear translocation of cell surface EGFR/ErbB-2, but not for that of FGFR-1. Thus, at least two different pathways exist to translocate cell surface receptors into the nucleus. This provides a new direction for investigating the trafficking mechanisms of various nuclear RTKs. Understanding the trafficking mechanisms as to how RTKs are transported from the cell surface to the nucleus will significantly contribute to understanding the functions of nuclear RTKs and identifying potential therapeutic targets for clinical application.

#### **Activation of Epidermal Growth Factor Receptor Modulates Bmi-1 Protein Level through miRNAs in Lung Adenocarcinomas.**

*E-H. Lin<sup>1</sup>, H-Y. Chang<sup>1</sup>, C-W. Wu<sup>1</sup>; <sup>1</sup>Institute of Biochemistry and Molecular Biology, National Yang Ming University, Taipei, Taiwan*

Bmi-1 is a member of the Polycomb Repressive Complex 1 (PRC1) that functions in the epigenetic silencing of genes governing self-renewal, differentiation, and proliferation. Bmi-1 was originally identified as an oncogene cooperating with c-Myc in c-Myc-induced lymphomagenesis. Later, Bmi-1 upregulation was found in a wide spectrum of human cancer types. In lung adenocarcinomas (LAC), ectopic expression of Bmi-1 shows an inverse correlation with the INK4 locus proteins (p16/p14ARF), and is associated with tumor progression. Although Bmi-1 has been suggested to regulate cancer cell growth and metastasis, how Bmi-1 is regulated in LAC remains unclear. Here, we show that Bmi-1 is specifically overexpressed in protein, but not in mRNA level, in LACs with EGFR mutations. In LAC cells with wild-type EGFR, addition of EGF ligand or overexpression of mutant EGFR enhanced Bmi-1 protein level within 24 hr. In contrast, overexpression of mutant K-Ras did not alter the Bmi-1 level. Further investigations identified that EGFR enhanced the Bmi-1 protein level through modulation of miRNAs including miR-200. Knockdown of Bmi-1 or overexpression of miR-200 severely blocked the colony forming and migration/invasion activities, and downregulated the (epithelial-mesenchymal transition) EMT markers in LAC cells. In conclusion, these results showed that in LACs, EGFR signaling modulates Bmi-1 protein level through miRNAs, which in turn drives the cell growth, EMT, and metastasis.

**Flotillin mediated stabilization of the receptor tyrosine kinase ErbB2.**

S. Pust<sup>1,2</sup>, T. I. Klokk<sup>1,2</sup>, N. Musa<sup>1,2</sup>, M. Jenstad<sup>2,3</sup>, B. Risberg<sup>3,4</sup>, B. Erikstein<sup>5</sup>, L. Tcatchoff<sup>1,2</sup>, K. Liestøl<sup>6</sup>, H. E. Danielsen<sup>3</sup>, B. van Deurs<sup>6</sup>, K. Sandvig<sup>1,2,7</sup>; <sup>1</sup>Dept. of Biochemistry, Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway, <sup>2</sup>Faculty of Medicine, Centre for Cancer Biomedicine, Oslo, Norway, <sup>3</sup>Institute for Medical Informatics, Oslo University Hospital, Oslo, Norway, <sup>4</sup>Department of Pathology, Oslo, Norway, <sup>5</sup>Oslo University Hospital, Oslo, Norway, <sup>6</sup>University of Copenhagen, Copenhagen, Denmark, <sup>7</sup>Faculty of Mathematics and Natural Sciences, Oslo, Norway

The receptor tyrosine kinase ErbB2 is a member of the epidermal growth factor receptor (EGFR) family. Amplification and overexpression of ErbB2 occur in up to 30% of all human breast cancers and high ErbB2 levels are correlated to poor prognosis for breast cancer patients. In contrast to the EGFR, ErbB2 receptors have low rates of endocytosis and are continuously recycled back to the cell surface. The low internalization rate results from Hsp90 mediated stabilization of ErbB2 at the membrane. Inhibition of Hsp90 by geldanamycin (GA) or analogues (e.g. 17-AAG/tanespimycin) leads to efficient downregulation and degradation of ErbB2. We elucidated a new function of flotillins, involved in the stabilisation of ErbB2 at the plasma membrane. In SKBR3 breast cancer cells and breast cancer tissue, a positive correlation between flotillin and ErbB2 expression levels could be demonstrated. Moreover, tissue microarray analyses of biopsies from 194 patients diagnosed with carcinomas of the breast showed that flotillin-2 emerged as a potential predictor of prognosis in breast cancer. Interestingly, depletion of flotillin-1 and flotillin-2 leads to internalisation and degradation of ErbB2. Furthermore, flotillin-1 and -2 were found to be in a molecular complex with ErbB2 and Hsp90. The depletion or functional inhibition of one of these proteins results in disruption of this complex, followed by destabilisation of ErbB2 at the membrane, its internalisation and degradation. As a consequence, phosphorylation of ErbB2 is reduced and ErbB2-triggered downstream signalling is inhibited. In summary, our data demonstrate a novel mechanism for interfering with ErbB2 signalling, which potentially can have clinical impact.

2402

**ErbB4 is a glycoprotein that is required for PI3K-Akt-Mdm2 signaling to degrade androgen receptor.**

P-C. Kuo<sup>1</sup>, T-W. Ma<sup>1</sup>, P-H. Chen<sup>1</sup>, H-P. Huang<sup>1</sup>, Y-P. Tsao<sup>2</sup>, S-L. Chen<sup>1</sup>; <sup>1</sup>Microbiology, National Taiwan University, Taipei, Taiwan, <sup>2</sup>Ophthalmology, Mackay Memorial Hospital, Taipei, Taiwan

Here we characterized ErbB4 (JMb/CYT1) as an N-glycosylated protein. With similar organization of extracellular domains to EGFR, of which the N-glycosylation sites were determined; accordingly we defined asparagine at the 358th amino acid of ErbB4 as an N-glycosylation site. The glycosylation is required for tyrosine autophosphorylation of ErbB4 that then stimulates PI3K/Akt/Mdm2 pathway resulting in AR polyubiquitylation/proteasome-mediated degradation. Hence ErbB4 can abolish the proliferation of prostate cancer cells. In this study, we provide the mechanisms of ErbB4 (JMb/CYT1) down-regulates proliferation rates of prostate cancer cells via PI3K-Akt-Mdm2 signalings. Additionally, 358th (Asn) of ErbB4 is an important N-glycosylation site for ErbB4-inducing PI3K-Akt-Mdm2 activation.

**FAM83A confers EGFR-TKI resistance in breast cancer.**S. Furuta<sup>1</sup>, S.-Y. Lee<sup>2</sup>, R. Meier<sup>3</sup>, M. E. Lenburg<sup>4</sup>, P. A. Kenny<sup>5</sup>, R. Xu<sup>6</sup>, M. J. Bissell<sup>1</sup>;<sup>1</sup>Department of Cancer and DNA Damage Repair, Lawrence Berkeley National Laboratory, Berkeley, CA, <sup>2</sup>Department of Molecular Biology, Pusan National University, Busan, Korea,<sup>3</sup>Sanofi-Aventis, Geneva, Switzerland, <sup>4</sup>Department of Pathology and Laboratory Medicine, Boston University School of Medicine, Boston, MA, <sup>5</sup>Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY, <sup>6</sup>Department of Molecular and Biomedical Pharmacology, University of Kentucky College of Medicine, Lexington, KY**Abstract**

Epidermal growth factor receptor (EGFR) is overexpressed often in breast carcinomas and correlates with poor prognosis. Therapeutic use of EGFR tyrosine kinase inhibitors (TKIs) for breast cancer treatment, however, is hampered by resistance, and the mechanisms remain largely unknown. EGFR mutations are rare in breast cancer, pointing to the need for further exploration of alternative mechanisms for EGFR-TKI resistance. We hypothesized that resistance may originate, at least in part, from molecular alterations that activate signaling pathways downstream of EGFR. Utilizing a novel screen based on 'reversion' of malignant breast cells into phenotypically non-malignant cells in three-dimensional gels (3D) after EGFR-TKI treatment (1), we identified FAM83A as a candidate cancer-associated gene capable of conferring resistance to the drug. FAM83A overexpression in breast cancer cells increased proliferation and invasion, and imparted EGFR-TKI resistance both in cultured cells and animals. Tumor cells that survived EGFR-TKI treatment in vivo had upregulated endogenous FAM83A levels. Additionally, FAM83A overexpression dramatically increased the number and size of transformed foci in cultured cells and anchorage-independent growth in soft agar. Conversely, FAM83A depletion in cancer cells led to reversion of the malignant phenotype, delayed tumor growth in mice and rendered cells sensitive to EGFR-TKI. Analyses of published clinical data revealed a significant correlation between high FAM83A expression and poor prognosis in breast cancer patients. We explored the molecular mechanism by which FAM83A exerts its effects on malignant transformation and found that FAM83A interacts with and causes phosphorylation of c-RAF and PI3K p85 subunit, upstream of MAPK and downstream of EGFR (2). These data provide a plausible additional mechanism by which tumor cells can become EGFR-TKI-resistant and suggest that targeting FAM83A (and some of its other family members (3)\*) may increase EGFR-TKI's efficacy for breast cancer treatment.

**Oncogenesis of Pancreatic Ductal Adenocarcinoma by Amplification of a Novel PEAK1/eIF5A/Hypusine Signaling Loop.**R. L. Klemke<sup>1</sup>, J. Kelber<sup>1</sup>, K. Fujimura<sup>1</sup>, T. Wright<sup>1</sup>; <sup>1</sup>Pathology, UC San Diego and Moores Cancer Center, La Jolla, CA

We recently identified PEAK1 (pseudopodium-enriched atypical kinase one, SGK269) as a catalytically active, non-receptor tyrosine kinase, that associates with the actin cytoskeleton and focal adhesions, where it regulates cell migration and proliferation (PNAS 107:10920-5. 2010).

Herein, we assess the roles of PEA1 expression as a biomarker and potential therapeutic target in human malignancies, and determine its mechanism of regulation in cancer cells. PEA1 upregulation occurs in multiple human malignancies including pancreatic ductal adenocarcinoma (PDAC). We find that PEA1 is sufficient and necessary for PDAC tumor growth and metastasis *in vivo*. Importantly, activated KRas induces a robust PEA1-dependent Src/PEA1/ErbB2 tyrosine kinase amplification loop that drives PDAC growth and metastasis. Interestingly, PEA1 protein amplification in PDAC results from a unique mechanism involving KRas-induced amplification of the translation elongation factor, eIF5A, which is activated by hypusine modification of lysine 50. Hypusinated eIF5A is amplified in more than 80% of PDAC patients and correlates with poor patient survival. Inhibition of eIF5A function using shRNA knockdown or pharmacological agents that prevent eIF5A hypusination prevent PEA1 expression and suppresses Src/ErbB2 signaling activities leading to cell cycle arrest and PDAC cell death. Together our findings indicate that activating KRas mutations, seen in the majority of PDAC patients, drive amplification of an eIF5A/PEA1 signaling axis, which controls Src/ErbB2 kinase signaling, PDAC cell growth, and metastasis. We conclude that eIF5A and PEA1 are excellent biomarkers of PDAC and possible new therapeutic targets to treat PDAC patients.

#### **Bax $\Delta$ 2, A Novel Tumor-Generated Functional Bax Subfamily.**

*B. Haferkamp<sup>1</sup>, H. Zhang<sup>1</sup>, J. Xiang<sup>1</sup>; <sup>1</sup>Biological and Chemical Sciences, Illinois Institute of Technology, Chicago, IL*

The pro-death Bcl-2 family protein and tumor suppressor Bax is frequently mutated in tumors with microsatellite instability (MSI). The mutation often results in a “Bax negative” phenotype and therefore is generally thought to be beneficial to the tumor development. Here, we report the identification of a group of novel Bax isoforms, Bax $\Delta$ 2 sub-family, generated by a unique combination of MSI mutation and alternative splicing. Bax $\Delta$ 2 is tumor-specific and only detected in Bax MSI positive cell lines and primary tumors. Bax $\Delta$ 2 turns out to be a potent cell death inducer but, unlike the parental Bax $\alpha$ , does not target to mitochondria. In addition, Bax $\Delta$ 2 selectively sensitizes certain MSI tumor cells to a sub-set of chemotherapeutic agents. Thus, our data provide evidence that mutation and alternative splicing of tumor suppressors such as Bax can result in new functional isoforms that can be detrimental to tumor development. This finding may have important implications in cancer prognosis.

2406

#### **Down Regulation of Gene expression in Cancer by Alteration of RNA Splicing.**

*C. Suh<sup>1</sup>, W. Kang<sup>1</sup>, J. Jang<sup>1</sup>; <sup>1</sup>Inha Univ. School of Medicine, Incheon, Korea*

Fibroblast growth factor (FGF) signaling plays a key role in a variety of processes, including cellular proliferation, cellular differentiation, and carcinogenesis. The FGFR family of membrane-spanning tyrosine kinase receptors consists of four members (FGFR1&#65533;4) that differ in their tissue expression, specificity for ligand, signal pathways, and biological effects.

FGFR3 are a member of FGFR tyrosine kinase proteins that contain an extracellular ligand-binding domain, a single transmembrane domain, and an intracellular tyrosine kinase domain. The extracellular region, which contains two or three Ig-like domains, is important for FGF binding and the subsequent dimerization and activation of FGFRs. FGFR3 is the most frequently affected receptor

with numerous mutations localized in or near the third Ig-like domain or in the sequence linking Ig-like domains II and III.

Alternative mRNA splicing of the FGFR gene specifies the sequence of the COOH-terminal half of Ig-like-III domain, resulting in either the IIIb or IIIc isoform of the FGFR. This alternative splicing event is regulated in a tissue-specific manner and dramatically affects ligand binding specificity.

A nested RT-PCR analysis of FGFR3 from human carcinomas revealed novel mutant transcripts caused by aberrant splicing and activation of cryptic splice sequences. Two aberrantly spliced transcripts were detected with high frequency in 50% of 36 primary tumors and in 60% of 10 human colorectal cancer cell lines.

**Secreted IGFBP3 and SFRP1 mediate cellular senescence.**

*D. J. Elzi<sup>1</sup>, M. Song<sup>1</sup>, K. Hakala<sup>2</sup>, S. T. Weintraub<sup>2</sup>, Y. Shii<sup>1,2</sup>; <sup>1</sup>Greehey Children's Cancer Research Institute, University of Texas Health Sciences Center San Antonio, San Antonio, TX, <sup>2</sup>Biochemistry, University of Texas Health Sciences Center San Antonio, San Antonio, TX*

Cellular senescence is implicated in tumor suppression and organismal aging, but signaling pathways mediating senescence are not well understood. By analyzing the proteins secreted from senescent cells, we identified two novel mediators of senescence.

1) Cancer cells can be reprogrammed to senesce in response to stresses such as chemotherapy. We observed that non-senescent MCF-7 breast cancer cells become senescent upon addition of the conditioned medium from senescent MCF-7 cells induced to senesce by doxorubicin treatment, which suggested the presence of secreted mediator(s) of senescence. Proteomic comparison of protein secretion from senescent and non-senescent MCF-7 cells revealed that IGFBP3 (insulin-like growth factor binding protein 3) is over-secreted from doxorubicin-treated senescent MCF-7 cells. IGFBP3 induced senescence through suppression of AKT and requiring p53 and Rb. We found that IGFBP3 can be cleaved and inactivated by t-PA (tissue-type plasminogen activator), which is in turn inhibited by another known secreted mediator of senescence, PAI-1 (plasminogen activator inhibitor 1). We have discovered a cascade whereby PAI-1 induces senescence through the elevation of IGFBP3 levels. Immunohistochemistry staining of human breast cancer tissues showed co-localization of PAI-1 and IGFBP3 in the tumor epithelium. RNAi suppression of PAI-1 or IGFBP3 inhibited senescence induction upon doxorubicin treatment of MCF-7, indicating that PAI-1 and IGFBP3 mediate doxorubicin-induced senescence in these cells.

2) Employing the quantitative proteomic analysis of secreted proteins, we determined that the Wnt signaling inhibitor SFRP1 (Secreted Frizzled-related Protein 1) is over-secreted from IMR-90 human primary fibroblasts induced to senesce by DNA damage (etoposide treatment). SFRP1 over-secretion occurred upon treatment with different DNA damaging agents or by oxidative stress, and was required for stress-induced senescence. We present evidence suggesting that secreted SFRP1 mediates senescence by inhibiting the Wnt signaling and activating the Rb pathway. Interestingly, cancer-associated SFRP1 mutants were defective for senescence induction.

These studies identified extracellular components of senescence signaling. Senescence mediators secreted from senescent cells may amplify the senescence response and provide a non-cell autonomous tumor suppression mechanism in precancerous cells as well as in chemotherapy-treated tumor cells.

**microRNAs as potential regulators of EGFR therapy resistance in breast cancer cells.**

L. Castillo-Pichardo<sup>1</sup>, L. D. Borrero-Garcia<sup>2</sup>, R. S. Redis<sup>3</sup>, G. A. Calin<sup>3</sup>, L. A. Cubano<sup>4</sup>, S. Dharmawardhane<sup>2</sup>; <sup>1</sup>Pathology and Laboratory Medicine, Universidad Central del Caribe, Bayamón, PR, <sup>2</sup>Biochemistry, University of Puerto Rico-Medical Sciences Campus, San Juan, PR, <sup>3</sup>Department of Experimental Therapeutics, University of Texas-MD Anderson Cancer Center, Houston, TX, <sup>4</sup>Anatomy and Cell Biology, Universidad Central del Caribe, Bayamón, PR

Signaling from epidermal growth factor receptors (EGFRs) is dysregulated in breast cancer, where it is associated with an aggressive phenotype and poor outcome. The success of targeted therapies for EGFR has been marred by *de novo* or acquired resistance. Gefitinib, a small molecule tyrosine kinase inhibitor specific for EGFR, has been used as therapy for advanced non-small cell lung carcinoma. However, clinical trials of gefitinib in breast cancer have failed due to therapy resistance and adverse toxic effects. We developed a gefitinib resistant syngenic variant of the gefitinib sensitive human breast cancer cell line SKBR3 (SKBR3.GR), with the objective of studying the role of microRNAs (miRNAs) in therapy resistance. A screening of miRNAs implicated in therapy resistance demonstrated that miRNA (miR-)200a was downregulated while miR-221 and miR-222 were upregulated in the SKBR3.GR cells compared to the parental cells. The miR-200 family plays a critical role in the suppression of epithelial-to-mesenchymal transition (EMT) by repressing key molecules involved in this process. Additionally, the miR-200 family can regulate tumor cell adhesion, migration, invasion and metastasis; and has been associated with EGFR inhibitor resistance. MiRs-221/222 promote EMT and have also been associated with cancer progression and acquisition of gefitinib therapy resistance in cancer cells. To elucidate the functional significance of the differential expression of miR-200a and miR-221/222 in therapy resistance, we compared the protein expression of known targets of these families in SKBR3.GR and parental cells. Our results show that in SKBR3.GR cells, EGFR expression was significantly increased while EGFR phosphorylation was inhibited by gefitinib treatment. The miR-200 targets Zeb1 and  $\beta$ -catenin, molecules that promote EMT, were significantly upregulated; while the miR-221/222 target PTEN, a tumor suppressor, was downregulated in SKBR3.GR cells. Our results suggest that decreased miR-200a levels, and thus, increased Zeb1 and  $\beta$ -catenin, a potent pro-cancer transcriptional activator; and elevated miR-221/222 expression, that downregulates the expression of tumor suppressors, are potential mechanisms of gefitinib resistance in aggressive breast cancer.

This study was supported by NIH/NIGMS SC3GM094824 to SD, the UCC Pilot Project Program, Title V PPOHA grant number PO31M105050 from U.S. Department of Education to LAC, and the UCC Postdoctoral Program sponsored by the PR Science, Technology and Research Trust.

**Cooperative phosphorylation of two kinases for the phosphorylation of FADD-serine 194.**

Y-J. Do<sup>1,2</sup>, M-S. Jang<sup>3</sup>, E. Kim<sup>1,2,4</sup>; <sup>1</sup>College of Biological Sciences and biotechnology, Chungnam national university, Daejeon, Korea, <sup>2</sup>BK21 Daedeok R&D Innopolis Bio Brain Center, Chungnam national university, Daejeon, Korea, <sup>3</sup>Samsung medical center, Seoul, Korea, <sup>4</sup>Graduate School of New Drug Discovery and development, Chungnam national university, Daejeon, Korea

Previous study [Mol. Cell, **19**:321-32, 2005; Cancer Res., **71**:7207-15, 2011] described that FADD can be phosphorylated at serine 194 by casein kinase 1 $\alpha$  (CK1 $\alpha$ ) and/or polo-like kinase 1 (Plk1) upon taxol treatment. However, the regulatory mechanism between CK1 $\alpha$  and Plk1 in phosphorylating FADD is yet to be clarified. In this study, we demonstrate the presence of

physical interaction and functional interplay between CK1 $\alpha$  and Plk1 in response to taxol treatment. Phosphorylation of FADD by Plk1 was clearly inhibited in CK1 $\alpha$ -depleted cells, whereas that by CK1 $\alpha$  remained unchanged in Plk1 depleted cells. Therefore, our results indicate that CK1 $\alpha$  acts upstream of Plk1 in phosphorylating FADD. Moreover, the catalytic domain of Plk1 (a.a 1 - 308) bound CK1 $\alpha$ . Therefore, this study adds CK1 $\alpha$  to the list of upstream kinases of Plk1. Collectively, our data demonstrate the presence of cooperative action between CK1 $\alpha$  and Plk1 to phosphorylate FADD. [This research was supported by the grant (KDDF-201202-10) from the Korea Drug Development Fund, and by grant (2011-0031223) from the National Research foundation at the Ministry of Education, Science and Technology in Korea.]

### **Critical role for Pim kinase-phosphorylated eIF4B in cellular transformation by v-Abl and Bcr-Abl oncogenes.**

*J. Yang<sup>1</sup>, K. Chen<sup>1</sup>, J. Wang<sup>1</sup>, G. Guo<sup>1</sup>, J. Chen<sup>1</sup>; <sup>1</sup>Institute of Microbiology, Chinese Academy of Sciences, Beijing, China*

Eukaryotic initiation factor 4B (eIF4B) is a multidomain protein that plays a critical role in the initiation of protein synthesis and has been known as a hyperphosphorylated protein. The Pim kinase family, which is consisted of three members: Pim-1, Pim-2, and Pim-3, has been implicated in various cellular processes including cell proliferation and survival and tumorigenesis. We demonstrated that Pim-1 physiologically interacts with eIF4B. Pim-1, Pim-2 but not Pim-3 could increase phosphorylation levels of eIF4B on Ser406 and Ser422 in HEK293T cell. Pim-1 and Pim-2 kinase directly phosphorylated eIF4B on Ser406 and Ser422 in vitro kinase assay. Interestingly, we found that Pim kinases in v-Abl transformed cells can enhance the expression and the phosphorylation of eIF4B protein. Our results also revealed that the expression and phosphorylation of eIF4B are Abl kinase-dependent because treatment with Abl kinase inhibitor disrupts these processes. Furthermore, phosphorylation of eIF4B was shown to be highly sensitive to Pim kinase inhibitor STI-4a and ectopic expression of eIF4B phosphomimetic mutants could promote survival of Abl-transformed cells treated with the Pim kinase inhibitor. In addition, eIF4B knockdown sensitizes v-Abl transformed cells to apoptosis and attenuated tumorigenicity of K562 cells. Abl transformation efficiency of bone marrow cells derived from eIF4B knockdown mice was greatly reduced as compared with wild-type mice. Together, we have identified eIF4B as a novel substrate of Pim kinases in Abl transformed cells. Our observations suggest that eIF4B may mediate some of the effects of the Pim kinases on hematopoietic cell transformation. The results reveal a novel Pim kinase-dependent eIF4B activation that plays a crucial role in Abl-mediated tumorigenesis.

### **Hsc70 functions as a novel interaction protein of Cx43 in G1/S transition.**

*T. Hatakeyama<sup>1</sup>, P. Dai<sup>1</sup>, Y. Harada<sup>1</sup>, H. Hino<sup>1</sup>, H. Tanaka<sup>1</sup>, T. Takamatsu<sup>1</sup>; <sup>1</sup>Department of Pathology and Cell Regulation, Kyoto Prefectural University of Medicine, Kyoto, Japan*

Heat shock cognate protein 70 (Hsc70) is a member of the heat shock protein 70 family, which shuttles between the cytoplasm and the nucleus and serves as a molecular chaperone. Several reports show that Hsc70 is involved in cell cycle progression during G1/S transition. Connexin 43 (Cx43) is known to act as a tumor suppressor. However, the underlying mechanisms of Cx43-mediated tumor suppression are still poorly understood.

To clarify the role of Hsc70 in Cx43-mediated cell cycle suppression, in this study, we used a proteomics approach to identify the novel Cx43-interacting partners, which are involved in Cx43-

mediated suppression of the cell cycle. We have identified a Cx43-interacting protein, Hsc70, from whole cell lysate of Huh-7 cells, which express Cx43 abundantly.

We confirmed that the Hsc70 directly binds to the C-terminal domain of Cx43 in vitro and in vivo. Overexpression of Cx43 in Huh-7 cells significantly suppresses cell proliferation. This suppression is abolished by co-overexpression with Hsc70. Taken together, our findings reveal that the Cx43-Hsc70 interaction might play an important role in Cx43-mediated tumor suppression.

### **Identification of the Molecular Machinery Regulating the Notch ligand Delta.**

*G. Assaker<sup>1</sup>, A-S. Guenier<sup>1</sup>, J. Duchaine<sup>1</sup>, G. Emery<sup>1</sup>; <sup>1</sup>IRIC-Université de Montréal, Montréal, QC, Canada*

#### **Introduction:**

The signaling receptor Notch plays a key role in stem cell self-renewal, cell proliferation, cell differentiation, and apoptosis. Consequently, it is involved in many diseases and cancers. Notch signaling is regulated by various cellular processes, including modulation of the activity of Notch ligands. These ligands need to be ubiquitinated, endocytosed, and in some cell types recycled back to the plasma membrane to trans-activate Notch. It has been suggested that the ligand Delta is processed while trafficking through endocytic compartments, but the nature of this putative modification is unknown. The aim of this project is to identify the molecular mechanisms regulating the activity of Delta, and subsequently modulating the signaling levels of Notch.

#### **Methods and findings:**

In order to identify new regulators of Delta, we performed a genome-wide shRNA screen using an in vitro Notch co-culture assay. We used the well characterized OP9-DL1 cell line as a signal-sending cell, and HeLa cells that natively express the Notch receptor as signal-receiving cells. Notch activity was monitored in HeLa cells using a luciferase reporter that we had cloned and stably transfected in these cells. We are currently developing various secondary assays in order to validate our screen. First, we will eliminate false positives, and then we will perform functional assays to identify which candidates are relevant for physio-pathological conditions. Some of the interesting hits that came out from the primary screen include endocytic regulators of Delta, components of the ubiquitination machinery, and genes involved in diseases/cancers.

#### **Conclusion and relevance:**

This project represents a unique opportunity to identify new regulators of Notch signaling, with potential application in the clinical field in order to develop new therapeutic targets for cancers involving Notch.

### The Nanomechanical Signature of Breast Cancer.

M. Plodinec<sup>1</sup>, M. Loparic<sup>1</sup>, C. A. Monnier<sup>1</sup>, E. Obermann<sup>2</sup>, R. Zanetti-Daellenbach<sup>3</sup>, P. Oertle<sup>1</sup>, J. T. Hyotyla<sup>1</sup>, U. Aebi<sup>4</sup>, M. Bentires-Alf<sup>5</sup>, C-A. Schoenenberger<sup>1,4</sup>, R. Y. Lim<sup>1</sup>; <sup>1</sup>Biozentrum and the Swiss Nanoscience Institute, University of Basel, Basel, Switzerland, <sup>2</sup>Institute of Pathology, University Hospital Basel, Basel, Switzerland, <sup>3</sup>Department of Gynecology and Gynecological Oncology, University Hospital Basel, University of Basel, Basel, Switzerland, <sup>4</sup>Maurice E. Mueller Institute for Structural Biology, Biozentrum, University of Basel, Basel, Switzerland, <sup>5</sup>Mechanisms of cancer, Friedrich Miescher Institute for Biomedical Research, Basel, Switzerland

Tumor mechanobiology is an important yet unresolved aspect of cancer progression. How the mechanical properties of cells evolve from a healthy stage to malignancy and manifest themselves in tissues is poorly understood. Here, we report on identifying individual stages of tumor progression in native human breast biopsies by means of their distinct nanomechanical signatures. Indentation-type atomic force microscopy (IT-AFM) analysis provided detailed maps of stiffness properties for normal, benign and malignant mammary tissues. Healthy ductal epithelium and benign lesions each exhibit uniform stiffness profiles with a distinct peak. Accounting for tissue heterogeneity, primary cancer lesions are characterized by a broad stiffness distribution with a prominent soft peak representing cancer cells. These findings are validated by the stiffness profiles from specific stages of tumor progression in MMTV-PyMT transgenic mice. Correlative analysis of extracellular matrix and cytoarchitecture show that invasive cancer tissues exhibit disorganized laminin-1, which indicates a loss of epithelial polarity typically associated with malignancy and invasiveness. In addition, collagen I was largely absent within nests of cancer cells and appeared far less structured in the nearby stroma compared to the tumor periphery. At the cellular level, a distinct co-expression of desmin and vimentin, both markers of epithelial-mesenchymal transition (EMT), was found in soft cancer cells. As a known promoter of aggressiveness and invasion, our nanomechanical data indicate that soft hypoxic regions have increased migration potential at the late cancer stage. Detecting the soft phenotype in lung metastasis suggests that the compliance of malignant cells in the primary tumor is correlated to the cancer metastasis. Our study reveals the clinical translational significance of nanomechanical signatures as potential diagnostic and prognostic markers of breast cancer.

### Electrically monitoring effects of transforming growth factor-beta on wound healing migration of breast cancer cells.

Y-C. Wu<sup>1</sup>, C-M. Lo<sup>1</sup>; <sup>1</sup>Biomedical Engineering, National Yang-Ming University, Taipei, Taiwan

The motility of cancer cells has been widely studied and considered as an intrinsic component of the metastasis process. Previous studies have indicated that transforming growth factor-beta (TGF- $\beta$ ) can activate downstream signaling pathways of breast cancer cells and facilitate their invasion and metastasis in vivo. The conventional methods to detect cell motion, however, are often qualitative and require human judgment or involve the acquisition of video images and subsequent processing of large amounts of data. The scratch assay is a widely used technique to investigate wound healing processes, but its reproducibility is low due to the lack of a defined wound gap between cells. Here, we applied electric cell-substrate impedance sensing (ECIS) to monitor and examine the effect of TGF- $\beta$  on breast carcinoma cells. The ECIS technique is an

approach to monitor the impedance of a small gold electrode used as a substratum for cells in culture. Fluctuations in impedance measured with this approach have been experimentally related to cell motility. We took wound-healing and micromotion measurements on MCF-7 and MDA-MB-231 cell layers, a non-invasive and a highly invasive human breast carcinoma cell lines. Our data showed that the wound healing rate of MDA-MB-231 cells significantly increased after cells were treated with 10 ng/ml of TGF- $\beta$ . In addition, an increase in the motile behavior of MDA-MB-231 cells was observed by the micromotion measurement for about 20-hr long though the effect decreased over time. On the contrary, exposure to TGF- $\beta$  caused little effect on MCF-7 cells. The results suggest that treatment of MDA-MB-231 cells with TGF- $\beta$  facilitates their scattering behavior. Treatment with an inhibitor of TGF- $\beta$  receptor kinase, SB-431542, effectively blocked the effect of TGF- $\beta$  on MDA-MB-231 cells.

2415

#### **Atypical PKC phosphorylates Par6 and facilitates TGF $\beta$ -induced EMT.**

A. D. Gunaratne<sup>1</sup>, J. Di Guglielmo<sup>1</sup>; <sup>1</sup>Western University, London, ON, Canada

Epithelial to mesenchymal transition (EMT) is controlled by cellular signalling pathways that trigger the loss of cell-cell adhesion and lead to the restructuring of the cell cytoskeleton. Transforming growth factor beta (TGF $\beta$ ) has been shown to regulate cell plasticity through the phosphorylation of Par6 on a conserved serine residue (S345) by the type II TGF $\beta$  receptor. Here we show that atypical Protein Kinase C (aPKC) is an essential component to this signalling pathway in non-small cell lung cancer (NSCLC) cells. We observed that the aPKC, PKC $\zeta$  interacts with TGF $\beta$  receptors through Par6, and that these proteins localize to the leading edge of migrating cells. Furthermore, Par6 phosphorylation on Ser 345 by TGF $\beta$  receptors is enhanced in the presence of aPKC. aPKC kinase activity as well as association with Par6 was found to be important for Par6 phosphorylation. Moreover, gene silencing of aPKC reduces TGF $\beta$  induced changes in cell morphology, E-cadherin loss, stress fibre formation and RhoA degradation. Finally, we report that introduction of a phospho-mimetic mutant of Par6 (Par6 S345E) into aPKC silenced cells rescues TGF $\beta$  induced EMT implicating a role for both aPKC and TGF $\beta$  in executing a full EMT phenotype. In conclusion, our results suggest that both aPKCs and the TGF $\beta$  receptors regulate phospho-Par6 levels to drive EMT and cell migration.

2416

#### **TWEAK functions as chemotactic factor for glioma cells via Lyn activation.**

H. D. Dhruv<sup>1</sup>, N. Jameson<sup>1</sup>, F. Patel<sup>1</sup>, M. Nakada<sup>1</sup>, B. Armstrong<sup>1</sup>, J. A. Winkles<sup>2</sup>, M. Berens<sup>1</sup>, N. Tran<sup>1</sup>; <sup>1</sup>Translational Genomics Research Institute, Phoenix, AZ, <sup>2</sup>University of Maryland, Baltimore, MD

The long-term survival of patients with glioblastoma multiforme is compromised by the tumor's proclivity for local invasion into the surrounding normal brain. These invasive cells escape surgery and display resistance to chemotherapeutic- and radiation-induced apoptosis. We have previously shown that tumor necrosis factor-like weak inducer of apoptosis (TWEAK), a member of the tumor necrosis factor superfamily, can stimulate glioma cell invasion and survival via binding to the fibroblast growth factor-inducible 14 (Fn14) receptor and subsequent activation of the Rac1/NF- $\kappa$ B pathway. In addition, we have reported previously that Fn14 is expressed at high levels in migrating glioma cells *in vitro* and invading glioma cells *in vivo*. Here we demonstrate that TWEAK can act as a chemotactic factor for glioma cells, a potential process to drive cell invasion into the surrounding brain tissue. Specifically, we detected a chemotactic migration of glioma cells to the concentration gradient of TWEAK using the Modified Boyden chamber assay. Because TWEAK has been shown to be expressed in normal astrocytes, microglia, and endothelial cells, we neutralized TWEAK using a recombinant soluble murine

Fn14-Fc decoy receptor and examined the effect on glioma cell invasion in the *ex vivo* rat brain slice model. Incubation of the brain slice with the Fn14-Fc decoy receptor reduced glioma cell invasion as compared to control IgG treated brain slice. Since Src family kinases (SFK) have been implicated in chemotaxis, we next determined whether TWEAK:Fn14 engagement activated these cytoplasmic tyrosine kinases. Our data shows that TWEAK stimulation of glioma cells results in a rapid phosphorylation of Src as detected by Western blot analysis using a pan-Src phosphorylation antibody. To determine which SFK member is phosphorylated by TWEAK, we applied the multiplex Luminex assay and identified Lyn as a candidate SFK. Immunoprecipitation of Lyn from TWEAK-treated cells verified that Lyn is phosphorylated as determined by phosphotyrosine immunoblot analysis. Immunodepletion of Lyn by siRNA oligonucleotides suppressed the chemoattractive effect of TWEAK on glioma cells. We hypothesize that TWEAK secretion by cells present in the glioma microenvironment induce invasion of glioma cells into the brain parenchyma. Understanding the function and signaling of the TWEAK-Fn14 ligand-receptor system may lead to development of novel therapies to therapeutically target invasive glioma cells.

**The *Mad1* 1673 G→A alters the function of the mitotic spindle assembly checkpoint and the sensitivity to treatment in patients with ovarian cancer.**

*M. Santibáñez<sup>1</sup>, A. López-Saavedra<sup>1</sup>, D. Prada<sup>1</sup>, J. Mendoza<sup>1</sup>, C. Castro<sup>1</sup>, D. Gallardo<sup>2</sup>, F. Morales<sup>2</sup>, D. Cantú de León<sup>3</sup>, L. Oñate<sup>3</sup>, A. Mohar<sup>1</sup>, L. Herrera<sup>1</sup>*; <sup>1</sup>Unidad de Investigación Biomédica en Cáncer (UIBC), Instituto de Investigaciones Biomédicas-Instituto Nacional de Cancerología (IBB/INCan), Mexico City, Mexico, <sup>2</sup>Departamento de Oncología Médica, Instituto Nacional de Cancerología (INCan), Mexico City, Mexico, <sup>3</sup>Subdirección de Investigación Clínica, Instituto Nacional de Cancerología (INCan), Mexico City, Mexico

**Background:** MAD1, a protein of the mitotic spindle assembly checkpoint (SAC), recognizes MAD2 through two leucine zippers, transporting and activating MAD2, which promotes a metaphase arrest signal. A SNP of *Mad1* was found to affect the SAC function that could be involved in a bad response to therapeutic agents that alter the dynamics of microtubules. **Objective:** To investigate the relationship of the polymorphism *Mad1* 1673 G→A with the efficiency of the SAC and the generation of aneuploidies, and with the therapeutic response of patients with ovarian cancer. **Methods:** The polymorphism was evaluated in 144 healthy individuals and 91 patients. The mitotic arrest and the presence of errors in segregation were analyzed in cultured human lymphocytes treated with nocodazol. Errors in segregation were also evaluated in 27 biopsies of patients. **Results:** Allele frequencies in healthy individuals were G: 50, A: 50, while in the patients, they were G: 38%, A: 62% ( $p < 0.05$ ). The percentage of cells with mitotic arrest was higher in GG cells ( $p < 0.05$ ). The frequency of micronuclei and nondisjunction events increased in AA cells ( $p < 0.05$ ). Tumors from polymorphic patients had a higher percentage of aneuploid cells ( $p < 0.05$ ). The GG patients showed a higher biochemical response, optimal cytoreduction and sensitivity to the treatment. There were no differences in progression-free or overall survival between both groups. **Conclusions:** the polymorphism *Mad1* 1673 G→A affects the SAC functionality, increasing the frequency of aneuploid cells. This polymorphism modifies the response to agents that alter the dynamics of microtubules in patients with ovarian cancer.

2418

**Changes in Cell Signalling and Colocalization of the OTR and AR in Prostate Cancer.**

*M. L. Gould<sup>1</sup>, H. D. Nicholson<sup>1</sup>; <sup>1</sup>Anatomy Department, University of Otago, Dunedin, New Zealand*

Background. Oxytocin (OT) is involved in regulating prostate growth. In normal prostate cells OT inhibits growth. In the androgen independent cancer PC3 cell line, OT and androgen increase cell proliferation. There is only a single isoform of the oxytocin receptors (OTR) and yet, the OT peptide is able to stimulate and inhibit proliferation in the same cell type.

In the cell membrane, there are cave-like invaginations called caveolae and flat lipid rafts. In normal prostate cells, OTR is thought to be localized to caveolae. Here, one of the main signalling pathways is through extracellular-signal-regulated kinases (ERK) phosphorylation resulting in inhibition of cell proliferation. However, in androgen independent prostate cancer, there is a loss of caveolae, so that OTR moves on to the flat part of the cell membrane [Gould et al, 2010]. In androgen independent cancer, androgen receptors (AR) also move from the cell nucleus to become incorporated into the cell membrane [Foradori et al, 2008].

The objective of this study was to investigate a) whether there is a change in ERK activation in PC3 cells and b) whether this is accompanied by colocalization of OTR and AR on the cell membrane.

Methods. Normal human prostate epithelial cells (PrEC) and androgen-independent (PC3) cancer cell lines were cultured in the presence of OT and androgens at varying concentrations for 4 days. The MTS assay measured cell proliferation. Changes in ERK phosphorylation were identified using the In-Cell-Western technique. OTR and AR expression was identified by immunocytochemistry. Colocalization of OTR with AR was identified using double immunolabelling. Colocalization was also measured by Duolink in situ.

Results. Low concentrations of OT alone ( $P=0.026$ ) and OT combined with testosterone (T) ( $P=0.044$ ) were able to stimulate cell proliferation in the PC3, but had no effect on PrEC cells. Treatment of PrEC cells with OT and T stimulated phosphorylation of the ERK signalling pathway, but in PC3 cells no activation of ERK was seen with any treatments. The PrEC cells expressed OTR in the cell membrane and AR in the nucleus, whereas PC3 cells expressed both OTR and AR in the cell membrane. OT or T alone increased colocalization of OTR and AR in the cell membrane of PC3 cells compared to PrEC cells. Colocalization was increased further following treatment with OT and T together.

Conclusion. This study provides evidence that OT and T were able to stimulate cell proliferation in prostate cancer cells and that these changes are accompanied by alteration of ERK phosphorylation. This study also shows an interaction between AR and OTR may occur

**Elevated expression of Fn14 in non-small cell lung cancer correlates with mutant KRAS or amplified MET and promotes tumor cell invasion and metastasis.**

*T. G. Whitsett<sup>1</sup>, S. P. Fortin<sup>1</sup>, L. Inge<sup>2</sup>, A. Riche<sup>2</sup>, P. A. Kurywchak<sup>1</sup>, J. LoBello<sup>3</sup>, C. B. Kingsley<sup>4</sup>, G. J. Weiss<sup>5</sup>, N. L. Tran<sup>1</sup>; <sup>1</sup>Cancer and Cell Biology, TGen, Phoenix, AZ, <sup>2</sup>Heart and Lung Institute, St. Joseph's Hospital and Medical Center, Phoenix, AZ, <sup>3</sup>Integrated Cancer Genomics, TGen, Phoenix, AZ, <sup>4</sup>Diabetes, Cardiovascular and Metabolic Diseases, TGen, Phoenix, AZ, <sup>5</sup>Virginia G. Piper Cancer Center at Scottsdale Healthcare/TGen, Phoenix, AZ*

Lung cancer remains the leading cause of cancer-related deaths in the world. Tumor invasiveness and therapeutic resistance strongly contribute to the low (<10%) five-year survival rate for advanced stage lung cancer; thus, identification of new targets affecting invasiveness and resistance for therapeutic intervention is a necessity. TWEAK (tumor necrosis factor-like

weak inducer of apoptosis) and its receptor, the fibroblast growth factor-inducible 14 (Fn14), are highly expressed in human cancers and play a role in cancer cell proliferation, tumor invasiveness and tumor survival. We have reported that Fn14 is highly expressed in non-small cell lung cancer (NSCLC) and Fn14 expression correlated with EGFR activation. In addition, H1975 cells, resistant to EGFR-tyrosine kinase inhibitors through a secondary mutation (T790M), retain elevated expression of Fn14, while suppression of Fn14 significantly inhibited cell invasion. Amplified c-Met and mutant kRas are also well known drivers of NSCLC aggressiveness and therapeutic resistance. We hypothesize that elevated Fn14 expression can be maintained by mutant kRas or c-Met activation, and that blockade of the TWEAK/Fn14 signaling axis can suppress NSCLC invasiveness and metastasis. Here we show that Fn14 correlated with c-Met activation, and kRas mutation in primary NSCLC tumors. Fn14 and c-Met were highly expressed in metastatic tumors, 86 and 92% respectively, compared to matched primary NSCLC tumors, suggesting a role in the metastatic phenotype. Expression of mutant kRas or amplified c-Met in lung epithelial cells and/or NSCLC cells enhanced Fn14 protein expression, while therapeutic suppression of these driver pathways decreased Fn14 protein expression. Increased expression of Fn14 induced by mutant kRas or c-Met activation was completely abrogated upon MEK inhibition, suggesting a common pathway of Fn14 modulation. Cancer cell migration and invasion driven by the activation of kRas or c-Met was significantly repressed by suppressing Fn14 expression levels. The knockdown of Fn14 in an activating kRas mutation cell line, A549, effectively suppressed *in vivo* metastasis. In the future, we aim to further understand the role and mechanisms governing TWEAK/Fn14 signaling downstream of known driver mutations in NSCLC to support rational therapeutic combinations and inform clinical patient selection for TWEAK/Fn14 inhibition. The TWEAK/Fn14 signaling axis appears to be a vulnerable target in NSCLC invasiveness and survival, including tumors resistant to frontline therapies such as EGFR-TKIs.

#### **Epithelial cells stimulate the formation of protrusions in invasive carcinoma cells.**

*M. Lee<sup>1</sup>, I. Aifuwa<sup>1</sup>, P-H. Wu<sup>1</sup>, D. Wirtz<sup>1</sup>; <sup>1</sup>Johns Hopkins University, Baltimore, MD*

Cell membrane protrusions, including invadopodia and pseudopodia, are critical for metastatic cancer cells to invade basement membrane and migrate through the interstitial matrix of the stroma. However, what factors regulate protrusion formation of invasive carcinoma cells is not fully understood. Here, we provide evidence that proteins secreted by normal breast epithelial cells (MCF10A) dramatically enhance membrane protrusions of invasive breast cancer cells (MDA-MB-231), not non-invasive breast cancer cells (MCF7). After exposure to MCF10A conditioned medium (CM), MDA-MB-231 cells projected multiple thin branching protrusions, while in regular medium (RM) these cells displayed broad membrane ruffling and conventional lamellipodia. Confocal images showed that the CM-induced protrusions were mainly composed of microtubule bundles wrapped by cortical actin filament bundles, a cytoskeletal organization different from filopodia and lamellipodia in MDA-MB-231 cells. The formation of these long protrusions required cooperative assembly of microtubules and actin filaments as well as Src signaling. Depletion of beta 1 integrin in MDA-MB-231 cells made cells insensitive to MCF10A CM, indicating that long protrusions may be induced by soluble extracellular proteins in MCF10A CM. Indeed, the induction of long microtubule-rich protrusions was recapitulated by soluble laminin-332 uniquely secreted by MCF10A. These results reveal a critical role of non-transformed cells in the enhanced formation of protrusions in metastatic carcinoma cells.

**Vimentin – from a marker to an active contributor of EMT.**

*E. Mattila<sup>1,2</sup>, R. Virtakoivu<sup>1,2</sup>, K. Vuoriluoto<sup>1,2</sup>, J. Ivaska<sup>1,2</sup>; <sup>1</sup>Centre for Biotechnology, University of Turku, Turku, Finland, <sup>2</sup>Medical Biotechnology, VTT Technical Research Centre of Finland, Turku, Finland*

Epithelial-mesenchymal transition (EMT) is involved in cancer progression and particularly metastasis, with epithelial cells detaching their cell-cell contacts and adopting fibroblast-like mesenchymal characteristics. The intermediate filament protein vimentin is an important marker of EMT and it also regulates cell migration. We have recently shown that vimentin is functionally involved in cancer cell invasion and EMT maintenance by upregulating several genes involved in EMT, e.g. tyrosine-kinase Axl (Vuoriluoto et al., 2011). This has prompted us to investigate the molecular details underlying the ability of vimentin to regulate EMT-linked proteins in cells.

Several transcription factors have been linked to EMT and cancer cell motility. Our recent data suggest that vimentin is required for the stability of EMT-related transcription factors on the protein level. This involves a positive feed-back loop whereby EMT induction results in upregulation of vimentin that is necessary and sufficient to enhance signalling by EMT-related kinases to phosphorylate specific transcription factors at novel sites.

Our aim is to investigate the interplay between vimentin, EMT-linked kinases and transcription factors in EMT induction and cancer cell migration, helping to unravel the details behind cancer cell metastasis.

**Regulatory mechanism of integrin  $\beta 1$  expression in collectively migrating cancer cells.**

*T. Kato<sup>1</sup>, A. Enomoto<sup>1</sup>, H. Haga<sup>2</sup>, S. Ishida<sup>2</sup>, M. Asai<sup>1</sup>, N. Asai<sup>1</sup>, M. Takahashi<sup>1</sup>; <sup>1</sup>Department of Pathology, Nagoya University Graduate School of Medicine, Nagoya, Japan, <sup>2</sup>Division of Biological Sciences, Hokkaido University Graduate School of Science, Sapporo, Japan*

Cancer cells frequently invade as cell group which retains cell-cell junctions, so-called collective migration/invasion. Migrating cell cohort can be distinguished into "leading cells" in the front row that guide "trailing cells" at the rear. Although pace-setting role of leading cells has been suggested, the molecular mechanism how leading cells contribute to the motile behavior of cell group remains elusive. Here we show that expression of integrin  $\beta 1$  is up-regulated in leading cells compared to trailing cells. Increase of integrin  $\beta 1$  expression is crucial for effective migration in cells moving as a group. Two transcriptional regulators, RET Finger Protein (RFP) and Myocardin Related Transcription Factor-B (MRTF-B), form complex responding to the partial loss of cell-cell adhesion in leading cells and up-regulates the integrin  $\beta 1$  expression. Knockdown of RFP or MRTF-B significantly impaired the collective invasion of squamous cell carcinoma cell line in organotypic culture model. These results suggest that up-regulation of integrin  $\beta 1$  by RFP and MRTF-B contributes to the property of leading cells to lead the cancer cell group.

**Cystatin SN is upregulated in colorectal cancer and interacts with cystatin C for the regulation of cathepsin B activity.**

S. Yoon<sup>1</sup>, B. Kim<sup>2</sup>, D-Y. Yoon<sup>3</sup>, J. Kim<sup>2</sup>, Y-K. Choe<sup>2</sup>, I. Ryou<sup>1</sup>, J-T. Kim<sup>1</sup>, S-J. Lee<sup>1</sup>, H. Lee<sup>1</sup>;  
<sup>1</sup>Immunotherapy Research Center, KRIBB, Daejeon, Korea, <sup>2</sup>Medical Genomics Research Center, KRIBB, Daejeon, Korea, <sup>3</sup>Bioscience and Biotechnology, Konkuk University, Seoul, Korea

Cystatin SN (CST1) is one of salivary cystatins that form tight equimolar complexes with cysteine proteases such as the cathepsin B and D. Previously, we reported the upregulation of CST1 and a significant correlation between high expression of CST1 and pTNM stage in gastric cancer. Here we report that CST1 is significantly overexpressed in colorectal cancer tissues compared to nontumor regions. We also examined the role of CST1 in tumor growth and metastasis, using a CST1 overexpressed HCT-116 cell tumor xenograft model. Increased cell proliferation and adhesive morphological changes were observed in HCT116 cell lines stably transfected with CST1 cDNA. T-cell factor and E-cadherin promoters were activated by exogenous overexpression of CST1 or CST3 and by recombinant CST1 (rCST1) or rCST3 treatment. Furthermore, CST1 interact with CST3 (cystatin C), a potent CTSB (cathepsin B) inhibitor, with a higher affinity than did CST3 with CTSB in the extracellular space of HCT116 cells. CTSB-mediated cellular invasiveness and proteolytic activities were inhibited by rCST3 treatment, but addition of rCST1 disrupted this inhibition. These results suggest that CST1 upregulation in colon cancer might be involved in adhesive tumor cell proliferation as well as in the regulation of CTSB activity via strong interaction with CST3.

**The role of novel gene fad104 in migration and invasion of cancer cells.**

D. Katoh<sup>1</sup>, M. Nishizuka<sup>1</sup>, K. Kishimoto<sup>1</sup>, S. Osada<sup>1</sup>, M. Imagawa<sup>1</sup>; <sup>1</sup>Nagoya City University, Nagoya, Japan

Fad104 (factor for adipocyte differentiation 104) is a novel gene expressed temporarily in the early stages of adipocyte differentiation. Previously, we showed that fad104 regulated cell proliferation, adhesion, spreading and migration. Since fad104 regulated cell migration, it was thought that fad104 regulated invasion and metastasis of cancer cells. In the present study, we clarified the role of fad104 in migration and invasion of A375 melanoma cells.

Using quantitative PCR and Western blotting, we first analyzed the expression levels of fad104 in highly metastatic A375SM cells and poorly metastatic A375C6 cells. The expression level of fad104 in A375SM cells was lower than that of A375C6 cells, implying that the expression level of fad104 in highly metastatic cancer cells is lower than that of poorly metastatic cancer cells. We next verified the effect of fad104 on migration and invasion of cancer cells using transwell assays. A375C6 cells transfected with fad104 siRNA increased in the number of migrated and invaded cells compared with control cells transfected luciferase siRNA, suggesting that the reduction of fad104 expression in A375C6 cells enhances migration and invasion of A375C6 cells. In contrast, fad104-expressing adenovirus-infected A375SM cells showed a reduction in migration and invasion compared with  $\beta$ -galactosidase-expressing adenovirus-infected A375SM cells (control cells). Furthermore, the expression of matrix metalloproteinase 2 in fad104 overexpressing A375SM cells was lower than that of control cells. These results suggest that fad104 contributes to suppression of migration and invasion in cancer cells.

Next, we investigated the molecular mechanism of fad104 in cancer cells. Our previous study revealed that fad104 suppressed osteoblast differentiation through the inhibition of bone morphogenetic protein (BMP)-Smad1/5/8 signal. BMPs are member of the transforming growth

factor- $\beta$  (TGF- $\beta$ ) family. It is well known that TGF- $\beta$ -Smad2/3 signal is critical for the regulation of invasion and metastasis in cancer cells. Therefore, we next assessed whether fad104 regulates TGF- $\beta$ -Smad2/3. A375SM cells with overexpression of fad104 showed the decrease in phosphorylation of Smad2/3 after being treated with TGF- $\beta$ . Taken together, we demonstrated that fad104 suppressed migration and invasion in cancer cells through the inhibition of TGF- $\beta$ -Smad2/3 signal.

#### **FERM domain-containing proteins in prostate cancer progression.**

*B. Tahmassebypour<sup>1</sup>, F. Valderrama<sup>1</sup>; <sup>1</sup>Division of Biomedical Sciences, St George's University of London, London, England*

Most prostate adenocarcinomas have their origins in preneoplastic lesions in the acinar structures of the prostate. These lesions alter the regular pattern of the prostate epithelia involving cell migration, cell-cell and cell-substrate reorganisation. Interaction with the surrounding environment is required and it is proposed that crosstalk between cell and stroma determines the fate of a prostate cell.

In order to reproduce the structural and functional differentiation of human prostatic acini *in vivo*, we have set up a 3-D microenvironment in Matrigel™. In this model, normal prostate (RWPE-1), low metastatic (DU-145) and highly metastatic prostate (PC-3) cancer cell lines are able to organize either as spheroids (cell aggregates) or as acinar-like structures. With this model we aim to investigate the progression from normal prostate to adenocarcinoma.

Four-point-one, ezrin, radixin, moesin (FERM) domains are present in a variety of mammalian proteins. There are around 50 distinct FERM domain-containing proteins (FDP) encoded by over 30 genes in the human genome. FDP are at the heart of a network of proteins linking the actin cytoskeleton with membrane dynamics at the leading edge of migratory cells. We have recently identified radixin as a key player in promoting cell migration of prostate cancer cells, by regulating Rac1-mediated epithelial polarity and formation of adherens junctions through Vav GEFs.

Using our model of prostate cancer progression we are now using an RNA interference approach and confocal microscopy techniques to identify the role of the FDP family in the formation and/or disruption of prostate acinar structures.

#### **Mechanism of Connective Tissue Growth Factor Inhibited Peritoneal Metastasis in Gastric Cancer.**

*C-I. Chen<sup>1</sup>, Y-C. Lin<sup>1</sup>, C-C. Chang<sup>2,3</sup>, Y-M. Cheng<sup>4</sup>, K-J. Chang<sup>3,5</sup>, C-N. Chen<sup>3,5</sup>, H. Lee<sup>1,3</sup>;*  
<sup>1</sup>*Institute of Zoology, National Taiwan University, Taipei, Taiwan,* <sup>2</sup>*Graduate Institute of Oral Biology, National Taiwan University, Taipei, Taiwan,* <sup>3</sup>*Angiogenesis Research Center, National Taiwan University, Taipei, Taiwan,* <sup>4</sup>*Department of Pathology, National Taiwan University Hospital, Taipei, Taiwan,* <sup>5</sup>*Department of Surgery, National Taiwan University Hospital, Taipei, Taiwan*

Connective tissue growth factor (CTGF) has diverse functions involved in wound healing, inflammation, cell adhesion, chemotaxis, apoptosis, tumor growth, and fibrosis. However, recent studies showed that over-expression of CTGF in human oral squamous cell carcinoma reduces cell growth and tumorigenicity. Similar tumor growth inhibitory effects were observed in lung

cancer cells in which CTGF over-expression were less angiogenic and metastatic due to blocking of the VEGF-A signaling pathway. CTGF was also reported to be a key regulator of colorectal cancer invasion and metastasis, and it appears to be a good prognostic factor. This study aims to investigate the roles of CTGF in peritoneal metastasis in gastric cancer (GC) and the underlying mechanisms. Our data demonstrated that CTGF overexpression inhibited adhesion and down regulation enhanced adhesion in vitro. In vivo tumorigenicity showed CTGF overexpression inhibited peritoneal dissemination. CTGF expression modulates peritoneal dissemination and is an important factor in prognosis. Patients expressed higher CTGF level have higher survival probability. Moreover, blocking integrin  $\alpha3\beta1$  prevented cell adhesion to recombinant CTGF and co-immunoprecipitation showed CTGF binding to integrin  $\alpha3\beta1$ . Co-inoculation of rCTGF and gastric cancer cells in mice demonstrated the effective inhibition of peritoneal dissemination and significantly increased survival probability. Together, these data demonstrated that GC peritoneal metastasis is mediated through cell surface integrin  $\alpha3\beta1$  binding to laminin. CTGF effectively blocks this interaction by binding to integrin  $\alpha3\beta1$ . Therefore, recombinant CTGF demonstrated its therapeutic potential in preventing peritoneal metastasis.

## Cancer Therapy II

### **Indibulin inhibits proliferation of MCF-7 cells by binding at a unique site on tubulin.**

*S. Kapoor<sup>1</sup>, M. Banerjee<sup>1</sup>, D. Panda<sup>1</sup>; <sup>1</sup>Biosciences and Bioengineering, Indian Institute of Technology, Bombay, Mumbai, India*

Indibulin (2-[1-(4-Chlorobenzyl)-1H-indol-3-yl]-2-oxo-N-pyridin-4-ylacetamide; D-24851), a synthetic inhibitor of tubulin assembly, has shown promising results in Phase I and Phase II clinical trials for cancer chemotherapy. In this study, indibulin was found to bind to pure tubulin with a dissociation constant of  $0.5 \pm 0.1 \mu\text{M}$ . Interestingly, indibulin did not affect the binding of several of the tubulin-binding agents including vinblastine, colchicine and curcumin to tubulin suggesting that it might have a unique binding site on tubulin. Indibulin inhibited the proliferation of MCF-7 cells in culture with a half maximal inhibitory concentration ( $\text{IC}_{50}$ ) of  $150 \pm 13 \text{ nM}$ . It depolymerized interphase and mitotic microtubules in MCF-7 cells in a concentration dependent manner. Indibulin treatment led to the formation of aberrant mitotic spindles in MCF-7 cells. The reassembly of cold-depolymerized microtubules was found to be significantly delayed in the presence of 300 nM indibulin suggesting that indibulin inhibits microtubule growth in these cells. Using live cell imaging of EGFP-tubulin expressing cells, indibulin (150 nM,  $\text{IC}_{50}$ ) was found to suppress the dynamics of individual microtubules in MCF-7 cells. The rates and extents of growth and shortening excursions of microtubules were reduced in the presence of indibulin. Further, the time spent by microtubules in the pause state increased strongly with a concomitant decrease in the time spent in both growing and shortening phases. The dynamicity of microtubules was also significantly reduced in the presence of 150 nM indibulin. In addition, indibulin perturbed the localization pattern of EB1, a microtubule plus end binding protein. In contrast to the control, where EB1 localized as a comet at the end of microtubules, EB1 was localized along the entire length of microtubules in cells treated with 75 and 300 nM indibulin. This study provides evidence indicating that indibulin binds to tubulin at a unique site and blocks mitosis by inhibiting microtubule dynamics.

### Caspase 3-independent Apoptosis and Autophagy Induced by the Oleanolic Acid in Human Malignant Melanoma Cells and in vivo Study of Anti-melanoma Effect of Oleanolic Acid.

C. Yang<sup>1</sup>, Y. Yang<sup>1</sup>; <sup>1</sup>Biological Sciences, Emporia State University, Emporia, KS

Objective: Malignant melanoma is extremely aggressive and highly resistant to current therapies. Oleanolic acid (OA), a naturally occurring triterpenoid widely distributed in food and medicinal plants, has drawn increasing attention due to its anti-inflammatory and anti-cancer effects. This study aimed to investigate the effects of OA on the induction of apoptosis and autophagy in human melanoma cells, identify the apoptotic pathway through which OA activates the apoptosis, and examine the potential therapeutic effect of OA on melanoma development in mouse xenograft model. Methods: MTT, colony formation, soft-agarose colony formation and wounding healing assays were employed to examine the effect of OA on the proliferation of human melanoma cell line WM1552C cells. The effects of OA on cell cycle progression and apoptosis were examined by the flow cytometry. Apoptosis and autophagy were visualized by Hoechst 33258 and MDC staining, respectively. The expression of apoptosis and autophagy related genes were measured by real-time qPCR and Western Blot. Subcutaneous inoculation and growth of melanoma cells in murine model were used for *in vivo* study of potential therapeutic effect of OA. Results: OA displayed a significant ( $p < 0.05$ ) inhibitory effect on the proliferation of WM1552C human melanoma cells in time- and dose-dependent manners ( $IC_{50}$  at 24h= 27 microM). OA significantly ( $p < 0.01$ ) decreased the colonogenic ability, anchorage-independent growth, motility and invasiveness of WM1552C cells. In addition, flow cytometry and Hoescht 33258 stain suggested that OA induced apoptosis. Z-VAD, a pan caspase inhibitor, significantly alleviated the cytotoxicity of OA on melanoma cells, suggesting the caspase-dependent nature of apoptosis induced by OA. However, caspase-3 inhibitor (Z-DEVD-fmk), did not significantly increase the viability of melanoma cells treated by OA. Western blot showed that OA did not significantly alter the expression of caspase 3 in OA-treated WM1552C melanoma cells. MDC staining showed autophagic vacuole and lysosome, and the expression of Light Chain-3 (LC-3) was up-regulated by the OA treatment. *In vivo* study showed that OA significantly reduced the tumor mass ( $p < 0.05$ ) in C57 BL/6 mice. Conclusion: OA inhibits the growth and invasiveness of malignant melanoma cells and induces autophagy and caspase 3-independent apoptosis. *In vivo* study suggests that OA is a potential chemotherapeutic candidate that potently inhibits the melanoma development.

### Rosehip Extracts Prevent Glioblastoma Cell Proliferation by Regulating Retinoblastoma Phosphorylation.

O. M. Idassi<sup>1</sup>, P. Cagle<sup>1</sup>, R. Minor<sup>2</sup>, I. Goktepe<sup>3</sup>, P. Martin<sup>1</sup>; <sup>1</sup>Biology, North Carolin Agricultural and Technical State University, Greensboro, NC, <sup>2</sup>Animal Sciences, North Carolin Agricultural and Technical State University, Greensboro, NC, <sup>3</sup>Family & Consumer Sciences, North Carolin Agricultural and Technical State University, Greensboro, NC

Glioblastoma multiforme (GBM) are malignant tumors that arise in the brain. The current system of clinical management for GBMs consists of surgical resection followed by radiotherapy and chemotherapy. However, this treatment regimen has not improved the lifespan of GBM patients in the past twenty years. Therefore, new therapeutic options are being aggressively investigated. Rosehip (*Rosa canina*) extracts have been used for centuries as alternative therapies. Recent studies demonstrate that rosehip extracts possess anti-tumor properties. Therefore, we tested the antiproliferative capacity of rosehip extracts against GBM cell lines. We

hypothesize that human GBM cell lines exposed to rosehip extract will demonstrate lower rates of cell proliferation as a result of cell cycle regulation. The human GBM cell lines, U-251 MG and U-1242 MG were treated with rosehip extracts (1 mg/mL – 25ng/mL) and demonstrated a decrease in cell proliferation. Utilizing a fluorescent-based labeling strategy (Live-Dead Assay), we examined whether rosehip extracts prevented cell proliferation by initiating apoptosis. Pretreatment of the GBM cells with rosehip extracts (1 mg/mL – 25ng/mL) induced the inhibition of cell proliferation without promoting apoptosis; whereas, cells treated with staurosporine (1  $\mu$ M), a known inducer of apoptosis, showed an increase in cell apoptosis. Furthermore, we assayed the phosphorylation level of the retinoblastoma (Rb) protein to determine the mechanisms by which rosehip extracts were preventing cell proliferation. Rb phosphorylation was decreased following exposure to the rosehip extracts, suggesting the extracts prevent cell cycle progression beyond the G1 phase. Taken together, these data suggest that rosehip extracts inhibit cell proliferation via a cytostatic mechanism that prevents cell cycle progression. Moreover, rosehip extracts may serve as an alternative, or supplement, to the current clinical management of GBMs.

**Apoptosis and Autophagy Induced by Zerumbone and in vivo and in vitro Study of Inhibitory Effect of Zerumbone on Human Malignant Melanoma.**

Y. Ni<sup>1</sup>, C. Yang<sup>1</sup>, C. Liu<sup>1</sup>, Y. Yang<sup>1</sup>; <sup>1</sup>Biological Sciences, Emporia State University, Emporia, KS

Objective: To investigate the underlying mechanisms by which sesquiterpene zerumbone (ZER) exerts its inhibitory effects on human malignant melanoma cells, and examine the potential therapeutic effect of zerumbone on melanoma development and lung metastasis in mouse xenograft model. Methods: the anti-proliferative effect of ZER on WM1552C and SK-MEL-28 cells was examined by MTS, soft-agarose colony formation and wound healing assays. Invasive ability of the cells was determined by Matrigel Transwell assay. The effects of ZER on cell cycle and apoptosis were examined by flow cytometry. The expression of apoptosis and autophagy related genes were measured by real-time PCR and Western Blot. Apoptosis and autophagy were confirmed by Hoechst and MDC staining, respectively. Subcutaneous inoculation and tail vein injection of melanoma cells in murine model were used for in vivo study of potential therapeutic effect of zerumbone. Results: ZER inhibited the proliferation of WM1552C and SK-MEL-28 cells in both time- and dose-dependent (IC<sub>50</sub> at 24h= 15.1  $\mu$ M and 10.8  $\mu$ M, respectively) manners. ZER significantly reduced the colony formation, anchorage-independent colony formation, motility and invasive ability of malignant melanoma cells. ZER caused a cell cycle arrest at G<sub>0</sub>/G<sub>1</sub> phase and induced apoptosis. Caspase-3 and light Chain-3 (LC3) were significantly up-regulated by ZER. MDC staining showed autophagic vacuole and lysosome. In vivo study showed that ZER significantly reduced the tumor mass and lung metastasis (P < 0.05) in C57 BL/6 mice. Conclusion: ZER may exert potent anti-melanoma effects by causing cell cycle (G<sub>0</sub>/G<sub>1</sub>) arrest and inducing apoptosis and autophagy. The in vivo study suggests that zerumbone can be a potential chemotherapeutic candidate for deterring growth and metastasis of melanoma .

2431

**Regulation of the cell cycle on progression in A549 cells and MCF-7 cells treatment by Gronwell seed.**

H. Tokuda<sup>1</sup>, T. Arai<sup>1</sup>, Y. Takimoto<sup>1</sup>, J. M. Strong<sup>1</sup>, A. Schneider<sup>1</sup>, N. Suzuki<sup>1</sup>; <sup>1</sup>Complementary and Alternative Medicine Clinical R & D, Kanazawa Univ., Kanazawa, Japan

Gronwell seed(Coix lachryma-jobi seed)(GS) is a grass crop that has long been used and played a role in traditional medicine as a nourishing food, and for treatment of various ailments, particularly cancer. The pharmaceutical composition is expected to have an anti-neoplastic effect, anti-human papilloma viral disease effect, and effect against various cutaneous diseases, such that it is useful for chemoprophylaxis or therapy against tumors. Previously, we reported that extract essence of GS and including fatty type active compounds, Monoolein inhibited TPA-induced in vitro conventional assay and thereby acted as a chemopreventive agents against carcinogenic compounds, using mouse experimental systems. In this study, the purpose of other potency of this useful samples was to develop new active effect, cytotoxic function as an effective anti-proliferative test against cancer cells and cell cyclic phase was investigated by Western blotting analysis. GS and Monoolein had potent anti-proliferative effects against A549 cell and MCF-7 cell under usual condition. Exposure of the A-549 and MCF-7 cell lines to an increasing dose of inhibitor, GS (1 ug, 10 ug and 100 ug) resulted in a dose dependent inhibition in cell anti-proliferation (15.2%, 41.6% and 71.6% of untreated control, respectively). Furthermore, treatment with 10ug of Monoolein was associated with up to 30 % increase in the anti-proliferative potency on the both cell lines. The anti-proliferative effects of A549 and MCF-7 by Monoolein were found to be accompanied by a G1 arrest on cell cycle, following the expressions of cyclin D1 and cdk2. This notion was further supported by examination of other cell cycle-dependent expression and these results suggest that growth arrest induced by Monoolein blocks both cell in G1 phase of the cell cycle. Based on our these observation, it is tempting to speculate that GS and Monoolein may find its place as interesting agent for the prevention and/or treatment human cancer intervention.

**Cytotoxicity against natural killer cell resistant cancer cell can be increased by enhancing of NKG2D ligands expression.**

J. Lee<sup>1</sup>; <sup>1</sup>College of Education, Department of Biology Education, Cheongju, Chungbuk, Korea

This study was designed to demonstrate the importance of the expression level of NKG2D ligands on cancer cells in enhancing NK cell cytotoxic activity. In this presentation, I introduce the relationship between natural killer (NK) cell susceptibility and the surface markers of cancer cells. I have demonstrated that the cytotoxic activity of human naïve NK cells against six different cancer cell lines. NK cells showed a high cytolytic effect against K562 and Jurkat, but showed low cytolytic effect against Ramos, Hep3B, and Raji. Through phenotypic analysis, I found evidence that more susceptible cancer cell lines (K562 and Jurkat) express more NKG2D ligands (Major histocompatibility complex (MHC) class I chain-related A/B (MIC-A/B) and UL16 binding protein (ULBP)-1, ULBP-2). As expected, the blockade of NKG2D dramatically attenuated NK cytotoxicity of K562 and Jurkat. Upon *in vitro* stimulation with quercetin, low susceptible cancer cells increased NKG2D ligand expression, leading to enhancement of NK cell cytotoxic activity. Taken together, these results demonstrate that NKG2D ligands are important ligands for NK cell cytotoxicity.

2433

**Identification of coding single nucleotide polymorphisms that impair hBLM helicase function.***H. Mirzaei-souderjani<sup>1</sup>; <sup>1</sup>CMMB, USF, Tampa, FL*

A conserved family of DNA helicases, the RecQ-like family, has been demonstrated to have an important role in the maintenance of genome stability from prokaryotes to eukaryotes. Mutations in three of the five human homologs of the ancestral RecQ of *E.coli* result in syndromes with one or all of the following characteristics: 1) premature aging 2) development and skeletal abnormalities 3) severe predispositions to cancer. Here we demonstrate that we have successfully engineered a functional human-yeast chimera by fusing the N-terminus of the yeast Sgs1 to the catalytic and conserved C-terminus domains of the human BLM. This chimera was produced aided by protein disorder prediction algorithms of Sgs1 and BLM. We have characterized this chimeric protein by assessing its ability to suppress defect observed in an *sgs1* null strain when expressed under the Sgs1 native promoter. We have demonstrated that the SGS1-BLM chimera protein can reduce the rate at which gross chromosomal rearrangements appear in an *sgs1* null strain. Moreover the chimeric protein is able to fully suppress sensitivity to DNA damaging agent hydroxyurea (HU) in the absence of a functional Sgs1. The chimeric protein has provided us with a tool to characterize BLM mutants in a yeast system. Here we have illustrated that both the helicase deficient chimera and Bloom's syndrome causing point mutations result in an inactive protein. Additionally we have examined *blm* missense polymorphisms available in the SNPdb and other sources and have been able to identify SNPs that have an effect on the functionality of the Blm protein.

2434

**Hyper-O-GlcNAcation Supports Pancreatic Tumor Cell Survival and NF- $\kappa$ B Activation.***Z. Ma<sup>1</sup>, K. A. Vosseller<sup>1</sup>; <sup>1</sup>Department of Biochemistry and Molecular Biology, Drexel University College of Medicine, Philadelphia, PA*

Cancer cells shift energy production from oxidative phosphorylation to the less efficient glycolysis even in the presence of oxygen (the Warburg effect). Cancer cells are also addicted to glutamine for proliferation and survival. This metabolic reprogramming necessitates greatly increased uptake of glucose and glutamine. A fraction of glucose and glutamine entering cells flux through the hexosamine biosynthetic pathway (HBP), the end-product of which is utilized for the carbohydrate post-translational O-linked  $\beta$ -N-acetylglucosamine (O-GlcNAc) modification, suggesting potential cancer cell "hyper-O-GlcNAcation". O-GlcNAc is dynamically added by the O-GlcNAc transferase (OGT) to serine/threonine residues of cytosolic and nuclear proteins and removed by O-GlcNAcase (OGA). O-GlcNAcation in a manner analogous to O-phosphorylation plays crucial roles in signal transduction linked to a variety of cellular processes such as cell cycle control, cellular stress responses, and transcription. O-GlcNAc modifies a number of cancer-associated proteins including p53, c-Myc, and Snail. However, the possible roles of hyper-O-GlcNAcation in cancer are not fully understood. Here, we observed increased HBP flux and hyper-O-GlcNAcation in human pancreatic ductal adenocarcinoma (PDAC), which is one of the most lethal cancers, with a 6 month median survival time after diagnosis and an overall 5-year survival rate of  $\sim$  5%. Consistent with PDAC hyper-O-GlcNAcation, OGT levels were elevated and OGA levels were reduced respectively. Reducing hyper-O-GlcNAcation selectively suppressed PDAC cell proliferation, anchorage-independent growth, PDAC orthotopic xenograft mouse tumor growth, and triggered apoptosis, but did not affect the growth of non-transformed pancreatic cells. Conversely, increasing O-GlcNAc promoted PDAC cell survival in forced suspension culture. PDAC and many other cancers are supported by oncogenic constitutive NF-

$\kappa$ B activity. NF- $\kappa$ B transcriptional activity is regulated by posttranslational modifications such as phosphorylation and acetylation. Here, we showed that the p65 subunit of NF- $\kappa$ B and upstream kinases IKK $\alpha$  and IKK $\beta$  were O-GlcNAc modified in PDAC. Lowering hyper-O-GlcNAcation decreased IKK $\beta$  expression and attenuated p65 activating phosphorylation (S536), nuclear translocation, NF- $\kappa$ B transcriptional activity, and target gene expression. Conversely, elevating O-GlcNAc increased IKK $\alpha$  and p65 O-GlcNAcation and increased p65 nuclear localization, S536 activating phosphorylation and NF- $\kappa$ B transcriptional activity. Finally, reducing O-GlcNAcation on p65 by mutating two O-GlcNAc sites (T322 and T352) to alanines attenuated the induction of cancer cell anchorage-independent growth. Our data suggest that elevated O-GlcNAcation contributes to pancreatic cancer cell survival and oncogenic NF- $\kappa$ B upregulation and that suppression of hyper-O-GlcNAcation by targeting OGT may serve as a novel therapeutic intervention in PDAC.

### **STAT3-RANTES autocrine signaling is essential for tamoxifen resistance in human breast cancer cells.**

*E. Yi<sup>1</sup>, S-K. Ye<sup>1</sup>; <sup>1</sup>Pharmacology, Seoul National University, Seoul, Korea*

The acquisition of tamoxifen resistance in breast cancer is a major therapeutic problem. We have developed tamoxifen resistance MCF-7 (TRM-7) cell line to elucidate the molecular mechanisms and factors involved in acquiring the resistance. In this study, we demonstrate that phosphorylation of STAT3 at tyrosine 705 (Y705) and RANTES expression are increased in response to tamoxifen in human breast cancer cells. Based on these results, we hypothesize that up-regulated STAT3 phosphorylation and RANTES may correlate with development of drug resistance. Here, we demonstrate that STAT3 and RANTES can contribute to maintenance of drug resistance. STAT3 phosphorylation is constitutively retained via RANTES autocrine loop, and this in turn up-regulates anti-apoptotic signals in TRM-7 cells. A STAT3-RANTES autocrine signaling affected expression of anti-apoptotic BCL-2 family genes and also prevented TRM-7 cells from the programmed cell death through inhibition of PARP and caspase-9 cleavage. Subsequently, blockade STAT3 and RANTES resulted in the reduction of anti-apoptotic signal in TRM-7 cells. Then reduced anti-apoptotic signal is rescued by exogenously treated RANTES protein, eventually drug resistance is rescued too. Taken together, our results suggest that STAT3-RANTES autocrine signal is essential to maintain the drug resistance and protect cell from programmed cell death. Introducing the mechanisms of STAT3-RANTES autocrine signaling can provide a new strategy to manage tamoxifen resistance tumor patients.

### **Cells Resistant to Vorinostat Show Increased Hallmarks of ER Stress and Elevated Sensitivity to Bortezomib Induced Cell Death.**

*M. A. Kinal<sup>1,2,3</sup>, D. Dupere-Richer<sup>1,2,3</sup>, T. Nielsen<sup>1,2,3</sup>, S. Del Rincon<sup>1,2,3</sup>, F. Pettersson<sup>1,2,3</sup>, W. H. Miller Jr.<sup>1,2,3</sup>; <sup>1</sup>Experimental Medicine, McGill University, Montreal, QC, Canada, <sup>2</sup>Lady Davis Institute for Medical Research, Montreal, QC, Canada, <sup>3</sup>Segal Cancer Center, Montreal, QC, Canada*

Histone deacetylase inhibitors (HDACi) are anti-cancer agents, which have shown promising activity in hematological malignancies. However, only a small percentage of patients initially respond to treatment and all will eventually develop resistance. HDACi are known to inhibit the deacetylation of histones as well as various non-histone proteins. Revealing mechanisms of HDACi resistance will help elucidate their modes of action, as well as help overcome *de novo* and acquired resistance in the clinic. To study HDACi resistance in hematological malignancies we developed two vorinostat resistant cell lines by a dose escalation protocol from the

monocytic-like lymphoma cell line U937 and the diffuse-large B cell lymphoma cell line SU-DHL6. Molecular profiling of our resistant cells show that they express hallmarks of ER stress, such as (1) a dilated ER, (2) increased XBP1 mRNA, (3) cleaved ATF6, and (4) increased GRP78 protein and mRNA. Endoplasmic reticulum (ER) stress is caused by an accumulation of misfolded proteins in the ER lumen that causes a multifaceted response that is primarily cytoprotective called the unfolded protein response (UPR). The misfolded proteins that are deemed unsalvageable by the ER are targeted for degradation by the proteasome. Vorinostat resistant cells do show an accumulation of ubiquitinated proteins and an increase in proteasomal activity compared to their parental counterparts. We hypothesize that adaptive ER stress could be a mechanism of vorinostat resistance because the UPR induces the upregulation of pro-survival genes and autophagy, which we recently showed is required to maintain HDACi resistance. We show that vorinostat resistant cells die in response to treatment with the proteasome inhibitor bortezomib and this correlates with an upregulation of some ER stress markers. Understanding vorinostat resistance holds clinical relevance in terms of improving HDACi therapy and being able to identify subsets of patients who would benefit most from combination therapy such as vorinostat with bortezomib.

**Antitumor properties of acetoxychavicol acetate on glioblastomas.**

Q. A. Quick<sup>1</sup>; <sup>1</sup>Natural Sciences, Southern University at New Orleans, New Orleans, LA

Acetoxychavicol Acetate (ACA), an antioxidant agent acts as an inhibitor of xanthine oxidase, which plays an important role in the catabolism of purines and catalyzes the oxidation of hypoxanthine to xanthine and xanthine to uric acid. By products of xanthine oxidase oxidation (uric acid) has been implicated in several abnormal physiological processes such as brain ischemia, vascular injury, inflammatory diseases, and most notably tumor lysis syndrome. Additionally, it was shown that brain tumors express increased xanthine oxidase levels as compared to normal brain tissue. Furthermore, early studies demonstrated that the xanthine oxidase inhibitor, ACA, was a chemopreventive agent that suppressed tumor formation in the oral cavity and colon, while subsequent studies revealed that ACA exerted positive anti-tumorigenic effects on leukemia, breast, colon, and myeloma cancers. We demonstrated in the present study that ACA induces anti-tumorigenic properties in glioblastomas by antagonizing glioblastoma cell proliferation and migration. Additionally, we assessed the involvement of reactive oxygen species (ROS) and the unfolded protein endoplasmic reticulum stress response for their mechanistic roles in ACA induced glioblastoma cell death.

**aPKC iota/lambda regulates Hh signaling during basal cell carcinoma growth.**

S. X. Atwood<sup>1</sup>, M. Li<sup>1</sup>, J. Y. Tang<sup>1</sup>, A. E. Oro<sup>1</sup>; <sup>1</sup>Dermatology, Stanford University School of Medicine, Stanford, CA

Basal cell carcinoma (BCC) initiation and expansion requires high levels of Hedgehog (Hh) signaling. While Smoothed (Smo) inhibitors are effective, early tumor resistance illustrates the need for additional downstream targets for therapy. Here we identify atypical Protein Kinase C iota/lambda (aPKC) as a novel BCC oncogene essential for Hh signaling. Genetic knockdown using shRNA against aPKC, or pharmacological inhibition of aPKC, inhibits proliferation, Hh signaling, and ciliogenesis of the murine BCC cell line ASZ001. Genome-wide transcriptome analysis of BCC cells reveals pharmacological inhibition of aPKC or Smo target similar pathways. aPKC is a Hh target gene that is overexpressed in mouse and human BCCs and functions downstream of Smo to bind and phosphorylate Gli1, resulting in maximal DNA binding

and Hh activation. Consistent with its role in regulating Hh signaling, application of a topical aPKC inhibitor suppresses Hh signaling and tumor growth in primary murine BCC tumors. As acquired drug resistance is a growing problem, we also demonstrate Smo antagonist-resistant BCC cells and human tumors overexpress active aPKC and pharmacological inhibition of aPKC suppresses proliferation. These results demonstrate polarity signaling is critical for Hh-dependent processes and suggest aPKC may be a new therapeutic target for the treatment of naïve and resistant BCCs.

2439

**Extreme autophagy after high dose gamma irradiation or mixed modality irradiation due to a shift in autophagic flux.**

*L. Yasui<sup>1</sup>, K. Owens<sup>1</sup>, A. Schuck<sup>1</sup>; <sup>1</sup>Biological Sciences, Northern Illinois University, DeKalb, IL*

Radiation-induced cell death by different radiation modalities was investigated in human brain tumor cells, glioblastoma multiforme (GBM) by transmission electron microscopy (TEM). Essentially all cells contained autophagosomes but irradiated GBM cells showed an increase in number and size of autophagosomes indicating activation of autophagy. Gamma radiation induced autophagy has been previously reported but the activation of autophagy by irradiation with thermal neutrons or gadolinium neutron capture is presented here for the first time. Acridine orange staining confirmed the increase in autophagosomes observed by TEM relative to the different radiation treatments and increasing time after irradiation. The increased number of autophagosomes in irradiated cells could be due to either an increase in autophagosome formation or decrease in clearance of autophagosomes. The equilibrium between these two is defined as autophagosome flux. A defective autophagic flux is a prominent characteristic of cells irradiated with thermal neutrons or with gadolinium neutron capture. An extreme example of disruption in the autophagic flux is shown in cell profiles having massive accumulation of damaged intracellular components without proper disposal or recycling via lysosomal enzyme digestion. Indeed, it appears that the autophagosomes are engulfing other autophagosomes. Others suggest that the failure to degrade autophagosomes compromises cellular viability, so it is not unreasonable to expect that the representative cell received a lethal hit of radiation and will not survive the accumulation of the massive autophagosomes within the cytoplasm. The image of extreme autophagy also shows a flattened membrane extension that is part of the membrane wrapping around an autophagosome. The membrane extension appears to be in the process of searching out more cargo and engulfing that cargo to add to the pre-existing autophagosome. This morphological clue suggests that the defective steps in this cell irradiated with Auger electrons from Gd neutron capture are cargo recognition steps and membrane engulfment steps. It is suggested that these later steps in autophagy are compromised by the high dose gamma irradiation or mixed mode irradiations so that the GBM cells are unable to complete normal recycling by lysosomal enzyme digestion processes.

This research was supported by the Department of Defense, US Army Medical Research Acquisition Act.

**Trajectories of Organelle Morphology Changes During Malignant Transformation.**

S. Bianco<sup>1,2</sup>, Y-H. M. Chan<sup>2,3</sup>, S. M. Rafelski<sup>3,4</sup>, M. L. Truitt<sup>5</sup>, W. F. Marshall<sup>2,3</sup>, D. Ruggero<sup>5</sup>, C. Tang<sup>1,2,6</sup>; <sup>1</sup>Bioengineering and Therapeutic Sciences, UC San Francisco, San Francisco, CA, <sup>2</sup>Center for Systems and Synthetic Biology, UC San Francisco, San Francisco, CA, <sup>3</sup>Biochemistry and Biophysics, UC San Francisco, San Francisco, CA, <sup>4</sup>Developmental and Cell Biology, UC Irvine, Irvine, CA, <sup>5</sup>Urology, UC San Francisco, San Francisco, CA, <sup>6</sup>Center for Theoretical Biology, Peking University, Beijing, China

Organelle morphology changes provide the basis for many histological screens for cancer. However, little is understood about how the molecular changes during malignant transformation affect organelle morphology or how these changes to organelle morphology in turn affect the proper function of the biochemical pathways they encapsulate. In this study, we overexpressed oncogenic Ras and oncogenic Myc either alone or in combination in primary mouse embryonic fibroblasts (MEFs). Using novel computational analyses, we extracted metrics of cell, nucleus, nucleolus, and mitochondrial morphology from individual cells. Malignant transformation of MEFs requires two oncogenic "hits" and typically, changes in organelle morphology are most pronounced in the Ras and Myc doubly transformed population. For instance, the nucleus in the doubly transformed cells is larger relative to cell size and rounder when compared to other conditions. Organelle morphology can also exhibit progressive changes, as in the case of nucleolus size which is smallest in the control cells, larger in either of the two single transformations, and largest in the double transformation. Multidimensional parameter analysis will reveal which morphological changes associate most strongly to the different genetic states. These data indicate that organelle morphology can indicate intermediate states during malignant transformation, and will inform development of future diagnostic and therapeutic tools.

**Engagement of cellular prion and heat shock organizing protein as a novel therapeutic target for glioblastoma.**

M. H. Lopes<sup>1</sup>, N. T. Queiroz-Hazarbassanov<sup>2</sup>, B. R. Rodrigues<sup>3</sup>, T. G. Santos<sup>3</sup>, I. W. Cunha<sup>3</sup>, S. M. Oba-Shinjo<sup>4</sup>, S. K. Marie<sup>4</sup>, V. R. Martins<sup>3</sup>; <sup>1</sup>Cell and Developmental Biology, University of Sao Paulo - Institute of Biomedical Sciences, Sao Paulo, Brazil, <sup>2</sup>Animal Patology, University of Sao Paulo - Faculty of Veterinay Medicine, Sao Paulo, Brazil, <sup>3</sup>Cell and Molecular Biology, Hospital A. C. Camargo- International Center for Research, Sao Paulo, Brazil, <sup>4</sup>University of Sao Paulo - Faculty of Medicine, Sao Paulo, Brazil

A main concern in cancer therapy is resistance of tumors such as glioblastoma to current treatments protocols. Here, we report that glioblastoma proliferation mediated by cellular prion protein (PrPC)- secretable STI1/hop (Stress inducible protein 1/hsp70-hsp90 organizing protein) interaction, is blocked by STI1/hop<sub>230-245</sub> peptide, which mimics PrPC binding site, in tumor cells in vitro and in malignant glioma in vivo. Both STI1/hop and PrPC are highly expressed and co-localize in glioblastoma cells (U87MG). STI1/hop is secreted by U87MG either cultured in vitro or xenografted orthotopically. In vitro, proliferative effect induced by recombinant STI1/hop was inhibited by STI1/hop<sub>230-245</sub>, an irrelevant peptide from STI1/hop amino-terminal domain (STI1/hop<sub>61-76</sub>) had no effect. Most importantly, local therapy of established U87MG orthotopic xenograft with STI1/hop<sub>230-245</sub> significantly delayed tumor growth and improved survival on nude mice. Consequences of STI1/hop<sub>230-245</sub> treatment in vivo were strongly decreased cell proliferation and U87MG cells sensitization for apoptosis, which can contribute to the observed anti-tumor effects. Remarkably, PrPC silencing by shRNA impaired the tumor growth in vivo and STI1 treatment had no effect upon proliferation in PrPC-silencing cells, indicating the critical role

of PrPC-STI1 interaction for tumor maintenance. Interestingly, real time RT-PCR and tissue microarray from surgical samples demonstrated that STI1/hop gene expression is significantly enhanced in high-grade gliomas (grades III and IV) when compared to non-tumoral tissues, which renders it a powerful tumor marker. Thus, STI1/hop<sub>230-245</sub> is promising candidate for cancer therapy by acting as adjuvant for currently established medications.

**A New Anti-Cancer Agent, Acetyltanshinone IIA, Inhibits Estrogen Receptor Positive Breast Cancer Cell Growth by Inducing ER $\alpha$  mRNA Reduction and Protein Degradation**

K. Q. Luo<sup>1</sup>, T. Yu<sup>1</sup>, G. Lopes<sup>2,3</sup>; <sup>1</sup>Division of Bioengineering, School of Chemical and Biomedical Engineering, Nanyang Technological University, Singapore, Singapore, <sup>2</sup>Medical Oncology, Johns Hopkins Singapore International Medical Center, Singapore, Singapore, <sup>3</sup>School of Medicine, Johns Hopkins University, Baltimore, MD

Acetyltanshinone IIA (ATA) is a new anti-cancer agent with good *in vitro* and *in vivo* anti-tumor activity. Recently, we found that ATA displayed a strong growth inhibition effect on breast cancer cells that are estrogen receptor positive (ER+). More importantly, ATA exhibited much stronger growth inhibition potency than the commonly used hormonal agent tamoxifen. The IC<sub>50</sub> values for ATA are 6.7 to 6.8 fold less than those for tamoxifen in MCF-7 and T-47D breast cancer cells. ATA was found to be metabolized into hydroquinone tanshinone IIA (HTA) in MCF-7 cells and HTA can dock at the same site where estrogen binds to ER. ATA was found to significantly reduce ER $\alpha$  but not ER $\beta$  protein. The reduction occurred only in the nucleus, not in the cytosol, indicating that it is target and location specific. The ATA-mediated ER $\alpha$  reduction was blocked by a proteasome inhibitor, MG132. In addition, ATA also reduced the mRNA level of the ER $\alpha$  encoding gene, ESR1, which distinguishes ATA from another anti-estrogen drug, fulvestrant. Finally, real-time PCR revealed that ATA caused mRNA level reduction of GREB1, which is an ER-responsive gene. In summary, we propose that ATA may inhibit ER+ breast cancer cell growth by reducing ER $\alpha$  mRNA levels and causing ER $\alpha$  degradation via a proteasome dependent pathway. As ATA can selectively degrade ER $\alpha$  but not ER $\beta$ , and ATA can reduce ER $\alpha$  gene expression, ATA may be used to treat ER+ breast cancer patients who are resistant or non-responsive to fulvestrant and tamoxifen.

**Treatment targeting hypoxic tumor cells enhances therapeutic effect of sunitinib.**

S. Liu<sup>1</sup>, X. Xu<sup>1</sup>; <sup>1</sup>University of Pennsylvania, Philadelphia, PA

Angiogenesis is a critical step during tumor progression. Although antiangiogenic therapy has shown early promise in cancer treatment, the modest benefits antiangiogenic therapy exerts in delaying tumor progression often do not translate into an overall prolongation of survival time. One possible explanation for this is that antiangiogenic therapy actually promotes the emergence of a more aggressive cancer cell phenotype by generating increased hypoxia in the primary tumor—a well-recognized promoter of tumor progression. TH-302 is a 2-nitroimidazole triggered hypoxia-activated prodrug (HAP), which has been shown in human tumor xenograft models to selectively target the hypoxic tumor compartment and reduce tumor volume. Here, we show that melanoma cells grown under hypoxic conditions exhibit increased resistance to a variety of chemotherapeutic agents and generate larger and more aggressive tumor xenografts than control cells grown under normoxic conditions. Melanoma cells grown under hypoxic conditions exhibit a pronounced sensitivity to TH-302—a phenotype exacerbated by the addition of sunitinib. Finally, TH-302 prolonged the overall survival of melanoma bearing transgenic mice (Tyr::CreER; BRafCA/+; Ptenlox/lox) in a series of chemotherapeutic and chemoprevention treatment regimens of varying duration—both alone and in combination with

sunitinib, and this correlated with a statistically significant reduction in tumor size and thickness as well as a reduction in the expression of hypoxia-induced genes. Interestingly, the combination of temozolomide with TH-302 did not exert the same effects on survival, suggesting that TH-302 requires sunitinib-dependent tumor hypoxia for its additive effects to be realized. These studies provide a translational rationale for combining TH-302 with antiangiogenics to enhance the treatment benefit of antiangiogenics in melanoma.

**Short synthetic double stranded RNA with dual activity - oncolytic and immune modulatory - for hepatocellular carcinoma.**

S. Bot<sup>1</sup>, F. He<sup>2</sup>, W. G. Newmin<sup>1</sup>, A. Ghaneka<sup>2</sup>; <sup>1</sup>Department of Research and Development, MultiCell Technologies, Woonsocket, RI, <sup>2</sup>Division of Cellular and Molecular Biology, Toronto General Hospital Research Institute, Toronto, ON, Canada

Hepatocellular carcinoma (HCC) is the most common form of primary liver cancer and a leading cause of cancer death. Current pharmacological approaches for the treatment of human HCC are very limited in their efficacy. A potential role for noncoding double stranded RNAs (dsRNAs) in the control of tumours has recently emerged in a variety of models with recognition of their ability to stimulate an immune response or directly effect cell death. We sought to determine the efficacy of dsRNAs of different molecular weights against human HCC cells in vitro. We utilized synthetic polyA:polyU of either 5 base pairs (low molecular weight [LMW]) or 70 base pairs (high molecular weight [HMW]) in length as well as 2O'-methylated versions of these dsRNAs. LMW dsRNA in the culture supernatant had a rapid, pronounced, dose-dependent negative effect on cell viability as measured by MTT assays when tested against human HCC cell lines (HepG2, Huh7, PLC/PRF/5), primary human HCC cells, a murine HCC cell line (Tib-75), and a human monocyte cell line (THP-1), though this effect was less pronounced in a normal human hepatocyte cell line (THLE-2). Annexin V and propidium iodide staining revealed a role for apoptosis in cell death caused by LMW dsRNA. Multiplex analysis of culture supernatants revealed that exposure to LMW dsRNA was associated with the production of tumor necrosis factor-alpha and interleukin-6. In contrast, HMW dsRNA had no effect on cell viability and elicited production of different cytokines. These observations define a novel category of synthetic dsRNA of reduced size and dual activity, both oncolytic and immune modulatory. Altogether, these findings support further mechanistic and in vivo studies to explore the safety, effectiveness and utility of such dsRNAs with dual biological activity as novel therapeutic agents in HCC and other cancers.

**Cytotoxicity of Human Recombinant Arginase [Co]-PEG5000 in the presence of Citrulline is dependent on decreased Argininosuccinate synthetase expression in human cells.**

V. Agrawal<sup>1,2</sup>, J. Woo<sup>1,2</sup>, J. Mauldin<sup>2</sup>, C. Jo<sup>1,2</sup>, E. M. Stone<sup>3</sup>, G. Georgiou<sup>3</sup>, A. E. Frankel<sup>1,2</sup>; <sup>1</sup>Internal Medicine, Texas A&M Health Science Center, Bryan, TX, <sup>2</sup>Cancer Research Institute, Scott & White Hospital, Temple, TX, <sup>3</sup>Department of Chemical Engineering, University of Texas at Austin, Austin, TX

A number of cancers are auxotrophic for L-arginine. Depletion of extracellular L-arginine has been accomplished by dietary restriction and enzyme therapy including pegylated recombinant arginine deiminase, pegylated recombinant human arginase I, and pegylated cobalt substituted recombinant human arginase I-Co-ArgI-PEG. We tested the latter on tumor and normal cell lines in the presence and absence of L-citrulline and correlated sensitivity with cytosolic levels of argininosuccinate synthetase-ASS and ornithine transcarbamylase-OTC. Three day thymidine and leucine incorporation and seven day MTS assays were performed. Immunoblots were used

to quantify ASS and OTC. In the presence of supplemental citrulline, Co-ArgI-PEG was cytotoxic to tumors lacking ASS but not normal cells. In addition to the above cytotoxicity assays, Balb/c mice were treated with weekly or twice weekly doses of IP Co-ArgI-PEG. Animal toxicity, PK and PD were measured. Co-ArgI-PEG depleted serum L-arginine for 3-4 days from first injections. Co-ArgI-PEG was measurable for over a week in the blood with a beta phase half life of 3 days. Toxicities was limited to weight loss and marrow necrosis. We further developed an NSG mouse model of A375 melanoma cells, an ASS negative cancer. We treated the mice with the MTD of Co-ArgI-PEG in the presence or absence of citrulline. Dramatic tumor growth inhibition was observed. After one month, half of the relapsing tumors showed ASS induction. Co-ArgI-PEG has been produced under cGMP and vialled. Quality control tests are ongoing. GLP pharmacology/toxicology in mice has been initiated. We hope to begin phase I clinical studies with Co-ArgI-PEG in solid tumor patients that are ASS negative in 2013.

2446

**A microscopy-based cell-microarray assay for quantifying cytotoxicity (ADCC/CDC) and cellular response at single cell resolution.**

S. Hsiao<sup>1</sup>; <sup>1</sup>Adheren, Berkeley, CA

A novel single cell microarray assay has been developed for the determination of complement dependent cytotoxicity (CDC) and antibody dependent cellular cytotoxicity (ADCC). And this single cell microarray assay can be applied to cellular response assay such as quantifying Fc-gamma receptors. Not only does this new cell microarray assay allow cytotoxicity analysis to be conducted on a single cell basis, but it also overcomes the need for hazardous radiochemicals. Additionally, fluorescence labeled antibodies can be used to easily identify individual cells with antibodies bound that remain alive. In other words, this assay can specify which cells are resistant to CDC/ADCC of a specific antibody. In addition, this assay provides real-time imaging and data of cell toxicity and other cellular responses over a period of time.

**Multicellular tumor spheroid models to explore cell cycle checkpoints in 3D.**

J. Laurent<sup>1</sup>, C. Frongia<sup>1</sup>, O. Mondesert<sup>1</sup>, M. Cazales<sup>1</sup>, B. Ducommun<sup>1</sup>, V. Lobjois<sup>1</sup>; <sup>1</sup>CNRS - ITAV, Toulouse, France

MultiCellular Tumor Spheroid (MCTS) mimic the organization of a tumor and is considered as an invaluable model to study cancer cell biology and to evaluate new antiproliferative drugs. We report how the characteristics of MCTS in association with new technological developments can be used to explore the regionalization and the dynamics of cell cycle checkpoints in 3D. Spheroids expressing fluorescent reporters were engineered and used to explore cell cycle distribution and regionalization during growth. In these models we monitored cell cycle arrest in response to checkpoint activation after growth factor starvation, DNA injury or treatment with drugs. The kinetics and regionalized aspects of the response were investigated both on fixed sections and on live spheroids using light sheet microscopy. All together, our data demonstrate the power of the combination of spheroids made of genetically modified cells expressing cell cycle reporters with both classical antibody-based detection and the use of innovative 3D imaging strategy. This study paves the way for the investigation of the molecular aspects of checkpoint response in 3D models and the dynamic studies of the 3D response to novel antiproliferative agents.

**Angiogenic and proliferative factors in the prostatic microenvironment: senescence and angiogenesis inhibition x lesions in the transgenic adenocarcinoma of mouse prostate (TRAMP) model**F. Montico<sup>1</sup>, A. C. Hetzl<sup>1</sup>, E. M. Cândido<sup>1</sup>, L. A. Kido<sup>1</sup>, R. M. Lorencini<sup>1</sup>, V. A. Cagnon<sup>1</sup>;<sup>1</sup>Structural and Functional Biology, University of Campinas, Campinas, Brazil

Prostatic microenvironment in the senescence resembles cancer-associated reactive stroma, characterized by stimulated cell proliferation and angiogenesis. In this context, angiogenic inhibitors, such as SU5416 and TNP-470, represent promising alternatives in prostate cancer treatment. Thus, the aim herewith was to characterize proliferative and angiogenic aspects of the prostatic stroma in elderly mice submitted to antiangiogenic therapy in comparison with stromal features in TRAMP mice lesions.

Control groups received subcutaneous saline injections: Young (YNG), Prostatic Intraepithelial Neoplasia (PIN) and Cancer (PC) controls (18-week-old FVB, 8 and 18-week-old TRAMP mice, respectively). Experimental groups (52-week-old FVB mice) were: Senile (SEN): same treatment as controls; SU5416 (SU): intraperitoneal SU5416 injections; TNP-470 (TNP): subcutaneous TNP-470 injections; SU5416 + TNP-470 (ST): same treatments as SU and TNP groups. After 21 days of treatment, dorsolateral prostate was collected for light microscopy, immunohistochemical and Western blotting analyses for vascular endothelial growth factor (VEGF), fibroblast growth factor-2 (FGF-2) and insulin-like growth factor receptor-1 (IGFR-1).

Senescence was associated with proliferative lesions similar to those verified in TRAMP mice, such as PIN and well-differentiated adenocarcinoma, even though with lower frequency. Prostatic molecular features in the senescence also resembled those in the TRAMP lesions and were characterized by increased VEGF, FGF-2 and IGFR-1 immunolabelling and protein levels. Antiangiogenic therapy interrupted the progression and/or led to regression of the lesions observed in the SEN group, mainly following SU5416 and TNP-470 association. In addition, angiogenesis inhibition, especially in the TNP and ST groups, resulted in reduction of VEGF and FGF-2 levels in a similar pattern, whereas this was not observed for IGFR-1.

The findings indicated that senescence predisposes to prostatic malignancies, considering the morphological similarity with PIN and PC groups, as well as the activation of molecules involved in angiogenesis and cell proliferation, leading to a reactive stroma-like microenvironment in this life period. The decrease pattern of VEGF and FGF-2 levels following angiogenesis inhibition showed the effectiveness of this therapy and also pointed to a crosstalk among molecular pathways involving these pro-angiogenic factors. However, the maintenance of increased IGFR-1 levels after antiangiogenic treatment suggests that this therapy demand further analysis, considering the proliferative role of this molecule and its involvement in several pathways which can activate angiogenesis.

**Tumor-specific silencing of COPZ2 gene encoding coatamer protein complex subunit  $\zeta$ 2 renders tumor cells dependent on its paralogous gene COPZ1.**

E. Levina<sup>1</sup>, M. Baig<sup>2</sup>, D. Oliver<sup>2</sup>, E. Brode<sup>2</sup>, M. Nikiforov<sup>3</sup>, S. Carmack<sup>4</sup>, Y. Ding<sup>4</sup>, F. Wieland<sup>5</sup>, R. Buttyan<sup>6</sup>, I. Roninson<sup>2</sup>, M. Shtutman<sup>2</sup>; <sup>1</sup>Biological Sciences, University of South Carolina, Columbia, SC, <sup>2</sup>Drug Discovery and Biomedical Sciences, South Carolina College of Pharmacy, University of South Carolina campus, Columbia, SC, <sup>3</sup>Cell Stress Biology, Roswell Park Cancer Institute, Buffalo, NY, <sup>4</sup>Computational & Structural Biology, Wadsworth Center, New York State Department of Health, Albany, NY, <sup>5</sup>Biochemistry Centre, Heidelberg University, Heidelberg, Germany, <sup>6</sup>Urologic Sciences, Vancouver Prostate Centre, Vancouver, BC, Canada

Anticancer drugs are effective against tumors that depend on the molecular target of the drug. Known targets of cytotoxic anticancer drugs are involved in cell proliferation; drugs acting on such targets are ineffective against nonproliferating tumor cells, survival of which leads to eventual therapy failure. Function-based genomic screening identified the coatamer protein complex  $\zeta$ 1 (COPZ1) gene as essential for different tumor cell types but not for normal cells. COPZ1 encodes a subunit of coatamer protein complex 1 (COPI) involved in intracellular traffic and autophagy. The knockdown of COPZ1, but not of COPZ2 encoding isoform coatamer protein complex  $\zeta$ 2, caused Golgi apparatus collapse, activation of unfolded protein response, blocked autophagy, and induced apoptosis in both proliferating and nondividing tumor cells. In contrast, inhibition of normal cell growth required simultaneous knockdown of both COPZ1 and COPZ2. COPZ2 (but not COPZ1) was down-regulated in the majority of tumor cell lines and in clinical samples of different cancer types. Reexpression of COPZ2 protected tumor cells from killing by COPZ1 knockdown, indicating that tumor cell dependence on COPZ1 is the result of COPZ2 silencing. COPZ2 displays no tumor-suppressive activities, but it harbors microRNA 152, which is silenced in tumor cells concurrently with COPZ2 and acts as a tumor suppressor in vitro and in vivo. Silencing of microRNA 152 in different cancers and the ensuing down-regulation of its host gene COPZ2 offer a therapeutic opportunity for proliferation-independent selective killing of tumor cells by COPZ1-targeting agents.

**Apical surface dynamics during early EPEC attachment to intestinal epithelial cells.**

D. A. Shifrin<sup>1</sup>, S. W. Crawley<sup>1</sup>, M. J. Tyska<sup>1</sup>; <sup>1</sup>Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

Enteropathogenic *Escherichia coli* (EPEC) is a common food-borne pathogen and one of the leading causes of infantile diarrhea and death in third world nations. EPEC colonizes the intestine by hijacking the actin cytoskeleton of host enterocytes and forming an actin-rich pedestal under the site of attachment while causing effacement of surrounding microvilli. The signaling cascade leading to pedestal formation has been extensively studied; however, events surrounding initial EPEC contact with an enterocyte are not well characterized. Using live cell and scanning electron microscopy on Caco2<sub>BBE</sub> intestinal epithelial cells in culture, we show here that microvilli play a critical role in early EPEC attachment. Immediately following first contact of an EPEC cell, nearby microvilli extend and orient towards the bacterium, in some cases “tethering” the bacterium. Microvilli also cluster together around the bacterium, an event likely mediated by the adhesion molecule protocadherin-24 (PCDH24) which is concentrated at microvillar tips. Following these events, which occur within the first few minutes of bacterial

contact, we observed a rapid depletion of PCDH24 and other apical proteins around sites of attachment concomitant with microvillar effacement and actin pedestal formation. Strikingly, assays using PCDH24-overexpressing and knockdown cells show that EPEC attachment is inversely proportional to the amount of PCDH24 present in the brush border. Together, these data suggest that, as in early brush border formation, PCDH24 functions to stabilize microvilli through inter-microvillar adhesion during infection. The host cell could use this function as a means to maintain brush border integrity and prevent or slow intimate bacterial attachment. In the absence of PCDH24, brush border integrity is compromised, allowing greater access to EPEC and subsequently higher levels of bacterial colonization.

**Cell-to-cell spread of *Listeria* and *Rickettsia* displays distinct morphokinetics and utilizes different bacterial and host factors.**

R. L. Lamason<sup>1</sup>, M. D. Welch<sup>1</sup>; <sup>1</sup>University of California, Berkeley, Berkeley, CA

Intracellular bacterial pathogens invade host cells and spread from cell to cell to promote replication and avoid elimination by the host. Several species, including *Listeria monocytogenes* and *Rickettsia parkeri*, spread by hijacking the host cell's actin cytoskeleton to form actin tails, which propels them into the plasma membrane and induces protrusions that are engulfed by neighboring cells. Previous work showed that *L. monocytogenes* and *R. parkeri* use distinct bacterial and host factors to polymerize and organize actin, resulting in different motility characteristics and actin tail architectures. This suggests they might also utilize distinct pathways for spread. Here, we show that the cell-to-cell spread process differs morphologically and kinetically between the two pathogens. Using live cell imaging, we found that *L. monocytogenes* forms protrusions that are 3.6 times longer than *R. parkeri*. Spread is initiated at 3-4 h post infection (hpi) for *L. monocytogenes* versus 16 hpi for *R. parkeri*. The delayed initiation of spread for *R. parkeri* is likely due to its longer doubling time compared to *L. monocytogenes* (8 h versus 40 min). Once spread is initiated, the overall kinetics for an individual bacterium are similar between the two pathogens (25 min). However, *L. monocytogenes* is slower than *R. parkeri* in the timing of protrusion engulfment into a recipient cell. This kinetic difference, along with the morphological differences seen for protrusion formation, suggests the two pathogens are internalized into neighboring cells by distinct mechanisms. To characterize the pathways that regulate cell-to-cell spread, two independent screens are underway to isolate host and bacterial genes important for this process. We have identified several factors, including *Rickettsial* Sca2 actin polymerizing protein and host capping protein (CAPZB) as critical components for *R. parkeri* cell-to-cell spread. Future work will identify and characterize additional bacterial and host factors critical for regulating spread with the ultimate goal of defining shared and divergent spread pathways exploited by different pathogens.

**Integrated analysis by RNAi screening of mammalian cell invasion by the bacterial pathogen *Listeria monocytogenes*.**

A. Kühbacher<sup>1,2,3</sup>, M. Emmenlauer<sup>4</sup>, P. Rämö<sup>4</sup>, C. Dehio<sup>4</sup>, P. Cossart<sup>1,2,3</sup>, J. Pizarro-Cerda<sup>1,2,3</sup>; <sup>1</sup>Unité Interactions Bactéries-Cellules, Pasteur Institute, Paris, France, <sup>2</sup>USC2020, INRA, Paris, France, <sup>3</sup>U604, INSERM, Paris, France, <sup>4</sup>Biozentrum, Basel, Switzerland

The gram-positive bacterium *Listeria monocytogenes* is the causative agent of human listeriosis, a food-borne disease characterized by gastroenteritis, meningitis and abortions. A crucial stage in infection is the bacterial internalization and intracellular replication in phagocytic and normally non-phagocytic cells. Invasion of epithelial cells requires the interaction of host cell

receptors with surface *L. monocytogenes* proteins from the internalin family, characterized by the presence of leucine-rich repeats involved in protein/protein interactions; in particular, internalin A (InIA) is able to bind the adherens junction molecule E-cadherin while the hepatocyte growth factor receptor (also known as Met) recognizes InIB. The InIB-Met interaction leads to the activation of a signaling cascade which results in an actin- and clathrin-dependent uptake of *L. monocytogenes*.

In order to understand the global regulation of the *L. monocytogenes* internalization process in an integrated approach that involves the characterization of the invasion processes by other bacterial and viral pathogens, our laboratory joined the InfectX ([www.infectx.ch](http://www.infectx.ch)) -a consortium belonging to the SystemsX.ch initiative. The aim of InfectX is to define a 'human infectome' network for several bacterial and viral pathogens by using a comparable RNAi screening and data analysis approach for pathogen entry into human cells. In the case of our particular *L. monocytogenes* screening protocol, we established an immunofluorescence-based assay relying on the cytosolic detection of InIC, a bacterial protein from the internalin family that is highly expressed and secreted by intracellular *L. monocytogenes*, allowing for a robust quantification of the infection. Results of kinome screens confirmed the functionality and stability of our assay and we are currently upscaling the screen to a genome-wide level.

#### **Cytological Changes Due to Chlamydial Infection are Not Conserved Among Species.**

*H. M. Brown<sup>1</sup>, T. S. Richards<sup>1</sup>, R. K. Patel<sup>1</sup>, S. S. Grieshaber<sup>1</sup>; <sup>1</sup>Oral Biology, University of Florida, Gainesville, FL*

Chlamydiae are obligate intracellular bacteria that cause a variety of diseases in both humans and animals. Previous studies have established that *C. trachomatis* L2 causes shortened mitosis, declustering of amplified centrosomes and cytokinesis failure resulting in multinucleation, all potential mechanisms for transformation of cells. Here, we have investigated the cytological changes that have been established for *C. trachomatis* and performed a comparison to *C. muridarum* and *C. caviae* to determine the conservation of these effects between different Chlamydia species. First, we observed a greater percentage of multinucleated cells due to *C. trachomatis* infection than the other Chlamydia species. Therefore, we aimed to determine if the other established cytological changes are conserved among Chlamydia species. All three species were able to cause a decrease in mitotic index and amplified centrosomes. However, we observed the greatest spindle multipolarity in *C. trachomatis*, with an intermediate phenotype in *C. muridarum* and the least multipolarity in *C. caviae*. The spindle multipolarity follows the trend in multinucleation that was first observed.

Furthermore, when cells were infected with *C. trachomatis*, the cell was unable to cluster centrosomes as efficiently as the other species. These results suggest Chlamydia species may interact differently with host centrosomes. We hypothesize that different cytological changes among species may correlate with the ability to cause transformation.

2454

#### **The *Pseudomonas aeruginosa* N-Acylhomoserine Lactone Quorum Sensing Molecules Target IQGAP1 in Human Epithelial Cells.**

*T. Karlsson<sup>1</sup>, M. V. Turkina<sup>1</sup>, K-E. Magnusson<sup>1</sup>, E. Vikström<sup>1</sup>; <sup>1</sup>Department of Clinical and Experimental Medicine, Linköping University, Linköping, Sweden*

Quorum sensing (QS) signaling allows bacteria to control gene expression once a critical population density is achieved. The Gram-negative human pathogen *Pseudomonas aeruginosa*

uses *N*-acylhomoserine lactones (AHL) as QS signals, which coordinate the production of virulence factors and biofilms. There is increasing evidence suggesting that AHLs can induce changes in phenotype in neighboring cells, including other bacteria and eukaryotic host cells. Still, rather little is known about the exact mechanisms of action of AHL on eukaryotic cells and their direct targets or receptors.

In the present study, we have designed and validated new 3O-C<sub>12</sub>-HSL probes, which we utilize to find out the human protein target of 3O-C<sub>12</sub>-HSL in epithelial Caco-2 cells.

Using 3O-C<sub>12</sub>-HSL biotin- and fluorescein-based probes for LC-MS/MS and confocal imaging, respectively, we demonstrated for the first time that 3O-C<sub>12</sub>-HSL interacts and co-localizes with the IQ-motif-containing GTPase-activating protein IQGAP1 in Caco-2 cells. The interaction between IQGAP1 and 3O-C<sub>12</sub>-HSL was further confirmed by pull-down assay using a GST-tagged protein with subsequent Western blot of IQGAP1 and identification of 3O-C<sub>12</sub>-HSL with a sensor bioassay. Moreover, 3O-C<sub>12</sub>-HSL induced changes in the phosphorylation status of Rac1 and Cdc42 and localization of IQGAP1 as evidenced by confocal and high resolution STED microscopy and Western blots. Rac1 and Cdc42 are the upstream effectors of filamentous actin remodeling, and thereby of cell shape and motility in mammalian cells. The RasGAP homology domain in IQGAP1 directly interacts with the Rho-family GTPases, Rac1 and Cdc42 in their phosphorylated and GTP-bound state.

Our findings imply that the IQGAP1 is a novel partner for *P.aeruginosa* 3O-C<sub>12</sub>-HSL and, likely an integrator of Rac1 and Cdc42- dependent altered cell migration. We propose that the targeting of IQGAP1 by 3O-C<sub>12</sub>-HSL can trigger essential changes in the cytoskeleton network and thereby be an essential component in bacteria – human cell communication.

### Identifying Interactions between *Legionella pneumophila* Effector Proteins and Endocytic Rabs.

C. Valladolid<sup>1</sup>, D-P. Stein<sup>1</sup>; <sup>1</sup>Department of Biology, California State University, Northridge, Northridge, CA

The *Legionella pneumophila* bacterium is a respiratory pathogen phagocytized by alveolar macrophages. Through the use of a Dot/Icm type IV secretion system, *Legionella* is able to inject effector proteins into a host cell to ensure its survival. Secreted effector proteins allow the bacteria to evade degradation within the endocytic pathway as well as enable intracellular replication. Inhibiting lysosomal fusion for removal from the cell suggests an interaction between endocytic cell proteins and *Legionella* effector proteins. Previous studies have identified interactions between Dot/Icm substrates, bound to the membrane of a *Legionella*-containing vacuole, and Rab proteins localized to the late endosome and lysosome. In our lab, yeast two-hybrid assays have been used to examine interactions between early endosomal Rab proteins, Rab4a, Rab5a, Rab15, Rab22a, and Rab35, and various *Legionella* effector proteins. LegC7, known to disrupt vesicular trafficking and the endolysosomal pathway, was one of many *Legionella* effector proteins found to bind to Rabs in the yeast two-hybrid assay. I am examining the interaction between *Legionella* LegC7 and Rab5 proteins. Methods used to characterize these interactions include: amplifying genes of interest using PCR, GC Cloning, gel extractions, ligations, bacterial transformation, protein expression and DNA sequencing. Analyses of protein-protein binding will be investigated by GST- and Nickel-pull-down assays. Confirming the interactions between *Legionella* proteins and Rab GTPases will allow for a better understanding of how *Legionella* is able to modify the endocytic pathway using a Dot/Icm secretion system. This may provide insight into how bacteria manipulate host cells for survival.

**Cellular aspects of the infection by *Acanthamoeba castellanii*.**

M. Sabanero<sup>1</sup>, K. Soto<sup>1</sup>, L. Flores<sup>1</sup>, G. Barbosa<sup>2</sup>; <sup>1</sup>Biología, Universidad de Guanajuato, Guanajuato, Mexico, <sup>2</sup>Ciencias Medicas, Universidad de Guanajuato, León, Mexico

Acanthamoebiasis in the human causes amebic keratitis and granulomatous encephalitis (Marciano-Cabral et. al. 2000). Particularly, *A. castellanii* induce human infection, this process require amoebas viability and actin microfilaments. In *A. castellanii* little know on surface proteins and actin cytoskeleton during host cell interaction (Yang et. al. 1997). In this work, we hypothesize that *A. castellanii* express ligands on their surface that binds to a receptor on host cell. Moreover, analyzed the actin filaments during parasite-host cells interaction. Operationally, the trophozoites of *A. castellanii* were cultured in Chang medium with 10% fetal calf serum. Epithelial (L929, ATCC CCL-2) and neuronal cells (SHSY5Y, ATCC CRL-2266) were used as host cells. Interaction assay was performed by adding 105 trophozoites to cell monolayers at different times (15, 30 and 45 min). After, cells were exposed to antibodies against *A. castellanii*, secondary antibody -Rhodamine and co-stain with Ph-FITC. The preparations were observed by confocal microscopy. Biotin and biotinylated lectins (AGT and ConA) were used to labell the protein and glycoprotein of trophozoite surface. To determine the proteins that could present affinity to host cells, biotinylated proteins of *A. castellanii* were added to the host cells. The bind proteins were detected by streptavidin-peroxidase. During the infection, there are alterations of cytoskeleton of host cells and trophozoite maintained the actin filaments in acanthopodia. *A. castellanii* show surface proteins with Mr> 180-108kD, Mr> 85-32kD, Mr> 28-17kD. Three proteins with MW > 130, 90 and 54 kD show affinity to epithelial and neuronal cells, some of this molecules are glycoproteins. In summary: i) in model in vitro our study, show that the host cell response to contact *A. castellanii* and show adherence parasite. ii) After, injuries and eventually kills cells and iii) the molecules that show affinity to host cell initiate the adhesion process and cell invasion. We are currently working to identify these molecules and characterize signal mechanism that regulated the invasion.

Acknowledgments. Work in our laboratory is supported by grants from the CONACYT 157577 and DAIP, UG-2011-MSL.

**The Role of Lipid Raft Aggregation in the Infection of Type II Pneumocytes by *Mycobacterium tuberculosis*.**

K. F. Coulson<sup>1</sup>, B. Reaves<sup>1</sup>, R. Karls<sup>1</sup>, F. Quinn<sup>1</sup>; <sup>1</sup>Infectious Diseases, University of Georgia, Athens, GA

Dynamic, cholesterol-dense regions of the plasma membrane, known as lipid rafts (LR), have been observed to develop during and may be directly involved in infection of host cells by various pathogens. This study focuses on LR aggregation induced in alveolar epithelial cells during infection with *Mycobacterium tuberculosis* (*Mtb*) bacilli. We report dose- and time-dependent increases in LR aggregation after infection with *Mtb* bacilli at multiplicities of infection of 1, 10 and 100 from 2-24 hr post infection (hpi). Specific strain-dependent variations in the number of LR aggregates produced were noted among H37Rv, HN878 and CDC1551 during the 24 hour infection period. Treatment of epithelial cells with culture filtrate protein, total lipids and gamma-irradiated whole cells from each strain failed to induce the level of LR aggregation observed during infection with any of the live strains. However, filtered supernatants from infected epithelial cells did produce comparable LR aggregation, a process that was inhibited in the presence of a bacterial protein synthesis inhibitor, suggesting a secreted mycobacterial

protein produced during infection of host cells is responsible for LR aggregation. Disruption of lipid raft formation, with the LR-disruption agent Filipin III, prior to infection indicates that *Mtb* bacilli utilize LR aggregates for internalization and survival in epithelial cells. This study provides evidence for significant mycobacterial-induced changes in the plasma membrane of alveolar epithelial cells and that *Mtb* strains vary in their ability to facilitate aggregation and utilization of LR.

### **AHNAK is Required for the Formation of *Salmonella*-Induced Plasma Membrane Ruffles During Invasion of Nonphagocytic Cells.**

C. Jolly<sup>1</sup>, S. Winfree<sup>1</sup>, T. Starr<sup>1</sup>, O. Steele-Mortimer<sup>1</sup>; <sup>1</sup>*Salmonella* Host-Cell Interactions Section, NIH/NIAID/Rocky Mountain Laboratories/LICP, Hamilton, MT

Acute gastroenteritis due to nontyphoidal *Salmonella* infection is one of the most common foodborne illnesses in the world, with an estimated 90 million cases and 150,000 deaths occurring annually. A crucial component of *Salmonella* pathogenicity is their ability to actively invade nonphagocytic intestinal epithelial cells. To do this, *Salmonella* use a type III secretion system to translocate a cohort of bacterial effector proteins into the host cell cytosol where they drive actin polymerization at the entry site. Rapid rearrangement of the actin cytoskeleton leads to the localized formation of prominent plasma membrane ruffles that engulf the bacteria in a manner reminiscent of macropinocytosis. Several aspects of *Salmonella* invasion are well understood but we still lack a complete understanding of which host cell proteins are required. We recently demonstrated that the giant phosphoprotein AHNAK is enriched at *Salmonella*-induced plasma membrane ruffles. AHNAK is a membrane-associated protein that has been implicated in vesicle-mediated membrane repair processes, interacts with actin, and potentially acts as a scaffolding protein during membrane signalling events. To examine the role of AHNAK in *Salmonella* invasion, we performed siRNA-mediated knockdown of AHNAK in HeLa cells and consequently observed a ~75% decrease in *Salmonella* invasion. To validate these results, we examined the ability of *Salmonella* to invade mouse embryonic fibroblasts (MEFs) isolated from AHNAK<sup>+/+</sup> and AHNAK<sup>-/-</sup> mice and found that *Salmonella* invasion was decreased by ~80.0% in the AHNAK<sup>-/-</sup> MEFs. These results clearly demonstrate that AHNAK is required for efficient *Salmonella* invasion. Our next objective was to determine the mechanism by which AHNAK contributes to *Salmonella* invasion. Formation of *Salmonella*-induced plasma membrane ruffles is a hallmark of invasion. Therefore, we examined the ability of *Salmonella* to induce plasma membrane ruffles during invasion of AHNAK-depleted cells. Surprisingly, we were unable to identify *Salmonella*-induced plasma membrane ruffles on AHNAK-depleted cells using either immunofluorescence microscopy or scanning electron microscopy. Future experiments will include examination of *Salmonella* invasion by live-cell fluorescence microscopy. This technique will allow us to observe the interaction between the bacteria and host cell in real-time and will allow us to better determine how AHNAK contributes to the formation of the *Salmonella*-induced plasma membrane ruffles.

### The Role of ELMO1 in the Internalization of Enteric Bacteria and Regulation of Inflammatory Responses.

S. Das<sup>1</sup>, K. A. Owen<sup>2</sup>, A. Sarkar<sup>1</sup>, S. Fox<sup>1</sup>, M. R. Elliott<sup>3</sup>, K. Ravichandran<sup>4</sup>, J. E. Casanova<sup>2</sup>, P. B. Ernst<sup>1</sup>; <sup>1</sup>Pathology, Univ of California San Diego, San Diego, CA, <sup>2</sup>Cell Biology, University of Virginia, Charlottesville, VA, <sup>3</sup>Microbiology and Immunology, University of Rochester Medical School, Rochester, NY, <sup>4</sup>Microbiology, University of Virginia, Charlottesville, VA

The World Health Organization estimates that each year as many as 4-6 million people die of enteric bacterial infections. After invading intestinal epithelial cells, bacteria gain access to the subepithelial tissue and the lamina propria where they encounter and infect phagocytes. However, little is known about how phagocytes internalize enteric bacteria reaching the lamina propria in order to clear the infection. Clearance of bacteria by phagocytes plays an essential role in the host response to infection. Bacterial internalization requires the activation of small Rho GTPases such as Rac1 that leads to rearrangement of the actin cytoskeleton and creation of the plasma membrane ruffle. It has been shown previously that the BAI1-ELMO1-Dock180 pathway stimulates Rac1 activation which has a pivotal role in producing the membrane ruffle. ELMO1 was first identified as a protein required for Engulfment and cell Motility and phagocytosis of apoptotic cells. Recently we found that BAI1 (Brain Angiogenesis Inhibitor 1) recognizes Gram-negative bacteria through their lipopolysaccharide (LPS) and therefore acts as a receptor for bacterial attachment. We hypothesized that recognition of Gram-negative bacteria by BAI1 leads to ELMO1-mediated signaling events that regulate bacterial internalization and the subsequent host inflammatory responses in the intestine. Phagocytes in which ELMO1 expression was depleted by shRNA (J774 cells) as well as macrophages isolated from the small intestines of ELMO1 KO or wildtype mice were exposed to Salmonella. Subsequently, bacterial binding, internalization, Rac activation and cytokine responses were assayed. In addition, ELMO1 KO mice were infected and the bacterial burden and inflammatory response assessed in multiple tissues. We found that the down regulation of ELMO1 in macrophages reduced internalization of Salmonella and decreased Rac1 activation following infection. Bacterial internalization was virtually ablated in intestinal macrophages isolated from infected ELMO1 KO mice. Interestingly, inhibition of the ELMO1/Rac function significantly impaired the pro-inflammatory response to infection in cells examined in vitro. Moreover, ELMO1-deficient mice showed attenuated inflammatory responses in the ileum, spleen and cecum. Together these findings suggested a novel role for ELMO1 in Rac1 activation to control bacterial internalization into intestinal macrophages and the subsequent inflammation during enteric diseases.

### Infection of A549 human type II epithelial cells with *Mycobacterium tuberculosis* induces changes in mitochondrial morphology, distribution and mass that are dependent on the early secreted antigen, ESAT-6.

K. Fine-Coulson<sup>1</sup>, F. D. Quinn<sup>1</sup>, B. J. Reaves<sup>1</sup>; <sup>1</sup>Infectious Diseases, University of Georgia, Athens, GA

Pulmonary infection by *Mycobacterium tuberculosis* (*Mtb*) involves the invasion of alveolar epithelial cells, however host-pathogen interactions in these cells are just starting to be characterized. In electron microscopy studies we observed extensive redistribution and remodeling of mitochondria in A549 type II human alveolar epithelial cells infected with the virulent strain *Mtb* Erdman at late stages of infection, specifically 72 and 96 hours post-infection (hpi). In order to further investigate these changes, we used Mitotracker Red® to assess changes in mitochondrial morphology/ distribution and mass from 6-72 hpi by both confocal microscopy and flow cytometry respectively. Early in infection there was no apparent effect on

mitochondrial morphology, however, by 36-48 hpi mitochondria appeared fragmented with small spheres clustered in a perinuclear localization. In addition, the median intensity fluorescence (MFI) in flow cytometry experiments decreased by 30% (average of 3 experiments) at 48 hpi with a further decrease at 72 hpi suggesting a reduction in mitochondrial mass. Mitotracker Red® accumulation is dependent on mitochondrial membrane potential ( $\Psi_m$ ), so these results could indicate either a reduction in  $\Psi_m$  or a direct effect on numbers and structure of mitochondria. Extensive colocalization of Mitotracker Red® with the integral membrane protein COXIV at 48 hpi indicated that the decrease in numbers and changes in distribution/morphology of the mitochondria were due to direct effects on structure. In contrast, mitochondria in cells infected with the non-virulent strain *M. bovis* BCG appeared similar to uninfected control cells. A virulence factor present in *Mtb* Erdman that is lacking in *M. Bovis* BCG is the early secreted antigen, ESAT-6 which has been shown to be important for infection in type II pneumocytes. Therefore, we performed similar experiments using the parental strain *Mtb* Erdman, an ESAT-6 deletion mutant and its complement. MFI decreased in the WT and complemented strains versus uninfected controls by 65% and 45% respectively; no decrease was detected in the deletion mutant. These results indicate an involvement of ESAT-6 in the perturbation of mitochondria by virulent *Mtb*. Current studies are addressing whether this is a direct effect of ESAT-6 on mitochondrial membranes and whether other co-effectors are necessary.

### **Bax/Bak Orchestrate Ion Transport, Apoptosis and Inflammatory Response of Host Cells to *Pseudomonas aeruginosa* Quorum-Sensing Molecule Homoserine Lactone.**

C. Schwarzer<sup>1</sup>, Z. Fu<sup>1</sup>, M. Grabiner<sup>1</sup>, S. Shuai<sup>1</sup>, J. Kim<sup>1</sup>, T. E. Machen<sup>1</sup>; <sup>1</sup>Molecular and Cell Biology, Univ. California - Berkeley, Berkeley, CA

*Pseudomonas aeruginosa*, which accumulate in the lungs of cystic fibrosis (CF) patients, use N-(3-oxododecanoyl)-homoserine lactone (C12) as a quorum-sensing molecule. C12 also affects host cells: activating the IP<sub>3</sub> receptor, stimulating cAMP and CFTR, triggering the ER unfolded protein response and apoptosis and both pro- and anti-inflammatory responses. The present work tested whether Bax and Bak were involved in the effects of C12 on fibroblasts. In wild type mouse embryo fibroblasts (wt MEF's) C12 (50µM) elicited apoptosis-associated blebbing of plasma membranes, condensation of nuclei, release of cytochrome C from mitochondria and activation of caspase 3/7. C12 also caused the ER to release Ca<sup>2+</sup> and mitochondria to depolarize. C12 caused none of these effects in Bax<sup>-/-</sup>/Bak<sup>-/-</sup> (dko) MEF's. C12 caused NF-κB p65 to enter the nucleus from the cytosol, but also inhibited NF-κB-regulated luciferase expression in wt but not in dko MEF's. C12 stimulated expression/transcription but inhibited secretion of proinflammatory cytokines IL6 and KC in untreated and in TNFα-treated wt MEF's. In contrast, C12 did not affect NF-κB or expression or secretion of cytokines in either untreated or in TNFα-treated dko MEF's. Thus, C12-triggered events all required Bax/Bak, indicating the responses were mediated through a common mechanism that shares many characteristics with pattern associated molecular pattern receptors (e.g., TLR's and NODs). It is proposed that C12 regulates Bax/Bak, which causes: (i) depolarization of mitochondria; (ii) release of cytochrome C (leading to activation of caspase 3/7 and apoptosis); (iii) activation of IP<sub>3</sub>R (and release of Ca<sup>2+</sup> from the ER into the cytosol, activation of STIM1 and adenylate cyclase and cAMP/PKA and CFTR); (iv) activation of NF-κB and expression of cytokine genes but inhibition of cytokine production and secretion resulting from effects of C12 to trigger ER stress and inhibit protein synthesis.

**Role of Aquaporin 9 in Leukocyte Activation and Differentiation.**A. Holm<sup>1</sup>, J. Gardin<sup>1</sup>, T. Karlsson<sup>1</sup>, V. Loitto<sup>1</sup>, J. Wetterö<sup>1</sup>, E. Vikström<sup>1</sup>, K-E. Magnusson<sup>1</sup>;<sup>1</sup>Clinical and Experimental Medicine, Linköping University, Linköping, Sweden

The aquaporins (AQPs) are a family of water channels that transports water and other small uncharged solutes over the plasma membrane. They are involved in cellular events like volume and shape regulation. The aquaglyceroporin AQP9 is the main AQP in human leukocytes and has been suggested to play a pivotal role in inflammatory responses like cell migration, differentiation and metabolism. Thus, we chose to investigate the role and regulation of AQP9 expression in human primary immune cells in response to inflammatory stimuli. The AQP9 mRNA expression increased upon inflammatory stimuli both with *Salmonella* lipopolysaccharide (LPS) and with *Pseudomonas aeruginosa* quorum-sensing molecule N-3-oxo-dodecanoyl-homoserine lactone (3O-C12-HSL). The administration of the TNF inhibitor Infliximab seemed to block the increase of AQP9 mRNA expression, further indicating the role of AQP9 in inflammatory responses and suggesting a regulatory pathway of expression through NFκB. Moreover, the human promyelocytic cell line HL-60 showed a significant increase in AQP9 expression when differentiated towards macrophages and neutrophils, suggesting additional importance for AQP9 in inflammatory cells and opening up for AQP9 as a differentiation marker with a role in functional cell maturation.

2463

**Role of The Type Three Secretion System effectors family NleG.**M. Lomma<sup>1</sup>, G. Frankel<sup>1</sup>; <sup>1</sup>Imperial College London, London, UK

Many bacterial pathogens use type III secretion systems (T3SS) to inject 'effector' proteins into the cytosol of the host cell to subvert multiple signalling pathways. T3SS effectors can either be pathotype specific, functional to a particular infection strategy, or common to multiple pathogens to target conserved host cell signalling pathways. Although *Salmonella* and *E. coli* use very different infection strategies, they express homologous effectors named NleGs.

The aim of this study is to elucidate the function of the NleGs and investigate their role during bacterial infection. Effectors belonging to the NleG family have been recently described as a new class of bacterial E3 ubiquitin ligase. Indeed, all NleGs share a conserved C-terminus domain, with a U-box fold and E3 ubiquitin ligase activity, and a more variant N-terminal domain. Importantly, our preliminary data show that different members of this family show different intracellular localisation, suggesting that they may serve very different functions during infection. As example, one of the NleGs expressed by enterohaemorrhagic *E. coli* O157:H7 binds the NA<sup>+</sup>/H<sup>+</sup> exchanger regulatory factors 1 (NHERF1) and is translocated to the nucleus upon transfection and during infection. Strikingly, NleG from *Salmonella enterica* serovar Typhi and its homologous in *Salmonella bongori* show a completely different localisation pattern as they are found on vesicles positive for the recycling endosomes marker Rab11 and the autophagosomal marker LC3.

The role of the ubiquitin ligases in *E. coli* and *S. Typhi* infection remains by large unknown, however understanding the function of this new class of T3SS effectors may shed a new light on the infectious strategies of enteric bacteria.

**A novel role for lipid droplets in the organismal antibacterial response.**

P. Anand<sup>1</sup>, S. Cermelli<sup>1</sup>, Z. Li<sup>2</sup>, A. Kassan<sup>3</sup>, M. Bosch<sup>3</sup>, R. Sigua<sup>1</sup>, A. J. Ouellette<sup>4</sup>, A. Pol<sup>3</sup>, M. A. Welte<sup>2</sup>, S. P. Gross<sup>1</sup>; <sup>1</sup>University of California, Irvine, Irvine, CA, <sup>2</sup>University of Rochester, Rochester, NY, <sup>3</sup>Institut d'Investigacions Biomèdiques August Pi i Sunyer, Casanova, Spain, <sup>4</sup>University of Southern California, Los Angeles, CA

Histones are fundamental components of eukaryotic chromatin, and are therefore abundant in essentially all animal cells. Histones and histone fragments are antimicrobial in in vitro assays. In principle, then, histones normally present in cells could confer protection against microbes that exploit intracellular niches. However, until now this has seemed unlikely for two reasons. First, histones typically are located in the nucleus, excluding contact with cytosolic bacteria. Second, because unconfined histones cause genomic instability, hypersensitivity to DNA-damaging agents, and lethality, cells minimize excess histones by active mechanisms. Lipid droplets (LDs), the ubiquitous highly dynamic organelles, found in a wide range of organisms store lipids, but much less are known about their other biological functions. Our recent study suggested that LDs could sequester proteins like histones that might otherwise cause cellular distress. Consistent with functional sequestration, we show that histones are tightly bound to droplets and could act as intracellular antibacterial defense system. We show that in a *Drosophila* embryo model system, wild type embryos having lipid droplets bound with histones are extremely resistant to bacterial challenge while mutant embryos having lipid droplets lacking histones are very susceptible. While more work remains to understand the role of histones in adult immunity, our initial data is consistent with the hypothesis that the embryonic system described above may function in adult flies as well. These findings prove that histones on lipid droplets contribute to innate immunity in flies. This intracellular antibacterial defense system may be conserved, since mice respond to a simulated bacterial infection by increasing droplet-bound histones in the liver.

**The role of orphan nuclear receptor NR4A1 in the defense against bacterial pore-forming toxins.**

F. C. Los<sup>1</sup>, A. J. Ratner<sup>1</sup>; <sup>1</sup>Dept. of Pediatrics, Columbia University, New York, NY

Pore-forming toxins (PFTs) are the most prevalent cytotoxic bacterial proteins and are generally required for pathogenesis in the large majority of problematic bacterial infections. PFTs function by perforating host cell membranes, mainly to ultimately aid bacteria in immune evasion and spreading to different compartments within the host. Membrane repair mechanisms and several physiological defense pathways have been identified, but fine details on how host cells defend against PFTs remain elusive. We performed genome-wide microarray analysis of human A549 cells exposed to the *Streptococcus pneumoniae* PFT pneumolysin. We found that 113 genes were differentially expressed specifically in response to the pore-forming activity of PLY. Among others, orphan nuclear receptors of the NR4A class were strongly upregulated. This effect extended to HeLa cells exposed to the *Gardenerella vaginalis* PFT vaginolysin. NR4A1 is a known player in metabolism and various immune responses, and depending on its phosphorylation state and associated subcellular localization, NR4A1 can trigger apoptosis (mitochondrial localization) or function as a transcription factor (nuclear localization). Using fluorescence microscopy and Western blotting, we confirmed upregulation of NR4A1 at the protein level, and found that PFT exposure alters the phosphorylation state of NR4A1 while its localization appears to remain predominantly nuclear. These and other, preliminary data are consistent with a role for NR4A1 as a transcription factor in cellular immune defenses against

PFTs. Investigation of the effect of loss or gain of NR4A1 function on PFT defense is ongoing, as are the identification of upstream regulators and downstream effectors.

**Chlamydia effectors target the host ESCRT system.**

F. Vromman<sup>1</sup>, A. Subtil<sup>1</sup>; <sup>1</sup>Biologie des Interactions Cellulaires, Institut Pasteur, Paris, France

*Chlamydiae* are Gram-negative obligate intracellular pathogens that replicate within a membrane-bounded compartment termed inclusion. Throughout their development they use a type III secretion (T3S) system to translocate effector proteins into the inclusion membrane or in the host cell cytoplasm, thereby modifying the eukaryotic environment. We have previously described a new family of T3S effector proteins present in all *Chlamydiae*. It is defined by a common C-terminal domain of unknown function, DUF582, found only in *Chlamydiaceae*. Each genome encodes 4 or 5 proteins of the family, which are expressed at the mid and late phases of the infectious cycle.

A yeast two-hybrid screen performed with the C-terminal domain of two members of the family from *C. trachomatis* suggested the ESCRT system as a target. The ESCRT system drives the sorting towards degradation compartments of ubiquitinated proteins and the formation of multivesicular bodies. We confirmed the two hybrid interaction data by immunofluorescence and immunoprecipitation in cells transfected with DUF582. During infection, one component of the ESCRT machinery gradually disappeared after the mid phase of infection, consistent with the kinetics of DUF582 protein expression. When overexpressed, it was recruited to the inclusion membranes at the late time points. Also, its depletion using different siRNA strongly stimulated *Chlamydia* development resulting in an increased progeny. The quantity of DUF582 proteins was specifically increased in depleted cells (compared to other bacterial markers), providing an independent link between the ESCRT system and this family of proteins.

Altogether, those results suggest that the ESCRT machinery normally limits *Chlamydia* growth and that *Chlamydia trachomatis* is manipulating it during infection. Our current work is focusing on understanding the resulting benefit for the bacteria.

**Luminal release of exosomal vesicles from biliary epithelium contributes to TLR4-mediated mucosal anti-Cryptosporidium parvum defense.**

G. Hu<sup>1</sup>, A-Y. Gong<sup>1</sup>, A. L. Roth<sup>1</sup>, N. D. Hanson<sup>1</sup>, X-M. Chen<sup>1</sup>; <sup>1</sup>Medical Microbiology and Immunology, Creighton University, Omaha, NE

Exosomes are membranous nanovesicles released by most cell types from multivesicular endosomes. They are speculated to transfer molecules to neighboring or distant cells and modulate physiological and pathological procedures, such as angiogenesis, cell proliferation, and tumor-cell invasion. Exosomes released from gastrointestinal epithelium to the basolateral side have been implicated in antigen presentation. Here, we reported that luminal release of exosomal vesicles from biliary epithelium is increased following infection by a protozoan parasite, *Cryptosporidium parvum*. Release of exosomal vesicles involves activation of TLR4/IKK2 signaling through promoting SNAP23-associated vesicular exocytotic process. Downregulation of let-7 family miRNAs by activation of the TLR4 signaling increases SNAP23 expression, coordinating exosome release in response to *C. parvum* infection. Intriguingly, exosomal vesicles carry antimicrobial peptides of epithelial cell origin, including cathelicidin-37

and beta-defensin 2. Activation of TLR4 signaling enhances exosomal shuttle of epithelial antimicrobial peptides. Exposure of *C. parvum* sporozoites to released exosomal vesicles decreases their viability and infectivity both in vitro and ex vivo. Direct binding to *C. parvum* sporozoite surface is required for the anti-*C. parvum* activity of released exosomal vesicles. Our data indicate that TLR4 signaling regulates luminal release of exosomes and exosomal shuttling of antimicrobial peptides from biliary epithelium, revealing a new arm of mucosal immunity mechanisms relevant to biliary antimicrobial defense.

### Investigating dynamics of microbial colonization of the zebrafish gut using light sheet microscopy.

M. Jemielita<sup>1</sup>, M. J. Taormina<sup>1</sup>, W. Z. Stephens<sup>2</sup>, A. R. Burns<sup>3</sup>, J. V. Troll<sup>2</sup>, K. Guillemin<sup>2</sup>, R. Parthasarathy<sup>1,4,5</sup>; <sup>1</sup>Department of Physics, University of Oregon, Eugene, OR, <sup>2</sup>Institute of Molecular Biology, University of Oregon, Eugene, OR, <sup>3</sup>Institute of Ecology and Evolution, University of Oregon, Eugene, OR, <sup>4</sup>Material Science Institute, University of Oregon, Eugene, OR, <sup>5</sup>Institute of Molecular Biology, Eugene, OR

Microbial colonization of the intestine is an important event in the development of vertebrate animals, playing a role in the maturation of host immunity and the establishment of normal digestive function. Recent advances in genomic technologies have led to a greater understanding of the composition of microbial communities in animals. However, genomic approaches lack the spatial and temporal resolution needed to characterize the dynamics of how complex symbiotic populations arise, and how their constituent members compete and cooperate with one another. Using light sheet microscopy we are able to achieve the speed, resolution, and large field of view necessary to image the initial bacterial colonization of initially germ-free zebrafish intestines. This technique allows us to characterize both bulk population dynamics over the length of the entire organ and the behaviors of individual bacteria in vivo.

### In vivo passage changes the protein profile of *Klebsiella pneumoniae* and may associate with bacterial virulence.

J. H. Wu<sup>1</sup>, K-C. Yeou<sup>1</sup>, J-Y. Chen<sup>1</sup>, F-Y. Chang<sup>1</sup>; <sup>1</sup>Microbiology and Immunology, Chang Gung University, Tao Yuan, Taiwan

Enterobacterium *Klebsiella pneumoniae* (KP) causes opportunist infections including urinary tract (UTI), wound and pulmonary infection. Emerging evidence indicates that the KP causes liver abscess (LA) in Southeast Asia and the disease is especially severe in diabetic patients. Comparison of 1-D protein profile of Kp3 (a UTI KP strain) and Kp5 (LA KP strain) revealed that TerD/E is unique in Kp5. Using a pair of primers amplify the KP genome of several clinical KP strains, we observed that gene *kpv1* only present in LA-KP strains, but not in UTI-KP strains. Attempt to compare the 2D gel protein profile of Kp3 and Kp5 did not show comprehensive results. As the Kp5 strain has been cultured in vitro for several passage, we wondered if passage in vivo (mice) might reveal different protein profile, we therefore compared the Kp5, HepG2- and mice-passed Kp5 (Kp5m) protein expression profile by 2D gel analysis. Results on MALDI-TOF analysis revealed that Kp5m expressed several changes in proteins, including ATP synthase subunit alpha / epsilon chain, TolB, Rbose-5-phosphate isomerase A, elongation factor Tu (EF-Tu) and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) Further analysis revealed that *terD/E* and *kpv1* genes are on a large (>200 kb) plasmid. Immune sera obtained from surviving mice infected with Kp5 detected bacterial EF-Tu, GAPDH, outer membrane protein A (OmpA) and fructose-bis-phosphate aldolase (FPA) indicating possible surface location of these proteins. Differential fractionation of Kp3, Kp5 and Kp5m bacterial extract

revealed that EF-Tu, OmpA, FPA and GAPDH were increased in membrane fraction for Kp5 and Kp5m; with higher amount in Kp5m than in Kp5. These results suggest that Kp5 may express EF-Tu, OmpA, FPA and GAPDH on surface detectable by immune serum during infection and may contribute to bacterial virulence in vivo, since antibodies to these proteins protect the infected mice.

2471

**Pleurocidin exerts synergistic antibacterial effect in combination with antibiotics and antibiofilm activity.**

H. Choi<sup>1</sup>, D. Lee<sup>1</sup>; <sup>1</sup>Kyungpook National University, Daegu, Korea

Pleurocidin, a 25-mer antimicrobial peptide, is known to exert bactericidal activity. However, the synergistic effect and its mechanism(s) of pleurocidin in combination with conventional antibiotics, and the antibiofilm activity of the peptide are weakly understood. All combinations of pleurocidin and antibiotics showed synergistic interaction against bacterial strains (fractional inhibitory concentration index (FICI)  $\leq 0.5$ ) except for *Enterococcus faecium* treated with a combination of the peptide and ampicillin (FICI = 0.75). In assay using fluorescent dye 3'-(*p*-hydroxyphenyl) fluorescein (HPF), we identified that pleurocidin alone and combinations with antibiotics induced formation of hydroxyl radical. The oxidative stress was caused by a transient NADH depletion and the addition of thiourea prevented bacterial death, especially in case of combined treatment of pleurocidin and ampicillin. Combination of pleurocidin and erythromycin increased permeability of bacterial cytoplasmic membrane. Additionally, the antibiofilm effect of pleurocidin was examined by tissue culture plate method. Pleurocidin exhibited a potent inhibitory effect on preformed biofilm of bacterial organisms. In this study, we suggest that pleurocidin synergizes with antibiotics by means of hydroxyl radical formation or membrane-active mechanism, and exerts to antibiofilm activity.

2472

**Classification of the normal gut microbiome of harvestmen (Order Opiliones, Class Arachnida).**

N. Morales<sup>1</sup>, T. Thomas<sup>1</sup>, C. Derne<sup>1</sup>, D. Petit-Homme<sup>1</sup>, B. Schoffstall<sup>1</sup>; <sup>1</sup>Barry University, Miami Shores, FL

The spider-like arthropods known as the “harvestmen,” or more commonly “daddy long-legs” (Order Opiliones, Class Arachnida) are familiar though rarely-studied animals. Fossil records of harvestmen indicate they have been in existence for over 300 million years. Although closely related to the true arachnid spiders (Order Araneae), harvestmen neither produce venom nor liquefy prey to ingest enzymatically pre-digested food as true spiders do. Rather, harvestmen are small-bodied predators and scavengers that masticate solid food, suggesting the necessity of a somewhat more complex digestive physiology than that of the true spiders. The normal gut bacterial flora of Order Opiliones has never been classified; we hypothesize that the normal digestive flora found in harvestmen will be more diverse than that found in true spiders. To investigate this hypothesis, we have begun a preliminary survey of aerobic bacterial isolates from the gut and feces samples of two harvestmen species, *Leiobunum* sp. and *Vonones ornata*. Our presumptive microbial identifications have initially been limited to aerobic, non-fastidious isolates using manual morphological and biochemical microbiology methods. We compared isolates from harvestmen to those from a common and representative true spider, *Gasteracantha cancriformes* (the spiny-backed orbweaver). From *V. ornata*, we have identified gram negative *Pseudomonas* spp., *Escherichia coli*, and *Klebsiella* spp., and gram positive *Staphylococcus* spp. From *Leiobunum*, we have identified gram negative *Escherichia coli*, *Enterobacter* spp., and *Salmonella enterica*., and gram positive *Streptococcus* spp.,

*Staphylococcus* spp. and *Bacillus subtilis*. In contrast, cultures from *G. cancriformes* have thus far only yielded identification of gram positive *Bacillus* spp. and *Lactobacillus* spp. From this preliminary survey of aerobic bacteria, we suggest the normal gut microbial flora of harvestmen do exhibit greater diversity than those of true spiders. Future studies will utilize genetic methods for bacterial identification confirmation, and will expand to include classifications of fastidious and anaerobic normal gut microbiota. Given recent interests in the influence of normal gut microbiome on health and disease, our findings will not only serve to further the understanding of the complex digestive system in this ancient lineage of arachnids, but may lead to a new invertebrate model for gut microbiome research.

**Tackling the *Coxiella burnetii* intracellular cycle by high-throughput screening.**

E. Martinez<sup>1</sup>, F. Cantet<sup>1</sup>, M. Bonazzi<sup>1</sup>; <sup>1</sup>UMR-5236 CPBS, CNRS, Montpellier, France

Bacterial pathogens have developed countless strategies to subvert signalling pathways of eukaryotic cells and invade the host, find a suitable replicative niche and spread the infection. Understanding host-pathogens interactions is therefore fundamental to elaborate effective strategies to counter the key steps of the infectious process. *Coxiella burnetii*, the agent of the zoonosis Q fever, is an extremely infectious emerging pathogen causing large outbreaks with a very high economic and health burden. Its obligate intracellular nature had so far severely hampered its study and we ignore most aspects of its interactions with host cells. However, the recent development of a specific axenic growth medium allows today the genetic manipulation of this microbe, opening the way to its detailed investigation. Our aim is to understand the cell biology of *C. burnetii* infections by a novel approach that brings together high-throughput screening and cellular microbiology. We are generating the first bank of *C. burnetii* mutants by transposon mutagenesis and developing high-content functional assays for the rapid and unbiased identification of the bacterial factors involved in the intracellular replicative cycle of *C. burnetii*. To date we have isolated 2000 mutants, 900 of which have been sequenced and screened. To understand how *C. burnetii* invades the host cell, we have identified 37 mutations that severely affect host cell invasion. Among these, we are further characterising three independent mutations in a gene that codes for a bacterial transmembrane protein. This could lead to the identification of the first bacterial ligand that mediates *C. burnetii* internalization within host cells. To understand how *C. burnetii* secretes bacterial effectors into the host cytoplasm we have characterised the phenotype of 19 mutations in genes involved in the bacterial type 4 secretion system (T4SS) and classified these genes into 3 functional classes depending on the morphological characteristics of their phenotype. Furthermore, we have identified 41 mutations that severely affect intracellular replication of *C. burnetii*. Of these, 27 mutations affect genes coding for proteins of unknown function which we are further characterising. The remaining 14 mutations are found in intergenic regions of the *C. burnetii* genome and may be key to the identification of bacterial non-coding RNAs that play an important role in infection. Additional screens are currently being optimised to identify the bacterial factors that protect *C. burnetii* infected cells from apoptosis and those regulating cell-to-cell spread of bacteria during infections. Importantly, our studies on *C. burnetii* will also serve to standardise novel, robust high-throughput assays for the study of other intracellular bacterial pathogens.

**Characterization of Foodborne Staphylococcus Profiles.***J. N. Onyekaba<sup>1</sup>, E. M. Arrey-Mbi<sup>1</sup>; <sup>1</sup>Natural Sciences, Clayton State University, Morrow, GA*

The cellular fatty acid profiles of eight strains of *Bacillus*, *Staphylococcus*, and *Enterobacteriaceae* (*Escherichia coli*, and *Salmonella*) were analyzed by comprehensive two-dimensional gas chromatography/time-of-flight mass spectrometry (GCxGC/TOF MS). A novel template method was developed to standardize the raw GCxGC retention data through the use of a chemical indexing mixture. Analyte retention coordinates were normalized in the primary dimension with respect to a series of n-alkanes (Kovats index) and in the secondary dimension with respect to a series of aromatic hydrocarbons (Lee index). Fatty acid profiles extracted from the templates were compared by multidimensional scaling (MDS) and principal component analysis (PCA). Differences in the profiles of Gram positive and Gram negative bacteria were observed, and a series of heterogeneous mixtures comprised of different fractions (containing one Gram positive and one Gram negative bacterium).

**Identification and characterization of the BI-ARC triple-A ATPase from *Bifidobacterium longum* subsp. *infantis****M. Guzmán-Rodríguez<sup>1</sup>, A. Barba de la Rosa<sup>1</sup>, L. Santos<sup>1</sup>; <sup>1</sup>Molecular biology, Ipcyt, San Luis Potosi, Mexico*

Analysis of *Bifidobacterium longum* genome revealed a new gene, *bl-arc*, which codes a 56.1-kDa protein containing one AAA domain. Phylogenetic classification made by CLANS positioned the sequence into the ARC AAA divergent branch of the AAA ATPase family of proteins. N-terminal sequence analysis indicates this protein is closely related to ATPases involved in the binding and recognition of proteins prior to their proteolysis such as *Rhodococcus erythropolis* ARC, *Archaeoglobus fulgidus* PAN and the human proteasomal Rpt1. We have cloned the gene; the full-length recombinant BI-ARC was over expressed in *E. coli*, and purified it as a homohexameric complex. Functional characterization shows that BI-ARC is Mg<sup>+2</sup>-dependent and *N*-ethylmaleimide-sensitive ATPase activity. ATP hydrolysis followed Michaelis-Menten kinetics with a Km for ATP of 327 μM and Vmax at 37°C of 492 pmol of ATP hydrolyzed per μg of BI-ARC per min. Maximum activity was reached at 37°C and pH 5.0, however it remained stable at a wide pH range (1.5-5.0). Gene organization of *B. longum* locates BI-ARC in a region flanked by a cluster of genes that include several pup proteins. These findings point to a possible role as a chaperone in the degradation pathway via pupylation.

2476

**Cholecystokinin inhibits inducible nitric oxide synthase expression in lipopolysaccharide induced peritoneal macrophages.***E. C. Carnio<sup>1</sup>, R. S. Saia<sup>1</sup>, L. G. Branco<sup>1</sup>; <sup>1</sup>Physiology, University of Sao Paulo, Ribeirao Preto, Brazil*

We investigate the possible modulatory role of cholecystokinin (CCK) on cytokines production and inducible nitric oxide synthase expression (iNOS) in lipopolysaccharide (LPS)-stimulated peritoneal macrophages of rats.

All experimental procedures were approved by the Comitê de Ética em Experimentação Animal - FMRP (protocol nº 152/2009). Male Wistar rats (200-250 g) were used to collection of peritoneal macrophage. Four days before the collection of peritoneal fluid, all rats received an intraperitoneal injection of thioglycollate broth. Cytokines (TNF-α and IL-10) were evaluated in

culture supernatant using ELISA kits, as well as iNOS expression in tissue and cell lysates. Data was compared using one-way analyses of variance (ANOVA) and significant differences were obtained using the Tukey multiple variances post hoc test.

Peritoneal macrophage culture pre-treated with different CCK concentrations (10<sup>-10</sup> or 10<sup>-6</sup> M) before LPS (1 µg/mL) reduced nitrite production at 24 and 48h (p<0.01), as well as iNOS protein and RNAm synthesis. The both CCK tested concentrations reduced NF-κβ p65 levels in the nucleus at 30, 60 and 120 minutes (≈ 52.97 - 58.1%), associated with increased p65 and IκBα cytoplasmatic contents in comparison to LPS group. However, only CCK 10<sup>-10</sup> M + LPS group increased IL-10 levels in macrophage culture supernatant (1221.90 ± 68.19 vs. 730.25 ± 43.70 pg/mL; p<0.05) at 24h after LPS stimulation. The IL-10 neutralization with specific polyclonal antibody reverted the inhibitory effect of CCK on nitrite and iNOS synthesis (p<0.05).

CCK may regulate negatively nitrite production and iNOS expression in LPS-stimulated peritoneal macrophage culture, through decreased NF-κβ activation, IκBα degradation and an auto-regulatory IL-10 mechanism.

**SDF-1/CXCL12 induces migration of lymphocytes by a mechanism pannexin1 hemichannel dependent.**

S. Velasquez<sup>1</sup>, J. A. Orellana<sup>2</sup>, J. C. Saez<sup>2</sup>, E. A. Eugenin<sup>1</sup>; <sup>1</sup>UMDNJ-PHRI, Newark, NJ, <sup>2</sup>Pontificia Universidad Catolica de Chile, Santiago, Chile

In the last few years the role that pannexin hemichannels play in immune cells has received extensive attention. Our previous work showed that HIV infection induced a biphasic opening of these channels, an early opening between 5-30 min and a late opening between 48-120 h after HIV exposure. The events of viral attachment and infection involves interaction of the virus with the cellular receptors, CD4 and CCR5 or CXCR4, depending on the HIV isolate used. Thus, we proposed that activation of specific chemokine receptors results in the physiological opening of pannexin-1 hemichannels in T lymphocytes.

We determined that treatment of T lymphocytes with SDF-1/CXCL12, a key chemokine in lymphocyte migration and HIV infection, induces a transient opening of pannexin-1 hemichannels, but not connexin43 hemichannels. Blocking pannexin-1 hemichannels blocked the lymphocyte migration induced by SDF-1/CXCL12, suggesting that opening of pannexin-1 hemichannels is essential for lymphocyte migration. Our studies of localization indicate that pannexin hemichannels are mainly localized at the leading edge of the cell during migration. Thus, our findings demonstrate that Panx1 hemichannels play an essential role in HIV infection and in lymphocyte migration.

**A Trojan host story: the role of MMP-7 in Giardia SM-induced host pathogenesis**

W-H. Yu<sup>1,2,3</sup>, C-H. Yu<sup>4</sup>, S-L. Yu<sup>5</sup>, S. C. Yu<sup>1,5</sup>, C. Lin<sup>1</sup>; <sup>1</sup>Department of Biochemistry and Molecular Biology, National Taiwan University, college of medicine, Taipei, Taiwan, <sup>2</sup>National Taiwan University, Graduate Institute of brain and mind sciences, Taipei, Taiwan, <sup>3</sup>National Taiwan University, Graduate Institute of developmental Biology and Regenerative medicine, Taipei, Taiwan, <sup>4</sup>Graduate Institute of Physiology, National Taiwan University, College of Medicine, Taipei, Taiwan, <sup>5</sup>Department of Clinical Laboratory Sciences and Medical Biotechnology, National Taiwan University, College of Medicine, Taipei, Taiwan

The intestinal barrier constitutes a single layer of intestinal epithelial cells that are linked by paracellular cadherin and tight junctions. The breach of epithelial barrier may lead to influx of antigen products and microorganisms located in the intestinal lumen. Giardiasis is one of the most commonly identified waterborne intestinal diarrheal diseases. The Giardia parasitic products enhance monolayer permeability and decrease of transepithelial electrical resistance were documented. However, the downstream signaling that cause intestinal epithelial barrier defects is unclear.

The downstream signaling or activation pathways responsible for Giardia duodenalis -induced epithelial barrier defects associated with cleavage of cadherin and tight junctions are unknown. One of the possible hypothesis is that the expression of MMP-7 could lead to cadherin junction destruction during the Giardia sonicate exposure. Interestingly, the significant increasing level of expression of MMP-7 was observed by immunofluorescence staining and western blot analysis. The destruction of intestinal mucosa microvillus correlated to Giardia duodenalis induced MMP-7 expression activities. The shedding and priming of microvillus cause the reduction of the thickness intestinal mucosa layer. The Giardia duodenalis GSM surface binding of MMP-7 were observed in the area where the active intestinal mucosa microvillus shedding and priming during the in vivo Giardia duodenalis GSM challenges and the Giardia surface binding of host MMP-7 could facilitate its invasiveness.

In order to investigate MMP-7 if the facultative protease responsible for intestinal epithelial junction destruction, the MMP-7 knock-out mice and wild type both were performed the intestinal obstruction procedure then the HRP flux was measured in the Ussing chamber assay for determining by the level of mucosal-to-serosal flux of horseradish peroxidase (HRP type II, MW = 44 kD, Sigma). The results demonstrates that the dramatic HRP fluxes observed after 30 minutes measuring in wild type mice, however MMP-7 OK demonstrated the intact epithelial junction barrier and no obvious HRP fluxes observed and the junctional destruction induced bacteria ntranslocation were determined by enteric bacteria translocation assay. The liver and spleen tissue homogenates from challenged mice at different time courses were inoculated into the fresh blood agar and the bacteria colonies were counted. The results demonstrate that the obvious reduction of colonies growth in liver and kidney of the challenged MMP-7 KO group compared to the wild type mouse

### Quantitative Intravital Microscopy of Liver Transport.

J. C. Ryan<sup>1</sup>, M. Ghabril<sup>1</sup>, B. Decker<sup>1</sup>, K. Dunn<sup>1</sup>; <sup>1</sup>Department of Medicine, Division of Nephrology, Indiana University School of Medicine, Indianapolis, IN

Because of its unique ability to collect fluorescence images from deep in biological tissues, intravital multiphoton microscopy has become a valuable tool in several areas of biological research, including neurobiology, cancer biology and immunology. Here we describe methods of quantitative intravital microscopy that we have developed to characterize cholestatic liver injury. Special methods of tissue immobilization, multiphoton microscopy and digital image analysis were developed to support dynamic measurements of the kinetics of transport from the sinusoids into the cytosol and from the cytosol into the bile canaliculi in individual hepatocytes *in vivo*. Using a combination of different fluorescent probes, we have combined transport assays with measures of microvascular function, inflammation and cell viability to provide integrated measures of liver injury. The sensitivity of this approach is demonstrated in quantitative analyses of the acute effects of cholestatic drugs and the effects of chronic kidney disease.

### Single-shot superresolution fluorescence image by modified spinning disk confocal microscope.

S. Hayashi<sup>1</sup>, Y. Okada<sup>2</sup>; <sup>1</sup>Optical Development, Olympus Corp, Tokyo, Japan, <sup>2</sup>Quantitative Biology Center, RIKEN, Osaka, Japan

Most of the recently developed superresolution fluorescence microscopy techniques sacrifice their temporal resolutions to break the diffraction barrier of spatial resolution. A single superresolution image is reconstructed from tens to tens of thousands of time-sequential signals, which often takes a few seconds or longer. The movement in the sample during this acquisition period makes motion blur, which challenges the application of superresolution techniques to live specimens. Here, we report a novel superresolution technique based on the spinning disk confocal microscopy. Theoretically an ideal confocal microscope with infinitesimally small aperture yields an image that contains the information of higher spatial frequency structures up to twice better than the diffraction limit. But its image is too weak for the application to the biological samples. Conventional confocal microscopes, therefore, usually use the aperture size close to the size of the Airy disk, which increases the signal with higher photon correction efficiency at the expense of spatial resolution close to the diffraction limit. We have modified the spinning disk to balance the resolution and the signal intensity. The apertures of the confocal slit were narrowed to increase the resolution. Their intervals were adjusted to achieve acceptable photon correction efficiency with minimal crosstalk between the adjacent slits. A single shot image taken with this modified spinning disk was further processed with a spatial frequency filter to enhance the higher spatial frequency components. This technique, thus, enables the high temporal resolution superresolution imaging with twice better resolution than the diffraction limit. It has no requirements on the fluorescent dyes, so that multi-color superresolution images were obtained with conventional fluorescent dyes or fluorescent proteins. This technique will be, thus, suitable for many cell biology applications.

**Live-cell molecular imaging in the oxidative environment using cysteine-free fluorescent proteins.**T. Suzuki<sup>1</sup>, S. Arai<sup>1</sup>, I. Wada<sup>1</sup>; <sup>1</sup>Cell Science, Fukushima Medical University, Fukushima, Japan

Direct visualization of target molecules using fluorescent proteins (FP) is a powerful approach to analyze molecular mechanisms in living cells. Extensive efforts have been devoted to improve the tag property. However, molecular imaging in the extracellular environment, including the lumen of the secretory pathway, has been limited due to cotranslational oxidation of cysteine residues in FP. Recently, accelerated folding of GFP was shown to reduce the chance of disulfide-bond formation (Traffic (2011) 12:543). Here, we report that each cysteine residue could be substituted with a specific amino acid without loss of molecular brightness (PLoS ONE (2012)7(5)e37551). Although a single molecule photobleaching experiment revealed that only the GFP monomer emitted fluorescence, the presence of cysteine in the fluorescent FP monomer largely affected both motion and folding of the fused protein in the endoplasmic reticulum (ER). An extreme case was a prion fusion protein whose fusion with the conventional FP caused the formation of a SDS-resistant aberrant structure and the retention in the early secretory pathway. Its tagging with cysteine-free (cf)-FP allowed rapid transport to the cell surface where transient raft-association of the single molecule was observed. We used these new tags to determine how many misfolded soluble cargo were trapped in a chaperone complex in the ER lumen. The photon counting histogram of the cf-FP fusion of permanently misfolded antitrypsin mutant, null(HongKong), indicated that only a monomer was found in a single complex and the inhibition of glucose processing did not alter the stoichiometry. This may explain the highly mobile nature of the misfolded cargo, which must be required for efficient quality control. Development of various types of cf-FP should help understanding the molecular mechanisms in secretion as well as various molecular events in the extracellular space.

**Engineering a bright monomeric green fluorescent protein derived from *Branchiostoma lanceolatum*.**N. C. Shaner<sup>1</sup>, G. G. Lambert<sup>1</sup>, A. Chamma<sup>2</sup>, Y. Ni<sup>2</sup>, P. J. Cranfill<sup>3</sup>, M. A. Baird<sup>3</sup>, B. R. Sell<sup>3</sup>, R. N. Day<sup>4</sup>, M. W. Davidson<sup>3</sup>, J. Wang<sup>2</sup>; <sup>1</sup>The Scintillon Institute, San Diego, CA, <sup>2</sup>Allele Biotechnology and Pharmaceuticals, Inc., San Diego, CA, <sup>3</sup>The Florida State University, Tallahassee, FL, <sup>4</sup>Indiana University School of Medicine, Indianapolis, IN

Here we report mNeonGreen, a novel monomeric yellow-green fluorescent protein derived from LanYFP. Most newly cloned green and yellow fluorescent proteins are not subjected to further engineering simply due to their lack of improved properties relative to existing GFPs. LanYFP, a tetrameric yellow fluorescent protein from the cephalochordate *Branchiostoma lanceolatum*, exhibits an unusually high quantum yield (~0.95) and extinction coefficient (~150,000 M<sup>-1</sup>cm<sup>-1</sup>), making it a very attractive candidate for further development. Cephalochordate fluorescent proteins are evolutionarily distant from all other fluorescent protein lineages, and LanYFP has no close homologs whose structures have been solved. However, structure prediction and docking algorithms allowed us to successfully identify the initial target side chains leading to monomerization, and to apply a traditional directed evolution approach to generate a monomeric variant. The final variant, mNeonGreen, is among the brightest monomeric green fluorescent proteins yet described, performs exceptionally well as a fusion tag, and shows great promise as a FRET acceptor for the newest generation of cyan fluorescent proteins.

**An optimized FRET trio for live-cell imaging of multiple protein-protein interactions.**

*B. L. Scott<sup>1</sup>, A. D. Hoppe<sup>1</sup>; <sup>1</sup>Chemistry and Biochemistry, South Dakota State University, Brookings, SD*

Fluorescence resonance energy transfer (FRET) microscopy is a powerful tool to quantify subresolution protein-protein interactions inside living cells. Recent efforts in fluorescent protein engineering, image acquisition and data analysis have made it possible to measure simultaneously, multiple protein-protein interactions inside living cells by FRET. Here, we characterized the optimal FRET trio to improve the spatiotemporal resolution of these measurements. We focused on readily available cyan, yellow, and red (C-Y-R) proteins that have high quantum yields, large extinction coefficients and exhibit the best possible photostability. Based on published data, we selected the following C-Y-R proteins: CyPet/TFP1, mCitrine/YPet, and TagRFP/mCherry. We generated structurally-equivalent constructs of linked donor/acceptor pairs and measured their FRET efficiency by acceptor photobleaching. Based on these FRET efficiencies and photostability, we determined that TFP, YPet and mCherry were the optimal FRET trio. This conclusion was confirmed by linked-trio constructs created with varied ordering and various fluorophores. Our optimal construct was a TFP-YPet-Cherry which exhibited the highest overall FRET efficiencies:  $E_{TFP-YPet} = 0.47$ ,  $E_{TFP-Che} = 0.15$  and  $E_{YPet-Che} = 0.37$ . We believe this construct will be a useful tool for calibrating microscopes for three-color FRET experiments leading to improved monitoring of multiple protein-protein interactions in live cells.

**New single-chain Rac1 biosensor shows GTPase function in invadopod dynamics.**

*Y. Moshfegh<sup>1</sup>, J. Bravo-Cordero<sup>1</sup>, J. Condeelis<sup>1</sup>, L. Hodgson<sup>1</sup>; <sup>1</sup>Anatomy & Structural Biology, Albert Einstein College of Medicine, Bronx, NY*

Members of the Rho family of small GTPases are heavily involved in cell motility and migration, and are thought to participate in the regulation of cancer metastasis. To study the function of Rac1 in highly invasive tumor cell migration, we developed a novel, genetically-encoded Rac1 FRET biosensor based on an intra-molecular design. The new biosensor is a substantial improvement over the previous-generation Rac1 biosensor because of its single-chain arrangement, ensuring an equimolar distribution of FRET donor and acceptor, and producing a more accurate readout. Additionally, our design maintains the correct C-terminal lipid modification of full-length Rac1, enabling proper interaction with upstream regulators (GEFs, GAPs, and GDIs).

We used this new biosensor to explore the molecular basis for the involvement of Rac1 in the turnover dynamics of invadopodia, which are F-actin-rich protrusions with proteolytic activity that are exclusive to invasive tumor cells and are thought to be crucial for cell invasion and metastatic phenotypes. The biosensor has shown that there is an exclusion of Rac1 activity from the core of the invadopodial structures of MTLn3 rat carcinoma cells. This exclusion dissipates and Rac1 activity is elevated when stable invadopods disappear, suggesting that a lack of Rac1 activity is necessary for invadopod maintenance, and activation of the GTPase could possibly be involved in disassembly. PAK1, one of the major downstream effectors of Rac1, phosphorylates cortactin, which is a key protein in these structures, and upon this kinase activity, PAK1 releases cortactin. Taken together, we have developed a model for the mechanism of invadopod disassembly, where Rac1 activation in the core of an invadopodium will induce kinase activity of PAK1, which will phosphorylate cortactin, causing a destabilization of the invadopod's principal structural molecule and therefore leading to dissolution. This mechanism may be critical for the proper turnover of the invasive structures during migration

and invasion of tumor cells *in vivo*, where a balance of invasive invadopodial matrix-degradation activity and the protrusive force of leading edge projections must be carefully coordinated to achieve a maximally invasive phenotype.

### Internalization of near infrared labeled transferrin into breast cancer cells using FRET tomography imaging.

K. Abe<sup>1</sup>, L. Zhao<sup>2</sup>, V. Venugopal<sup>2,3</sup>, X. Intes<sup>2</sup>, M. Barroso<sup>1</sup>; <sup>1</sup>Cardiovascular Sciences, Albany Medical College, Albany, NY, <sup>2</sup>Biomedical Engineering, Rensselaer Polytechnic Institute, Troy, NY, <sup>3</sup>Center for Molecular Imaging, Harvard Medical School, Boston, MA

Transferrin (Tfn) is an iron-binding protein used to transport iron via cell surface Tfn receptors (TFR) into the cytoplasm. The dimeric nature of TFR allows the use of Förster Resonance Energy Transfer (FRET) based detection methods to identify receptor-bound, fluorophore labeled Tfn donor and acceptor pairs from unbound Tfn. We report the use of near infrared (NIR)-FRET tomographic imaging to detect internalization of Tfn based on the reduction of donor fluorophore lifetime using a multispectral time resolved fluorescence molecular tomography (FMT) imaging system. Our main goal is to distinguish breast cancer cells (T47D) from normal cells (HMEC) via quantification of cellular Tfn uptake within live mice, due to the wide use of Tfn as a carrier for anti-cancer drug delivery systems. T47D and other cancer cells show higher TFR expression and more rapidly internalize Tfn compared to HMECs in which Tfn is co-localized to early endosome 1 (EEA1) positive markers, thus validating specific cellular internalization of Tfn. In support, we demonstrate increased % FRET efficiency (E%) at higher intensity thresholds of acceptor molecules in breast cancer cells compared to controls using confocal FRET analysis. To establish *in vivo* conditions, we tested temporal lifetime measurements of several donor NIR fluorophore candidates using our time-resolved imaging platform with data fitted into a bi-exponential decay function to estimate non-FRETing donor lifetimes. NIR FRET donor-acceptor AF700-Tfn and AF750-Tfn pair was selected as the optimal FRET pair under our imaging conditions due to the longer donor lifetime and higher quantum yield of AF700. Alexafluor NIR fluorophores AF700 and AF750 conjugated to Tfn molecules (AF700-Tfn/AF750-Tfn) were used for uptake studies into T47D and HMECs. Cells were imaged using a time-resolved wide-field illumination strategy, with whole-body functional and fluorescence tomographic data sets at high-spatial and high-spectral densities (690nm-1020nm spectral range), and acquired using a 300ps time gate and a 40ps time delay to obtain time point spread function (TPSF) over a 4.6ns time window (116 gates). Co-internalization of AF700-Tfn and AF750-Tfn into T47D cells show a positive increase in fractional amplitude of FRETing donor Tfn molecules as A:D ratios increased from 1:4 to 4:1, as expected using fluorescence lifetime based FRET tomographic imaging. In support, mean photon counts show FRET-induced quenching at 4:1 compared to the 1:4 A:D ratio. We demonstrate a detection of Tfn internalization based on FRET events in cancer cells at a threshold of approximately  $1 \times 10^4$  cells, a number well below current clinical detection capabilities. We thus show proof-of-principle detection of NIR FRET in breast cancer cells in which these signals could be a powerful and non-invasive tool to identify the presence of tumors *in vivo* and to optimize targeted delivery systems based on Tfn-TFR mediated uptake into cancer cells.

**Multispectral/Multimodal 3D Image Reconstruction without Dyes.**

*T. Holmes<sup>1</sup>, S. Larkin<sup>1</sup>, J. Larson<sup>2</sup>, M. Vaicik<sup>2</sup>, M. Turturro<sup>2</sup>, A. Jurkevic<sup>3</sup>, S. Sinha<sup>3</sup>, T. Ezashi<sup>3</sup>, G. Papavasiliou<sup>2</sup>, E. Brey<sup>2</sup>; <sup>1</sup>Lickenbrock Technologies, LLC, St. Louis, MO, <sup>2</sup>Biomedical Engineering, Illinois Institute of Technology, Chicago, IL, <sup>3</sup>Molecular Cytology Core, University of Missouri, Columbia, MO*

Multimodality and multispectral imaging, using 3D optical sectioning and 3D image reconstruction, are proposed as an approach to producing contrast with live samples without using exogenous contrast media. Contrast agents, such as fluorescent or absorbing dyes, can be toxic to live samples or alter cell behavior. Current modes of producing 3D image sets from a light microscope, such as 3D deconvolution algorithms and confocal microscopy, often require dyes. Phase contrast, brightfield and darkfield microscopy, with proper microscope adjustments, can generate contrast without using dyes. The image reconstruction algorithm is based on an underlying physical model that includes 3D distributions of scattering potential, which models the absorption and phase character of the sample. The algorithm is based upon optimizing/solving an objective function, called the I-divergence, while solving for the 3D scattering potential that provides this optimization. Unlike deconvolution algorithms, the method produces two output image sets instead of one. Preliminary images will be presented.

**Quantitative Imaging of Protein Complexes.**

*J. Boisvert<sup>1,2</sup>, J. Ryan<sup>2</sup>, A. Padeganeh<sup>2</sup>, V. De Rop<sup>2</sup>, P. Maddox<sup>2</sup>, J. Dorn<sup>2</sup>; <sup>1</sup>Bioinformatics, University of Montréal, Montréal, QC, Canada, <sup>2</sup>Institute for Research in Immunology and Cancer, Montréal, QC, Canada*

The dynamic composition of protein complexes can have a profound impact on their function. However, conventional pull-down assays cannot provide dynamic information, and sample preparation may affect complex stability. Here, we combine total internal reflection (TIRF) imaging with quantitative image and data analysis to examine the stoichiometry of protein complexes as well as the dynamics of protein associations. Fluorescently labeled proteins are immobilized on glass coverslips, and perfused with other fluorescently tagged proteins or small molecules. Complexes are imaged on a TIRF microscope to selectively illuminate bound proteins. We determine copy number and relative positions of fluorescent proteins inside complexes by counting photobleaching events, using computational super-resolution and mixture-model fitting algorithms for spot detection. We then statistically correct the results for experimental artefacts, such as expression levels and pre-bleaching of fluorophores, which can reach levels of 20%. We further determine binding kinetics by measuring dwell time of fluorescently labeled proteins on immobilized substrates using the same computational approach. Together these methods have allowed us to determine that CENP-A exists in octameric nucleosomes throughout the cell cycle, that myosin adopts multiple conformations on the cortex of the *C. elegans* zygote that are differentially sensitive to perturbations, and that the interaction of KNL2 with CENP-A depends on its phosphorylation and its Myb-domain structure.

**An image-based high content screening for chemotherapy-induced neurotoxicity.**

M.-Y. Lee<sup>1,2</sup>, L.-Y. Chang<sup>3</sup>, M.-R. Shen<sup>4,5</sup>; <sup>1</sup>Department of Pharmacology, National Cheng Kung University, Tainan, Taiwan, <sup>2</sup>Infectious Disease and Signaling Research Center, National Cheng Kung University, Tainan, Taiwan, <sup>3</sup>Cancer Center, National Cheng Kung University Hospital, Tainan, Taiwan, <sup>4</sup>Advanced Optoelectronic Technology Center, National Cheng Kung University, Tainan, Taiwan, <sup>5</sup>Department of Obstetrics & Gynecology, National Cheng Kung University, Tainan, Taiwan

Central and peripheral neurotoxicity are common complications associated with chemotherapy. Major pitfalls including inappropriate cell model, insufficient analytic parameters, and image selection bias are noticed in the most in vitro neurotoxicity studies. To differentiate the cellular and subcellular parameters associated with neuron morphology, we developed an image-based high content screening of neurotoxicity. We chose the primary culture of cortical neurons instead of immortalized neuronal-like cells or human stem cell-derived neural cultures. Three categories of parameters, including neuron viability, neurite outgrowth, and synapse formation, were analyzed in our image-based high content screening. Microtubule-associated protein 2 and synaptophysin I were utilized to stain neuronal dendrite and synaptic puncta, respectively. Automated image acquisition by high throughput fluorescent microscope enabled to take quantitative images for massive image information. Appropriate image analysis algorithms were designed to define neuron numbers in a heterogeneous cell population of primary neuron culture. Eleven chemotherapeutic agents were used to test their neurotoxic effects. Paclitaxel and vincristine, which disrupt microtubule dynamics, differentially damaged neuron number, neurite outgrowth, and synaptogenesis within their therapeutic concentrations. For platinum-containing drugs, cisplatin significantly affected the three categories of parameters compared to carboplatin in the therapeutic ranges. In terms of ifosfamide and its catabolite chloroacetaldehyde, chloroacetaldehyde severely affected neurite outgrowth and synaptogenesis. Topoisomerase inhibitors, including doxorubicin and its liposomal formulation lipo-Dox®, etoposide, and topotecan, as well as nucleoside analogue gemcitabine showed less neurotoxicity. Collectively, our data demonstrate that automated image acquisition and analysis can be used to effectively differentiate the effects of chemotherapeutic agents on cellular neurotoxicity. This high-content screening assay provides a useful platform to filter out neurotoxic chemicals and further discover neuroprotective agents.

**An in-focus 3-well glass-bottom plate suitable for simultaneous observation of untreated cells and cells treated with two different drugs and application to cell-lineage analysis of mouse m5S cells visualized with mCherry-histoneH3.**

A. Kawakita<sup>1</sup>, K. S. Murata<sup>1</sup>, K. Sugimoto<sup>1</sup>; <sup>1</sup>Life & Environmental Sci., Osaka Prefecture Univ., Sakai, Osaka, Japan

Focusing on living cells in multi-well glass-bottom plates is often tedious and frustrating, especially when performing multi-point time-lapse imaging at higher magnification over a long period. We designed an in-focus 3-well glass-bottom plate suitable for multiple-point long-term live-cell imaging under a microscope equipped with a 40x objective. The surface of the glass-bottom plate was made almost flat in order to capture time-lapse images of three wells in one experiment without an expensive focusing system such as Perfect Focus. We further constructed m5S mouse embryonic fibroblast cell lines whose nuclei have been visualized with mCherry-histone H3. The doubling time of one cell line, grown in each well for 30 h, was almost constant, indicating a nearly uniform culture condition in each well, including temperature and humidity. We further confirmed the effectiveness of this novel plate on multi-point time-lapse

imaging through the simultaneous observation of untreated cells and cells treated with taxol or thapsigargin. Drug-induced mitotic arrest or apoptosis was compared with the normal growth of untreated controls over the same time scale in individual experiments.

### Single cell visualization of RNA and DNA using oligonucleotide libraries and molecular beacons.

K. B. Bernick<sup>1</sup>, R. Ach<sup>1</sup>, N. Sampas<sup>1</sup>, P. Tsang<sup>1</sup>, K. Pekrun<sup>1</sup>, A. Scheffer-Wong<sup>1</sup>, N. A. Yamada<sup>1</sup>;  
<sup>1</sup>Agilent Technologies, Santa Clara, CA

Fluorescence microscopy is one of the best methods for following biological events at the single cell level, limited only by the availability of specific labeling reagents for the cellular components of interest. We have generated fluorescence probes to visualize DNA and RNA in single cells to further our understanding of the extent of cellular heterogeneity in populations of cells.

Fluorescence in situ hybridization (FISH) is a powerful technique for studying the structure, organization, and localization of nucleic acids within individual fixed cells. We have combined our ability to select in silico the highest performance metrics for FISH probe design with de novo chemical synthesis of DNA in massively parallel reactions to produce high resolution fluorescent paints for DNA and RNA. Using these oligonucleotide library-derived probes on DNA, human genomic regions as small as 1.8 kb and as large as whole chromosomes were visualized in both metaphase and interphase cells with the same simple assay protocol. RNA-specific probes were also generated that detect the localization of a variety of coding and non-coding RNAs with both conventional wide-field fluorescence and structured illumination microscopy. Using probes designed specifically to transcribed vs. non-transcribed regions, we have simultaneously detected DNA and RNA from the same locus in the same single cell. Our oligoFISH methods are also compatible with co-detection of cellular proteins by immunocytochemistry. The ability to generate high performance FISH probes using chemically synthesized oligo libraries that works flexibly with co-detection of other molecules yields a valuable tool for studies of how localization of specific nucleic acids impacts biological function.

Despite its advantages and applications, FISH is performed on fixed cells and is an inherently static measurement technique, whereas cellular processes are very dynamic. In order to better understand how RNA expression and localization change in living cells, we have employed molecular beacons to label mRNA and monitor the signal over time. Molecular beacons designed against nestin mRNA were validated in solution in a plate reader and ultimately tested in undifferentiated P19 cells, expressing high levels of nestin. FISH probes and molecular beacons are powerful and complementary tools for visualizing the heterogeneity in expression and localization of nucleic acids within populations of cells.

### Fluorescence imaging of protein dynamics on long single-stranded DNA.

K. Lee<sup>1</sup>, T. Ha<sup>1,2</sup>; <sup>1</sup>Department of Physics and Center for Physics in Living Cells, University of Illinois at Urbana-Champaign, Urbana, IL, <sup>2</sup>Howard Hughes Medical Institute, University of Illinois at Urbana-Champaign, Urbana, IL

Recent advances in single-molecule fluorescence imaging techniques have allowed the direct observation of protein dynamics on DNA, but the progress has been largely limited to double-stranded DNA (dsDNA) or short single-stranded DNA (ssDNA). Here, we present a single molecule imaging approach for observing dynamics of proteins on long ssDNA of thousands of nucleotides in length. Using a hybrid instrument combining single-molecule fluorescence and

force spectroscopy, we could visualize the dynamics of proteins interacting with a long ssDNA similar in length to what's generated during DNA metabolic processes. Our ultimate goal is to study many different proteins binding to the same long ssDNA and performing their function in coordination in each other. As a step toward the goal, here, we demonstrate the applicability of our methods to the dynamics of two different proteins: (1) the unidirectional motion of *Escherichia coli* (*E. coli*) UvrD helicase and (2) the diffusion of *E. coli* single-stranded DNA binding protein (SSB). With the multidimensional data obtained with our platform, we could capture the entire sequence of binding, translocation, unwinding initiation of UvrD helicase with single molecule resolution. With SSB, we found that the diffusion coefficient is three orders of magnitude higher than what was determined from SSB diffusion on short ssDNA suggesting that on long ssDNA that mimics physiological setting, SSB can migrate via a long range inter-segmental transfer. Force dependence of diffusion further supports the interpretation.

2492

**A robust and convenient tool for image segmentation.**

J. F. Dorn<sup>1</sup>, J. Boisvert<sup>1</sup>, M. Cagnello<sup>1</sup>, P. Roux<sup>1</sup>, P. S. Maddox<sup>1</sup>; <sup>1</sup>Pathologie et biologie cellulaire, Universite de Montreal, Montreal, QC, Canada

Fluorescence microscopy is a key method for unraveling spatial and temporal processes in cell biology. The advent of automated microscopy, as well as the desire to characterize ever more subtle phenotypes have increased the need for automated quantification of fluorescent image data.

Image segmentation is the first step of image quantification, where signal of interest is distinguished from the background. It is critical that segmentation is sensitive, specific and robust. Balancing sensitivity, specificity, and robustness is a challenge: Higher sensitivity can be achieved by employing more prior knowledge about the signal of interest, but the more prior knowledge is employed, the less robust the analysis becomes. In addition, image segmentation faces the challenge that employing more prior knowledge often requires optimizing multiple parameters for optimal performance, and that pre-processing of the image renders the determination of the threshold for classifying pixels into signal or noise highly unintuitive.

Here, we present a novel tool for image segmentation that is sensitive, specific, and robust, usually requires adjusting one intuitive parameter only, and that decides between signal and background on statistical grounds. Since our algorithm makes very limited assumptions about the fluorescent image, it is applicable to a wide range of signal sizes and shapes, from spots via chromosomes to cells.

Our segmentation algorithm relies on two assumptions about fluorescent images: that the signal is brighter than the background, and that noise is spatially uncorrelated. For each neighborhood in the image, the algorithm counts how many pixels are brighter than, say, two noise standard deviations. If there are significantly more bright pixels than what would be expected from a signal-free image containing only noise, the center of the neighborhood is considered to be a signal pixel. The significance level is set by deciding on the number of expected false positive pixels in the image, which directly allows controlling specificity. Even though the algorithm identifies signal through its spatial correlation, it compares favorably with state-of-the-art spot detection algorithms, such as H-Dome or MSVST, and it performs excellently on published benchmarks.

We demonstrate the power and convenience of using our segmentation tool on the example of the mechanism of P-body assembly. P-bodies, or mRNA processing bodies, are agglomerates of mRNA with factors involved in mRNA degradation and translation repression. Current understanding of P-bodies, especially the mechanisms of assembly, remains limited. Cellular perturbations affecting P-bodies are frequently reported to increase P-body size and number,

suggesting P-bodies assemble via passive precipitation. Here, we show that P-body nucleation and growth are independently regulated in mammalian cells. We use our segmentation tool to statistically identify P-bodies significant signal clusters in immunolabeled images, and we run the algorithm on the background fluorescence of the same staining to detect the cells. We report that phosphorylation of the eukaryotic initiation factor 4E-T by the kinase JNK is required for P-body growth, but not P-body nucleation.

In sum, we present an image segmentation tool that will make it possible for all cell biologists to conveniently and correctly segment fluorescent images, and thus allow accurate quantification of fluorescent image data.

### **ImageJ plugins for automated intelligent confocal microscopy and their application to systems biology questions.**

*C. Tischer<sup>1</sup>, M. Reiss<sup>2</sup>, F. Verissimo<sup>2</sup>, R. Pepperkok<sup>1,2</sup>; <sup>1</sup>Advanced Light Microscopy Facility, EMBL, Heidelberg, Germany, <sup>2</sup>Cell Biology and Biophysics, EMBL, Heidelberg, Germany*

In order to obtain statistically relevant information in microscopy experiments one often needs to image a large number of specimen. Recently, we presented "Micropilot" (Conrad et al., 2011, Nat. Methods), a software that communicates with microscopes, automatically detects relevant objects within an image (e.g. mitotic cells) and subsequently launches complex microscopy protocols in order to interrogate the object of interest in more detail. Micropilot is written in LabVIEW and uses supervised learning algorithms for object identification.

To enhance the flexibility and openness of our automated intelligent imaging efforts, we now present a series of ImageJ Plugins that retrieve the current image from a microscope, facilitate object detection, and signal whether a specific imaging protocol should be launched on the detected object. ImageJ is free, open-source, widely used in the biological community and contains a large number of image processing operations. Through "Macro Recording" one can readily set up an automated microscopy workflow, combining our Plugins with all ImageJ commands. This provides a wide range of (3-D) object detection methods, ranging from simple thresholding to pixel-based supervised classification.

To demonstrate the potential of the technology in systems biology applications we conduct automated fluorescence recovery after photobleaching (FRAP) experiments on a Zeiss LSM780 confocal microscope in order to measure the kinetics of vesicular coat complex II (COPII) components turnover at ER exit sites in cells treated with siRNAs targeting genes that have been proposed to play a role in ER to Golgi transport (Simpson et al., 2012, Nat. Cell Biol.).

### **The Open Microscopy Environment: Open Image Informatics for the Biological Sciences.**

*C. Allan<sup>1,2</sup>, J-M. Burel<sup>1</sup>, J. Moore<sup>2</sup>, C. Blackburn<sup>1</sup>, E. Hill<sup>1</sup>, R. Leigh<sup>1</sup>, M. Linkert<sup>2</sup>, S. Littlewood<sup>1</sup>, W. Moore<sup>1</sup>, C. Neves<sup>2</sup>, A. Patterson<sup>1</sup>, B. Pindelski<sup>1</sup>, A. Tarkowska<sup>1</sup>, J. R. Swedlow<sup>1,2</sup>, C. Rueden<sup>3</sup>, K. W. Eliceiri<sup>3</sup>; <sup>1</sup>Wellcome Trust Centre for Gene Regulation & Expression, University of Dundee, Dundee, UK, <sup>2</sup>Glencoe Software Inc, Seattle, WA, <sup>3</sup>Departments of Molecular Biology and Biomedical Engineering, University of Wisconsin at Madison, Madison, WI*

Despite significant advances in cell and tissue imaging instrumentation and analysis algorithms, major informatics challenges remain unsolved: file formats are proprietary, facilities to store, analyze and query numerical data or analysis results are not routinely available, integration of new algorithms into proprietary packages is difficult at best, and standards for sharing image data and results are lacking. We have developed an open-source software framework to address these limitations called the Open Microscopy Environment (<http://openmicroscopy.org>). OME has three components—an open data model for biological imaging, standardised file

formats and software libraries for data file conversion and software tools for image data management and analysis.

The OME Data Model (<http://ome-xml.org>) provides a common specification for scientific image data and has recently been updated to more fully support fluorescence filter sets, the requirement for unique identifiers, screening experiments using multi-well plates. The OME-TIFF file format (<http://www.loci.wisc.edu/ome/ome-tiff.html>) and the Bio-Formats file format library (<http://www.loci.wisc.edu/ome/formats.html>) provide an easy-to-use set of tools for converting data from proprietary file formats. These resources enable access to data by different processing and visualization applications, sharing of data between scientific collaborators and interoperability in third party tools like Fiji/ImageJ.

The Java-based OMERO platform includes server and client applications that combine an image metadata database, a binary image data repository and high performance visualization and analysis. The current release of OMERO (4.4.3; <http://openmicroscopy.org/site/support/omero4/downloads>) includes a single mechanism for accessing image data of all types—regardless of original file format—via Java, C/C++ and Python and a variety of applications and environments (e.g., ImageJ, Matlab and CellProfiler). Support for large images from digital pathology is included. This version of OMERO includes a number of new functions, including SSL-based secure access, distributed compute facility, filesystem access for OMERO clients, and a scripting facility for image processing. Demos of OMERO are available at <http://openmicroscopy.org/site/products/feature-list>.

## Proteomics and Genomic Methods

### PSI Structural Biology Knowledgebase: New Ways to Enable Your Research.

L. Gifford<sup>1</sup>, P. Adams<sup>1</sup>, Z. Fraczak<sup>2</sup>, M. Gabanyi<sup>3</sup>, J. Haas<sup>4</sup>, W. McLaughlin<sup>5</sup>, D. Micallef<sup>3</sup>, W. Minor<sup>2</sup>, R. Shah<sup>3</sup>, T. Schwede<sup>4</sup>, Y-P. Tao<sup>3</sup>, J. Westbrook<sup>3</sup>, M. Zimmerman<sup>2</sup>, H. Berman<sup>3</sup>;

<sup>1</sup>Lawrence Berkeley National Laboratory, Berkeley, CA, <sup>2</sup>University of Virginia Medical School, Charlottesville, VA, <sup>3</sup>Rutgers, The State University of New Jersey, Piscataway, NJ, <sup>4</sup>University of Basel, Basel, Switzerland, <sup>5</sup>The Commonwealth Medical College, Scranton, PA

The Protein Structure Initiative Structural Biology Knowledgebase (SBKB, <http://sbkb.org>) is the scientific web portal that integrates biological, experimental, and structural data about proteins. SBKB delivers comprehensive information, including 3D structures from the Protein Data Bank, annotations from 150+ open biological resources, target history and protocols from TargetTrack, theoretical models in Protein Model Portal, technology reports from the PSI Technology Portal, PSI articles from the PSI Publications Portal, and research and technical highlights from Nature Publishing Group. We will present several examples on how structural data found in the SBKB and its portals can enable biological research.

SBKB is supported by the National Institute of General Medical Science (U01 GM093324).

**The PSI: Biology-Materials Repository: A Resource for Protein Expression Plasmids.**

C. Cormier<sup>1</sup>, J. Steel<sup>1</sup>, M. Fiacco<sup>1</sup>, J. Park<sup>1</sup>, P. Hunter<sup>1</sup>, J. Kramer<sup>1</sup>, A. Sharma<sup>1</sup>, C. Sedillo<sup>1</sup>, J. LaBaer<sup>1</sup>; <sup>1</sup>Biodesign Institute, Arizona State University, Tempe, AZ

The Protein Structure Initiative: Biology-Materials Repository (MR; <http://psimr.asu.edu>) sequence-verifies, annotates, stores, and distributes protein expression plasmids and vectors created by the Protein Structure Initiative (PSI). Researchers can find and request PSI plasmids in a freely searchable database called DNASU (<http://dnasu.asu.edu>), which in addition to the PSI collection, distributes over 162,000 plasmids created by our laboratory, by other consortia, and by individual laboratories. Each plasmid links to detailed annotations, including the full-length sequence, vector information, associated publications, and resources such as the PSI Structural Biology Knowledgebase (<http://sbkb.org>), which facilitates cross-referencing of a particular plasmid to additional protein annotations and experimental data. As of September 2012, over 60,000 protein expression plasmids and 97 empty vectors from the PSI are available upon request from DNASU. In addition to providing these materials to the research community, the MR strives to expedite and simplify plasmid requests through its expedited material transfer agreement (EP-MTA) network, where researchers from network institutions can order and receive PSI plasmids without institutional delays. With the added biological focus in PSI: Biology, the distribution of these materials will help researchers expand the knowledge of the role of proteins both in normal biological processes and in disease.

**A genomic resource to study kinesin and myosin motors in mammalian cells.**

Z. Maliga<sup>1</sup>, I. Ibarlucea-Benitez<sup>2</sup>, I. Poser<sup>1</sup>, A. A. Hyman<sup>1</sup>; <sup>1</sup>MPI-CBG, Dresden, Germany, <sup>2</sup>Department of Molecular and Cell Biology, University of California, Berkeley. Berkeley, Berkeley, CA

Microtubules and actin filaments define orthogonal, polarized networks required for intracellular trafficking, cell motility and mitosis. An important class of proteins that works with these polymer systems is the P-loop cytoskeletal motor superfamily consisting of myosin and kinesin motor proteins. However, there is no comprehensive resource to study motor protein function in any given cell type and few of the 39 myosin and 43 kinesin genes in the human genome have been characterized to date. Bacterial artificial chromosome (BAC) transgenes are ideal vectors to investigate gene function because they contain native cis-regulatory sequences for proper control of expression and splicing. Here, we report a collection of 243 recombinant BAC transgenes and 227 stable HeLa BAC lines to investigate the function of 71 (of 82) kinesins and myosins. BACs derived from mouse or human BACs contain cleavable, universal N- or C-terminal tags containing GFP for live-cell imaging and systematic immunoaffinity capture. Motors endogenous to HeLa are expressed as full-length fusion proteins and are generally expressed at native levels. Moreover, the changes in protein levels through the cell cycle are similar for human kinesins and their mouse orthologs. Imaging of the HeLa BAC lines revealed that 21 (of 23 reported) motors were properly targeted as N- or C-terminal fusion proteins. A subset of motor transgenes was also introduced into mouse embryonic stem cells and displayed localization similar to HeLa, indicating the BAC transgene collection is a portable system to investigate motor protein function across multiple cell lines. The BAC and HeLa collection is available to the broader cell biology community with resource access described at this poster.

**Investigating natural genetic variation in lethal heat and salt shock survival in yeast.**

C. P. McNally<sup>1,2</sup>, J. S. Bloom<sup>1,2</sup>, L. Kruglyak<sup>1,3</sup>; <sup>1</sup>Lewis-Sigler Institute for Integrative Genomics, Princeton University, Princeton, NJ, <sup>2</sup>Department of Molecular Biology, Princeton University, Princeton, NJ, <sup>3</sup>Department of Ecology and Evolutionary Biology, Princeton University, Princeton, NJ

When exposed to a mild stress, yeast activate the environmental stress response, a transcriptional response involving hundreds of genes, thereby increasing their resistance to future stresses. This resistance to future lethal stress occurs even when the initial and future lethal stresses are different. Most studies that have identified genes underlying induced stress resistance traits use deletion strains or mutation screens in a single genetic background, commonly a laboratory strain. Here we seek to discover natural genetic variation between yeast strains that has a functional effect on induced stress resistance, using quantitative trait locus (QTL) mapping. QTL mapping is a method for identifying genomic positions where genetic variation underlies phenotypic variation. We use extremely large pools of yeast segregants and bulk selection, extreme QTL mapping (X-QTL), to map QTLs for survival of severe heat and salt shocks with or without pretreatment from either shock. Two parent strains, a lab strain and a clinical isolate, showed heritable differences in stress survival and were used for X-QTL. Using these techniques we have identified two QTL for survival of extreme salt shock, both favoring the allele from the clinical isolate. The mapping will be repeated for more conditions and the genes underlying the detected QTL will be identified by allele replacement.

2499

**Bridging the gap between tissue structural properties and gene expression.**

G. Plopper<sup>1</sup>, M. J. Zak<sup>2</sup>, B. Yener<sup>2</sup>; <sup>1</sup>Biology, Rensselaer Polytechnic Institute, Troy, NY, <sup>2</sup>Computer Science, Rensselaer Polytechnic Institute, Troy, NY

The structure/function relationship is fundamental to our understanding of biological systems at all levels, and drives most, if not all, techniques for detecting, diagnosing, and treating disease. The predominant means of collecting structure/function data in biomedicine is reductionist and has thus led to a proliferation of complex data (e.g., gene expression arrays, digital images) that capture only a fraction of this relationship because they are limited to one organizational scale each. Current systems-based analysis approaches are hindered by the lack of integration between different forms of reductionist data. Our goal is to overcome this data impedance barrier between molecular, cellular, and tissue-level scales, and vertically integrate them into a uniform feature space that facilitates development and testing of multiscale, mechanistic hypotheses. As proof of concept, we collected two different forms of data on human breast tissue: (1) structural features computed from graph theory-based models ("cell graphs") of histopathology images and (2) publicly available gene data sets (GDS) from the NCBI Gene Expression Omnibus (GEO) database. We queried three classes of expression data, which tightly correspond to similar classes for the structural features from histopathological image data, namely low (normal breast tissue/expression), medium (ductal carcinoma) and high (malignant) levels of cancer. We applied singular value decomposition on the matrices L, M, and H, to extract the top eigen-genes (linear combinations of all 14718 genes) that capture 75% of the total variance. Next we added up the contribution/coefficient of each original gene in each of the chosen eigen-genes scaled by the corresponding singular value, and finally selected the top k=100 genes for each class. These genes contribute the most to the eigen-genes, and thus may be considered to be the most informative in terms of variance. Ultimately, this results in a 207 x 3 matrix E of top genes, and their average normalized expression value in each of the three

classes. Next, we linked the expression data with a 35 x 3 structural feature matrix S comprising average cell-graph feature values from the histopathological images from the same three classes. We linked them by creating a 207 x 35 molecular x structural feature kernel matrix K obtained as a dot-product of each row of E and S. Finally, we identified the top genes that correlate well with the structural features. The results of this approach reveal correlations between cell graph features and specific genes that reflect the different phenotypes of the samples.

**On-chip activity assay of tissue transglutaminase and blood coagulation factor XIII in differentiated monocytic cells.**

*M-H. Kwon<sup>1</sup>, D-H. Kong<sup>1</sup>, Y-M. Kim<sup>1</sup>, K-S. Ha<sup>1</sup>; <sup>1</sup>Department of Molecular and Cellular Biochemistry, Kangwon National University, Chuncheon, Korea*

Transglutaminases (TGs) are a family of enzymes consisting of nine isozymes, including TG1-TG7, which are involved in Ca<sup>2+</sup>- and thiol-dependent post-translational modifications of proteins, and blood coagulation factor XIII (FXIII). Among the isozymes, FXIII and TG2 are transglutaminase family members that are involved in various physiological functions, including vascular pathophysiology, bone development, and cancer progression. However, investigation of their differential functions is limited by the lack of high-throughput and isozyme-specific activity assays. Therefore, we developed an on-chip activity assay system to simultaneously determine the transamidating activities of blood coagulation factor XIII (FXIII) and transglutaminase 2 (TG2) by use of fibrinogen arrays. For the on-chip activity assay, we fabricated protein arrays by immobilizing fibrinogen onto the 3-aminopropyltrimethoxysilane surface of well-type arrays, and we determined transamidating activity by probing biotinylated fibrinogen with Cy3-conjugated streptavidin on arrays. We optimized assay conditions, such as buffer pH, concentrations of dithiothreitol and 5-(biotinamido)pentylamine, and incubation time, and we created equations to determine specific FXIII and TG2 activities in samples. We successfully applied this assay system to monitor changes in FXIII and TG2 activities in THP-1 monocytic cells differentiated with phorbol 12-myristate 13-acetate and interleukin-4. This activity assay is sensitive and suitable for high-throughput determination of FXIII and TG2 activities and thus has a strong potential for investigating the differential functions of these isozymes in cell signaling and cardiovascular pathophysiology research.

**AdHTS: A high-throughput system for generating recombinant adenoviruses.**

*J-Y. Jeong<sup>1</sup>, E-W. Cho<sup>2</sup>, D-S. Seen<sup>3</sup>, Y. Song<sup>3</sup>, W-K. Huh<sup>3</sup>, T. Lee<sup>4</sup>; <sup>1</sup>Marine Biotechnology Research Group, Korea Institute of Ocean Science & Technology, Ansan, Korea, <sup>2</sup>Interdisciplinary program of Bioengineering, Seoul National University, Seoul, Korea, <sup>3</sup>School of Biological Sciences, Seoul National University, Seoul, Korea, <sup>4</sup>R&D Center, BRN Science, Seoul, Korea*

The need for efficient high-throughput gene delivery system for mammalian cells is rapidly increasing with the growing request for functional genomics studies and drug discoveries in various physiologically relevant systems. However, plasmid-based gene delivery has limitations in transfection efficiency and available cell types. Viral vectors have great advantages over plasmid-based vectors, but construction of recombinant viruses remains to be a big hurdle for high-throughput applications. Here we demonstrate a rapid and simple high-throughput system for constructing recombinant adenoviruses which have been used as efficient gene delivery tools in mammalian systems in vitro and in vivo. By combining Gateway-based site-specific recombination with Terminal protein-coupled adenovirus vector, the adenovirus high-throughput

system (AdHTS) generates multiple recombinant adenoviruses in 96-well plates simultaneously without the need for additional cloning or recombination in bacteria or mammalian cells. The AdHTS allows rapid and robust cloning and expression of genes in mammalian cells by removing shuttle vector construction, bacterial transformation, or selection and by minimizing effort in plaque isolation. By shortening the time required to convert whole cDNA library into desired viral vector constructs, the AdHTS would greatly facilitate functional genomics and proteomics studies in various mammalian systems.

**Systemically identify oxidized methionine peptides under different Photofrin location in human A431 cells by quantitative proteomics approach.**

*Y-J. Hsieh<sup>1</sup>, Y-F. Yang<sup>1</sup>, K-Y. Chien<sup>1</sup>, J-S. Yu<sup>1</sup>; <sup>1</sup>Chang Gung University, Tao-Yuan, Taiwan*

Photodynamic therapy (PDT) is a minimally invasive therapeutic clinical treatment for some cancer and non-tumor disorders. This process requires a photosensitizer which can absorb light and produce reactive oxygen species to damage biomolecules in target cells. Photofrin is the most widely used photosensitizer. Our previous studies showed that different distribution of Photofrin in cells results in distinct cell death after PDT. Using human epidermoid carcinoma A431 cells as model, we herein applied SILAC-based quantitative proteome approach and a unique methionine peptides enrichment protocol to systemically analyze the relationship between the subcellular location of Photofrin and the Photofrin-PDT-mediated protein oxidation (on Met residues). Our data showed that when Photofrin mainly localized to plasma membrane (condition I), intracellular organelles (condition II) and whole cell (condition III), the percentage of highly oxidized (i) membrane proteins is significantly higher in condition I (I: 13.33%, II: 3.03%, III: 0.76%) ; (ii) Golgi proteins in condition II (I: 3.33%, II: 18.18%, III: 9.09%); and (iii) mitochondrial proteins in condition III (I: 4.44%, II: 15.66%, III: 30.3%). The results indicate that PDT with Photofrin targeted to distinct subcellular localizations can affect the redox proteome in a site-specific manner in living cells. Among those highly oxidized proteins detected post Photofrin-PDT, we select cathepsin D and EGFR for further study. Mapping the observed oxidized Met residues into the 3D structure of cathepsin D and EGFR showed that these oxidized Met residues mainly distribute on the surface of the protein. We also provided evidence to show that Photofrin-PDT can directly inhibit the activity of cathepsin D and influence EGFR phosphorylation in vitro. Collectively, our data demonstrate for the first time that the relationship between protein Met oxidation and PDT with site-specific location of Photofrin in living cells.

**Nested PatchPCR for targeted RNA-seq.**

*I. A. Vasenkova<sup>1</sup>, K. Jansen Spayd<sup>1</sup>, T. Shvetsova<sup>1</sup>, D. A. Kloske<sup>1</sup>, R. C. Bachmeyer<sup>1</sup>, D. T. Moore<sup>1</sup>, K. E. Varley<sup>1,2</sup>; <sup>1</sup>Kailos Genetics Inc., Huntsville, AL, <sup>2</sup>HudsonAlpha Institute for Biotechnology, Huntsville, AL*

Using a next-generation sequencing approach to gene expression profiling (RNA-seq) offers significant advantages over microarrays. In addition to detecting gene expression ranges at greater sensitivity than microarray technology, RNA sequencing can be used to detect sequence variants (mutations and SNPs), provides allele specific gene expression information, and enables the discovery of splice junctions and fusion transcripts. While whole transcriptome profiling using next-generation sequencing is valuable, its use is limited by sample preparation techniques, low sample throughput and a requirement for ultra deep sequencing to obtain sufficient coverage of low and medium expressed transcripts in the presence of extremely high housekeeping gene expression. This results in high costs for sequencing and analysis. To

increase the utility of RNA sequencing in biomedical research, we have developed a low cost, high-throughput, targeted RNA sequencing method.

We describe the use of Nested PatchPCR, a sensitive, cost-effective and highly scalable target enrichment technology for the analysis of gene expression changes, detection of SNPs and fusion transcripts. Nested PatchPCR is a limited cycle PCR and selective ligation-based single-tube procedure allowing for simultaneous amplification and selection of tens to thousands of targeted regions. Platform-specific sequencing primers incorporated during the Nested PatchPCR reaction allow direct sequencing of products on Illumina or Ion Torrent next-generation sequencing platforms without time-consuming library construction. Here we utilized oligo-dT primed cDNA of K562, MCF7 and Jurkat cancer cell lines to target transcripts from 13 cancer-related genes including BRAF, EGFR, PTEN, TP53 and BCR-ABL1. The targeted RNA-Seq libraries were multiplexed for sequencing on an Illumina GAIIX resulting in 1-2 million read coverage per sample. We demonstrate potential utility of our target enrichment method as a cost-efficient RNA sequencing solution to conducting comparative gene expression studies, identification of variants and for detection of minimally expressed and fusion transcripts.

2504

**Serum IgG Autoantibodies: Possible Role in the Clearance of Tissue Debris Under Normal and Diseased Conditions.**

*M. Han<sup>1</sup>, E. P. Nagele<sup>2</sup>, C. DeMarshall<sup>1</sup>, N. Acharya<sup>1</sup>, R. G. Nagele<sup>3</sup>; <sup>1</sup>Graduate School of Biomedical Sciences, Uni. of Med. & Dent. of NJ - SOM, Stratford, NJ, <sup>2</sup>School of Osteopathic Medicine, Uni. of Med. & Dent. of NJ - SOM, Stratford, NJ, <sup>3</sup>New Jersey Institute for Successful Aging, Uni. of Med. & Dent. of NJ - SOM, Stratford, NJ*

The presence of self-reactive IgG autoantibodies in human sera is largely thought to represent a break-down in central tolerance and is regarded as a harbinger of autoimmune pathology. In the present study, immune-response profiling of human serum from 166 individuals of different age, gender and health status via human protein microarrays demonstrates that IgG autoantibodies are abundant in all human sera, usually numbering in the thousands. These autoantibodies recognize common as well as organ-specific proteins present both on cell surfaces and intracellularly. Furthermore, we found that serum IgG autoantibody profiles are remarkably stable over time, and that age, gender and the presence of specific diseases strongly influence individual autoantibody profiles. Similarly, both complex and stable autoantibody profiles also exist in rat and swine, suggesting evolutionary conservation of this immunological feature among mammals. We propose that expression of IgG autoantibodies has evolved as an adaptive mechanism for the clearance of cell and tissue debris generated day-to-day by the body. In accord with this hypothesis, we have identified specific alterations in autoantibody profiles associated with Alzheimer's and Parkinson's disease pathology. Using these alterations in expression of autoantibodies as biomarkers enables the diagnosis of Alzheimer's and Parkinson's diseases with over 90% accuracy. We anticipate successful identification of other serum autoantibodies as diagnostic biomarkers for a large number of other diseases which involve tissue damage in affected organs. Further investigations are underway to clarify the function of these autoantibodies and elucidate mechanisms underlying their production and abundant presence in human sera. Supported by the Osteopathic Heritage Foundation.

**Identification of serological biomarkers for the diagnosis of liver disease using tagged-internal standard assay-based normalization.**

*D-H. Kong<sup>1</sup>, J-W. Jung<sup>1</sup>, Y-M. Kim<sup>1</sup>, K-S. Ha<sup>1</sup>; <sup>1</sup>Department of Molecular and Cellular Biochemistry, and Institute of Medical Science, Chuncheon, Kangwon-Do, Korea*

For minimizing systemic experimental variation in the analysis of antibody array data, we developed a novel median-centered/IgM-tagged-internal standard (TIS) assay normalization using median-centering and TIS assay-based determination of serum IgM concentrations. We evaluated five normalization methods by analyzing correlation coefficients and coefficients of variation for six serum proteins using human serum samples from normal controls (n = 25) and patients with liver cirrhosis (n = 25) or hepatocellular carcinoma (HCC; n = 29). Median-centered normalization improved correlation coefficients, while IgM-based normalizations improved coefficients of variation. The TIS assay was more efficient, economical, and reproducible for determining IgM concentrations than enzyme-linked immunosorbent assay. Additionally, we normalized antibody array data for six serum proteins using the median-centered/IgM-TIS assay, and evaluated serum biomarkers through distribution analysis of normalized fluorescence intensities and receiver operating characteristic analyses for the diagnosis of liver cirrhosis and HCC. Apolipoprotein A-1 and a combination of alpha-fetoprotein and C-reactive protein were determined to be potential serological biomarkers for liver cirrhosis and HCC, respectively. Thus, median-centered/IgM-TIS assay normalization is a useful approach for analyzing antibody array data and evaluating serological biomarkers for the diagnosis of liver disease or cancers.

**Development of peptidomics assays for mapping the peptides epitopes derived from collagen I and II processing by different metalloproteases and cathepsins.**

*C. C. Clement<sup>1</sup>, L. Santambrogio<sup>1</sup>; <sup>1</sup>Pathology, Albert Einstein College of Medicine, Bronx, NY*

In recent years several lines of research indicate the relevance of extracellular matrix remodeling in tissue homeostasis. Several enzymes, including matrix metalloproteinases (MMPs), have been described as modulators of tissue microenvironment through degradation of the extracellular matrix (in particular collagen metabolism), processing of cytokines and growth factors and processing of cellular surface receptors. The MMPs are the primary enzymes involved in collagenolysis. Peptide fragments generated by collagen processing could be presented to the immune system for generation of either tolerance or immunity. In order to reveal new potential MHC class II restricted epitopes processed by MMPs that are distinct and additional to peptides processed by endosomal proteases, we developed peptidomics assays in which the antigen processing was coupled with nano-LC ESI MS/MS sequencing of the peptides epitopes. New peptides derived from collagen-I and -II processing by the recombinant cathepsins S, B, D and L and by the late endosomal fraction isolated from dendritic cells (DCs) were sequenced and compared with the epitopes derived from the activity of pure recombinant MMPs (such as MMPs 1, 2, 3, 7, 9, 13, 14)) and from the enzymatic activity of the plasma membrane fraction isolated from the human primary DCs, leading to the generation of new peptides epitopes (with molecular weights of 800-6,000 Da). The new discovered epitopes suggest new mechanisms for the extracellular antigen processing distinct from those present in the late endosomal compartment.

**Novel Chemifluorescent Substrate for Highly Sensitive Protein Detection.***V. Boveia<sup>1</sup>, K. Kundu<sup>1</sup>, W. M. Volcheck<sup>1</sup>, T. Urlacher<sup>1</sup>, N. Padhye<sup>1</sup>; <sup>1</sup>LI-COR, Inc., Lincoln, NE*

Detection of proteins in a complex biological sample with high sensitivity is playing an increasingly important role in understanding physiological and pathological processes. The low relative abundance of many proteins within a biological sample and the limited quantity of precious sample make sensitive detection of target proteins highly desirable in protein analysis. Chemiluminescence based detection has been the method of choice for the Western blot and ELISA, but the sensitivity of the analysis is compromised as the accumulation of signal intensity is not possible in chemiluminescence. Here, we present a novel near infrared chemifluorescent substrate, where the fluorescence signal will accumulate with each turnover by the HRP enzyme and thus lead to unprecedented sensitivity. The chemifluorescent substrate exhibits 32-fold sensitivity compared to chemiluminescent detection, and 16-fold sensitivity compared to fluorescent dye-conjugated secondary antibody detection in Western blots. The basic workflow remains unchanged and therefore, the chemifluorescent substrate based analysis is amenable to other methods of protein analysis, such as ELISAs and protein arrays.

**Streamlined analysis of heterogeneity in cell populations using single-cell gene expression profiling.***A. P. May<sup>1</sup>, R. Lebofsky<sup>1</sup>, A. Leyrat<sup>1</sup>, B. Fowler<sup>1</sup>, J. Shuga<sup>1</sup>, P. Chen<sup>1</sup>, J. Wang<sup>1</sup>, D. Toppani<sup>1</sup>, M. Thu<sup>1</sup>, M. Wang<sup>1</sup>, J. West<sup>1</sup>, S. Weaver<sup>1</sup>, B. Jones<sup>1</sup>, D. Kemp<sup>1</sup>, M. Norris<sup>1</sup>, M. Unger<sup>1</sup>, T-H. Charn<sup>1</sup>, B. Jones<sup>1</sup>; <sup>1</sup>Research & Development, Fluidigm Corporation, South San Francisco, CA*

Single-cell gene expression profiling has recently been used to characterize emergent properties in cell populations that drive lineage choice and specificity in reprogrammed cells; resolution of cell fate decisions in very early embryonic development, and for identification of cancer stem cell biomarkers in tumor biopsies. We have developed a simple, modular workflow for streamlined analysis of cell populations down to the single-cell level. The workflow is centered on two key components: the C<sub>1</sub><sup>™</sup> Single Cell AutoPrep System for automated cell isolation and cDNA preparation, and the Biomark HD<sup>™</sup> system for highly parallel gene expression analysis. Starting from samples containing only a few hundred cells, the preparation system isolates individual cells into discrete compartments within a microfluidic device. Cells can be inspected after isolation using either brightfield microscopy or fluorescent markers to verify cell number and type. Following cell inspection and verification, the selected individual cells are automatically processed to prepare and output high-quality targeted cDNA for gene expression analysis using quantitative or real-time PCR. Targeted cDNA samples are loaded and analyzed in parallel with up to 96 gene expression assays per cell on Dynamic Array<sup>™</sup> IFCs using the Biomark HD system. Data can be analyzed in R, using a custom set of scripts to enable clustering and visualization for identifying interesting expression profiles. This workflow has been used to analyze underlying heterogeneity in a variety of cell types (e.g. K562, HL60, primary keratinocytes, primary fibroblasts), revealing a broad spectrum of previously unappreciated transcriptional variation that underpins function in these diverse cellular systems. This approach provides a powerful, easy to use and high resolution path to generate highly detailed descriptions of heterogeneity and stochastic events within cellular populations.

### **The Heterogeneity of Cellular Response is Revealed by Gene Profiling at Single Cell Resolution.**

Y. Song<sup>1</sup>, B. Kakaradov<sup>1</sup>, A. Q. Vu<sup>1</sup>, G. W. Yeo<sup>1</sup>; <sup>1</sup>University of California at San Diego, La Jolla, CA

Many biologically important and clinically relevant cells are not only present in rare quantities, but are often found in mixtures with other cell-types. Measuring and modeling the gene expression and regulatory networks that are altered during signaling changes at single-cell resolution is technically and computationally difficult. Such challenges are particularly pertinent to the field of stem cell biology and cellular differentiation. Here, we describe the use of an integrated single-cell isolation and gene expression profiling platform to address the heterogeneity of cellular identities and responses to changes. This platform utilizes a C1 single cell capture system (Fluidigm, CA) coupled with a BioMark HD system (Fluidigm, CA), a high-throughput quantitative PCR platform. We have developed experimental and computational protocols to determine the sensitivity, reproducibility and accuracy of the platform. We have developed a probabilistic framework to incorporate notions of variability in analyzing gene expression in single cells. We have applied this Fluidigm system and our framework to analyzing hundreds of human embryonic stem cells (ESCs), patient induced pluripotent stem cells (iPSCs) and somatic cells at the single-cell level, identifying previously unidentified gene expression patterns that distinguish the pluripotent from differentiated states. Our study also revealed a dynamic and progressive response within each cell population when ESCs or iPSCs were subjected to stimuli or differentiation signals. In conclusion, multi-parallel gene profiling studies at single cell resolution will be fundamentally important and necessary to dissect cellular heterogeneity in biological processes.

### **Molecular basis of Morphogenesis in Multicellular Systems via High Content Screening.**

C. C. Bilgin<sup>1</sup>, S. Kim<sup>1</sup>, H. Chang<sup>1</sup>, J. Han<sup>1</sup>, G. Fontenay<sup>1</sup>, B. Parvin<sup>1</sup>; <sup>1</sup>Life Sciences, Lawrence Berkeley National Laboratory, Berkeley, CA

Cells in 3D culture have been shown to grow, interact, and behave more like cells in a living organism than those that are grown in a monolayer culture. This is in part due to cellular organization and cell-cell contact and unique cell-extracellular matrix (ECM) adhesions and motility phenotypes. 3D cell culture models offer certain advantages over the 2D models. In the former, each cell forms an ellipsoid with dimensions of 10-30  $\mu\text{m}$ , while in the latter, each cell remains flat with a thickness of a few micrometers. In the former, the entire cell surface is exposed to other cells or the ECM, but in the latter, a very small percentage of the cell surface area is exposed to other cells. These differences in shape and surface are especially significant, given that approximately 30% of the genome is thought to encode membrane-bound macromolecules. Studies have shown that these simple morphological organizations have a profound impact on cellular functions such as morphogenesis, differentiation, developmental, tumor progression, response to treatment, and patterns of gene.

A major barrier for morphometric analyses of multicellular systems has been accurate cell-by-cell analysis of each colony that has been imaged through confocal microscopy in 3D. We present a validated computational assay for characterizing morphometric indices on a cell-by-

cell basis in the context of the colony organization. The computational pipeline has been applied to four different cell lines of an epithelial origin, with known genetic aberrations, to characterize colony growth as a function of individual cellular morphology. The pipeline provides an integrated computational, storage, and visualization for morphometric and bioinformatics analysis of complex multicellular systems that are imaged in 3D. As a result, specific morphometric indices can be identified that correlate with colony morphogenesis. Finally, molecular data are also associated with a subset of morphometric indices to predict molecular aberration.

2511

**High throughput quantification of collective cells migration: Studying the effects of HGF/SF-Met and Glucose metabolism.**

A. Zaritsky<sup>1</sup>, S. Natar<sup>2</sup>, Y. Goikhman<sup>2</sup>, D. Zabezhinsky<sup>2</sup>, N. Manor<sup>1</sup>, L. Wolf<sup>1</sup>, E. Ben-Jacob<sup>3</sup>, I. Tsarfaty<sup>2</sup>; <sup>1</sup>Blavatnik School of Computer Science, Tel Aviv University, Tel Aviv, Israel, <sup>2</sup>Department of Human Microbiology, Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel, <sup>3</sup>School of Physics and Astronomy, Tel Aviv University, Tel Aviv, Israel

Collective cell migration plays a major role in many essential biological processes. Understanding the molecular and cellular mechanisms of this unique migration mode is limited despite decades of extensive investigations. Numerous computational methods, measures, and software tools exist for microscopic single-cells dynamics analysis, but the collective-migration setting has been neglected. The current explosive growth in the volume of microscopic data requires high throughput analyses to enable applications such as understanding molecular and cellular metastasis mechanisms and drug-screening.

We present a set of quantitative measures, based on live cell imaging of combined bright field and fluorescence confocal microscopy to demonstrate enhanced analyses and better understanding of collective cell motility in a high throughput manner. The toolbox includes multi-cellular segmentation, motion estimation and tracking, motion in clusters and a measure for cells' individuality, measures for indirect morphological features, and spatial-temporal motility measures and visualization.

We focus on the induction of collective tumor cell migration by Hepatocyte Growth Factor / Scatter Factor (HGF/SF) – Met-signaling, master regulators of cell motility in normal and malignant processes. It is demonstrated that HGF/SF-Met-signaling dramatically alters the morpho-kinetic dynamics of collective migration of breast cancer tumor cells: a "wave" of increasing velocities propagates back from the leading edge during in vitro wound healing assay. Met-inhibition reduces this wave.

An open-source, freely available software for high-throughput analysis of collective cell migration, currently developed in our laboratory, is applied to study the cross talk between glucose metabolism of cancer cells and Met tyrosine kinase growth factor receptor signaling. Preliminary results indicate that Met-activation by HGF/SF is more prominent than glucose metabolism in inducing collective migration of tumor cells.

Low concentrations of exogenous expressions of YFP- WT-Met, activating and inhibitory forms were expressed in a monolayer of tumor cells to simulate the phenomenon of cells that maintain amoeboid-like motility while traversing in a tissue consisting of epithelial cells. Individuality of cells is a fully-automated quantitative measure that examines the motility of transfected cells in relation to their vicinity of untreated cells. Activating Met-variants are generally characterized by

lower individuality derived from cells' amoeboid-like motility; Met-inhibition induces epithelial motility also characterized by lower individuality, while HGF/SF-induces increased individuality. It is concluded that the activation of Met-signaling by HGF/SF is the prominent component in individuality of cells.

Our findings may shed light on the molecular and cellular alterations that enable metastasis formation in breast cancer and aid in identifying new targets for therapy.

**Automated Bayesian inference approaches to characterize the nature and onset of particle motion in live cells and embryos.**

*N. Monnier<sup>1,2</sup>, J. Bigness<sup>1</sup>, S. Xie<sup>1,3</sup>, S-M. Guo<sup>1</sup>, A. Dey<sup>1</sup>, N. Kodali<sup>1</sup>, A. Martin<sup>3</sup>, M. Bathe<sup>1</sup>;*  
<sup>1</sup>Biological Engineering, MIT, Cambridge, MA, <sup>2</sup>Biophysics Graduate Program, Harvard University, Cambridge, MA, <sup>3</sup>Biology, MIT, Cambridge, MA

Quantitative analysis of particle motion from particle tracking datasets—such as cell trajectories during embryonic development, receptor dynamics in cell membranes, and chromosome and kinetochore motions during spindle assembly—is a powerful approach to understanding the mechanism of transport and onset of directed motion in biological systems. However, inferring motion models from single-particle trajectories (SPTs) is non-trivial due to noise from both sampling limitations and heterogeneity in biological samples. We present two complementary approaches based on Bayesian inference to perform objective and automated analysis of SPTs. The first is a multiple hypothesis testing approach to determine the most likely mode of motion from mean-square displacement (MSD) curves derived from particle trajectories. This approach handles a large set of competing motion models—including diffusion, anomalous diffusion, confined diffusion, and directed motion—and determines which model is most justified by the evidence present in the available MSD curves. The second approach fits raw particle trajectories with a Hidden Markov Model (HMM) to determine the most likely diffusion coefficient and velocity at each step along a trajectory, enabling the identification of transient motion states and dynamic transitions between motion models. These methods avoid overfitting by using an objective Bayesian framework to penalize model complexity and account for noise. We demonstrate the utility of these procedures by applying them to analyze cell dynamics during gastrulation in developing *Drosophila* embryos. We find that cells and cell junctions in embryos undergoing ventral furrow formation initially exhibit random motion that transitions to directed motion as the furrow begins to invaginate. The timing of the initiation of directed motion varies spatially across the embryo surface, providing insight into the mechanism of symmetry-breaking during this important furrowing event. These studies pave the way for use of these automated approaches in higher-throughput screens of particle trajectories in living systems.

**A Genetic Algorithm-based Method to Automatically Characterize and Classify Neurons.**

*E. Hwang<sup>1,2,3</sup>, H-L. Huang<sup>1</sup>, C-Y. Chao<sup>2</sup>, P-Y. Kao<sup>1</sup>, C-C. Ke<sup>4</sup>, M-H. Chiang<sup>2</sup>, S-Y. Ho<sup>1</sup>, S. Encalada<sup>5</sup>;*  
<sup>1</sup>Institute of Bioinformatics and Systems Biology, National Chiao Tung University, Hsinchu, Taiwan, <sup>2</sup>Institute of Molecular Medicine and Bioengineering, National Chiao Tung University, Hsinchu, Taiwan, <sup>3</sup>Department of Biological Science and Technology, National Chiao Tung University, Hsinchu, Taiwan, <sup>4</sup>Institute of Multimedia Engineering, National Chiao Tung University, Hsinchu, Taiwan, <sup>5</sup>Scripps Research Institute, La Jolla, CA

It has been well documented that neurons exhibit a large variety of morphologies, ranging from the highly complex Purkinje neurons to the simple bipolar retinal neurons. It has also been

shown that the morphology of neurons is affected under pathological conditions. Historically, the morphology of neurons was manually characterized by axonal projection, dendritic branching pattern, soma morphology, and dendritic spine density. As a result, the human characterization is an extremely time consuming and laborious task. This study proposes an automatic classification method by identifying a set of morphological features to characterize and classify neurons based on an inheritable bi-objective combinatorial genetic algorithm (IBCGA).

To evaluate the classification method in classifying neurons with different neuronal morphologies, we used shRNA-mediated gene silencing to suppress a subset of the microtubule-based motors (Kif2a, Kif3c, Kif5b, Kif11, Kif18a, Kif21b, Kif22, Kif23, and Dync1h1) in P19-derived neurons. Microtubule-based motors are responsible for intracellular transport and force generation in neurons; hence, they are essential for neuronal morphogenesis. When these motors are individually suppressed by shRNA, the motor-suppressed neurons each possess a specific morphological phenotype. High-throughput fluorescence microscopy was utilized to acquire these neuronal images. Automated image analysis and IBCGA were then used to quantify and distinguish these 10 classes of morphologically distinct neurons (1 un-suppressed control and 9 motors suppressed). During the training process, 17 out of 703 bioimage features were selected by IBCGA and the classifier of using support vector machine with the 17 features has a prediction accuracy of 92% in distinguishing these 10 classes of morphologically different neurons. To test whether our proposed method can use phenotypic output to predict genotypic perturbation, we classified 3 additional sets of neuronal images (Kif5c-, Dctn2-, and Dync1h1-suppressed) into previously characterized 10 classes. These 3 sets of motor-suppressed neurons were correctly assigned into their respective classes that were consistent with their reported functions. Taken together, the proposed classification method provides an unbiased and efficient way to characterize and classify neurons based on the identified 17 morphological features. This opens up the possibility of using phenotypic output to predict the genotypic perturbation.

### **Wrangling phosphoproteomic data to elucidate cancer signaling pathways.**

*M. L. Grimes<sup>1</sup>, W.-J. Lee<sup>2</sup>, L. van der Maaten<sup>3</sup>, P. Shannon<sup>4</sup>; <sup>1</sup>Division of Biological Sciences, University of Montana, Missoula, MT, <sup>2</sup>Pattern Recognition Group, Delft University of Technology, Delft, Netherlands, <sup>3</sup>Bioinformatics Group, Delft University of Technology, Delft, Netherlands, <sup>4</sup>Fred Hutchison Cancer Research Institute, Seattle, WA*

Analysis of biological data sets is essential for generating hypotheses that guide research, yet the rate of data generation has exceeded our capacity to evaluate the data. The challenge is to discern meaningful patterns in complex data sets, and then convey results in a way that can be easily appreciated. Proteomic data is especially challenging because mass spectrometry detectors often miss peptides in complex samples, resulting in sparsely populated data sets. Using the R programming language and techniques from the field of pattern recognition, we have devised methods to resolve and evaluate clusters of proteins related by their pattern of expression in different samples in proteomic data sets. We examined tyrosine phosphoproteomic data from lung cancer and samples and neuroblastoma cell lines. We calculated dissimilarities between the proteins based on Pearson or Spearman correlations and on Euclidean distances, whilst dealing with large amounts of missing data. The dissimilarities were then used as feature vectors in clustering and visualization algorithms. The quality of the clusterings and visualizations were evaluated internally based on the primary data and externally based on gene ontology and protein interaction networks. The results show that t-distributed stochastic neighbor embedding (t-SNE) followed by minimum spanning tree methods groups sparse proteomic data into meaningful clusters more effectively than other methods such as k-means and classical multidimensional scaling. Furthermore, our results show that

using a combination of Spearman correlation and Euclidean distance as a dissimilarity representation increases the resolution of clusters. Our analyses show that many clusters contain one or more tyrosine kinases and include known effectors as well as proteins with no known interactions. Visualizing these clusters as networks elucidates previously unknown tyrosine kinase signal transduction pathways that drive cancer. Our approach can be applied to other data types, and can be easily adopted because open source software packages are employed.

Microtubules are a highly conserved, crucial element for most vital processes in eukaryotes including global cell shape, intracellular transport, organelle positioning, and cell division. Therefore, elucidating the mechanisms involved in precise microtubule organization is essential to understanding many fundamental aspects of all eukaryotic life. Furthermore, it may provide critical insights into microtubule-associated diseases, including cancer and Parkinson's disease.

We have developed a high-throughput/high-content microscopy pipeline to screen a genome-wide collection of fission yeast (*Schizosaccharomyces pombe*) knockout mutant strains for knockouts deregulating interphase microtubules. Using a custom-made automated image processing and data analysis pipeline that segments cells in 2D and microtubules in 3D, we have quantitatively analyzed over half a million images of GFP-tubulin expressing cells and extracted over one hundred individual feature measurements from close to two million cells representing more than 3000 different gene knockouts. We used microtubule and cell shape features to quantitatively characterize the mutants based on statistical and geometric features, and applied statistics and data mining techniques to classify strains based upon their microtubule patterns, cell cycle stage and cell shape phenotype. In parallel, visual screening was carried out for comparison and quality control.

Tens of genes known to regulate cellular shape and microtubules, such as those encoding the prefoldin complex of chaperones, were successfully identified as well as hundreds of novel candidate gene regulators that we are in the course of testing and validating. Here, we describe the development and current status of the screen.

**Development of New Near IR Dye for In Vivo Imaging Applications.**

M. C. Nlend<sup>1</sup>, B. R. Dworecki<sup>1</sup>, S. J. Hong<sup>1</sup>, W. M. Leevy<sup>2</sup>, J. M. Diener<sup>2</sup>, M. Wenzel<sup>3</sup>, F. Lehmann<sup>3</sup>, P. Czerney<sup>3</sup>, M. Anderson<sup>1</sup>, G. V. Los<sup>1</sup>, G. Hermanson<sup>1</sup>, S. Desai<sup>1</sup>; <sup>1</sup>Thermo Fisher Scientific, Rockford, IL, <sup>2</sup>Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN, <sup>3</sup>Dyomics GmbH, Jena, Germany

Near infra red (NIR) fluorophores are commonly used in cell-based assays or *in vivo* imaging applications. They can be useful in specific imaging or assay application based on the dye's characteristic excitation and emission spectra properties, or relative Hydrophilicity/hydrophobicity attributes. In this study we have evaluated a new cyanine-based

dye with excitation /emission of 684 / 706 nm, and features that demonstrate excellent characteristics for *in vivo* and *ex vivo* imaging. In general, the dyes that contain a greater number of negative charges display high water solubility and clearance, while more hydrophobic dyes often clear via a hepatic pathway. This dye was conjugated to primary and secondary antibodies which were then used for fluorescence immunostaining in various cell types. In addition, the dye was tested in *in vivo* for optical biodistribution and clearance in nude mice. For *in vivo* studies, the mice received an IV injection of dye via the retro orbital plexus, and were imaged on a Carestream MSFX imager (690nm excitation / 750nm emission) before injection and at 0h, 3h, 6h, 12h, and 24h post injection. After the final time point, animals were sacrificed and organs were collected for *ex vivo* imaging. Toxicity of the dye was evaluated by histological analysis of the dissected tissue section.

The data showed that when this dye was conjugated to an antibody at low molar excess, it had high labeling efficiency that resulted in high fluorescence intensity, good specificity, high signal-to-background ratio, and photostability in cellular imaging applications. The biodistribution and clearance of this dye showed rapid clearance through kidney and/or gastro-intestinal tract. This new NIR dye is an excellent tool for imaging through tissues to circumvent endogenous fluorescent biomolecule interference or quenching.

#### Identifying transience: considerations in dynamic monitoring of biological events in *Arabidopsis thaliana* biosensors.

C. Modavi<sup>1</sup>, K. Jiang<sup>1</sup>, G. Hines<sup>2</sup>, A. Packard<sup>2</sup>, L. Feldman<sup>1</sup>, K. Poolla<sup>2</sup>; <sup>1</sup>Department of Plant and Microbial Biology, University of California, Berkeley, CA, <sup>2</sup>Department of Mechanical Engineering, University of California, Berkeley, CA

One of the major advantages of Fluorescent Proteins (FPs) is their robust and easy detection; this is in addition to their ability to be fused to other protein domains that can confer additional properties such as organelle compartmentalization or altered stability levels. These properties have practical ramifications when designing a biosensor. Specifically, we consider different aspects of both reporter-protein and promoter dynamics in relation to characteristics (e.g. kinetics, "calibration", and baseline measurements) that render our FP-based biosensor suitable as a tool for real-time measurement and analysis. Our work is contextualized in a proof-of-concept system for automated monitoring of plant temperature stress, through interfacing cellular heat shock responses with a computer-linked fluorescence meter. Overall we demonstrate the value of particular biosensor characteristics and the feasibility of using a cell's genetic response to stimuli for achieving practical goals in the monitoring or control of biological systems. This is further aided by our preliminary work towards developing new FP-reporter constructs for more dynamic visualization of promoter activity in plants.

#### Direct labeling of 19F-perfluorocarbon onto engineered multilayered cell sheet for MRI-based non-invasive cell tracking.

J. Oliva<sup>1</sup>, F. Bardag-Gorce<sup>1</sup>, A. Wood<sup>1</sup>, B. Helfer<sup>2</sup>, A. Balducci<sup>2</sup>, A. Wesa<sup>2</sup>, H. Sota<sup>1</sup>, Y. Niihara<sup>1</sup>; <sup>1</sup>Medicine, LA Biomed, Torrance, CA, <sup>2</sup>Celsense, Pittsburgh, PA

Background: Regenerative medicine with the use of stem cells has appeared as a potential therapeutic alternative for many diseases. Numerous questions remain regarding the viability, biology and the fate of grafted cells. Recent technological advances in chemistry and imaging have allowed monitoring the injected cells in a non-invasive way. However, only individualized group of cells were labeled and tracked *in vivo* so far, since the cell labeling techniques chiefly relies on the inherent cellular uptake mechanism upon foreign labeling agents. In order to

investigate the possible cell migration from the grafted cell sheet to other vital organs, the present study undergoes cell sheet labeling optimization. For the first time, we propose a direct labeling of an organized multilayered cell sheet, for MRI-based in vivo cell tracking post grafting. A perfluorocarbon tracer will be employed to enable specific, quantitative evaluation of the graft by 19F MRI. Using a new temperature-responsive culture surface (UpCell®, CellSeed Inc, Japan), we engineered a multilayered cell sheet, which will be labeled with CS-1000 perfluorocarbon (Celsense, Inc., Pittsburgh, PA). Experiment: Oral mucosal epithelial cells were isolated from rabbit oral mucosal epithelium and were cultivated in the unique culture surfaces to engineer multilayered cell sheets. A dose response study was performed to determine the optimal concentration of the reagent CS-1000 19F-perfluorocarbon. A multiple labeling approach was also used with optimal concentration to successfully label the cellsheet. The labeled cell sheets were harvested, and ten thousands cells were sampled and re-isolated for colony forming assays (CFAs) to validate the clonogenicity of the cells. The remaining part of cell sheets was subjected to 19F NMR spectral analysis at 7T to determine the labeling efficiency. Results: Labeled cells incubated twice with 5 mg/ml of CS-1000 showed a 3.7-time higher labeling efficiency than those labeled only 1 time at the same concentration. The efficiency climbed with increasing the concentration, reached the plateau at 10 mg/ml, and kept steady until the concentration of 20 mg/ml (10 mg/ml was the maximum efficient labeling concentration). Therefore, labeling at 10 mg/ml of CS-1000 2 times during the culture of a cell sheet was found to be an optimal condition. H&E staining of the labeled cell sheet showed that the labeling did not change the cell morphology. As well, no apparent negative effects of the CS-1000 on the clonogenicity of cell sheet were observed. In addition CS-1000 labeling didn't change the p63 expression and the proliferative potential of the engineered cell sheets and no significant effect was observed on the number of cells and the cell viability. Conclusion: We have succeeded in labeling an organized multilayer cell sheet with 19F CS-1000 perfluorocarbon, without apparent toxic effects. This new approach opens new perspective to monitor the migration of cells, coming from an organized engineered tissue.

### **Stretching Von Willebrand Factor Multimers and Dimers with the Optical Trap.**

*J.-Y. Shao<sup>1</sup>, Y. Shan<sup>1</sup>, J. Hao<sup>1</sup>, L. A. Westfield<sup>2</sup>, J. E. Sadler<sup>2</sup>; <sup>1</sup>Department of Biomedical Engineering, Washington University in St. Louis, Saint Louis, MO, <sup>2</sup>Department of Medicine, Biochemistry and Molecular Biophysics, Washington University in St. Louis, Saint Louis, MO*

Von Willebrand Factor (VWF) is a multimeric plasma protein that is critical for both hemostasis and thrombosis. VWF size in blood is mediated by ADAMTS13, a metalloprotease that cleaves the Tyr1605-Met1606 bond in the A2 domain of VWF. This process is regulated by many factors including denaturing agents like urea, shear stress in blood, and other VWF domains like A1. It has been found that single A2 domains, either in its native or recombinant form, can be unfolded by an increasing pulling force and the unfolding force depends on the force loading rate. A2 unfolding facilitates its cleavage by ADAMTS13. In this work, we stretched both native VWF multimers and recombinant VWF dimers with the optical trap. The VWF molecules were immobilized on plastic beads with antibodies. We found that some A2 domains ( about 16%) of native VWF multimers showed an intermediate state before its fully-unfolded conformation. The unfolded length of this intermediate state was about 35 nm. We also found that the A2 domains of recombinant VWF dimers were unfolded at smaller forces, compared with native VWF multimers. With deletion of the A1 domain or deglycosylation, the unfolding forces became even smaller. Three mutations in VWF dimers (G1609R, G1629E, and G1631D) rendered them devoid of any unfolding behavior, indicating that the A2 domains in them became so weak that their unfolding forces were not measurable. From stretching VWF dimers, we calculated an extensional stiffness of about 0.5 pN/nm for VWF monomers before any domain unfolding.

These data show clearly how VWF molecules are extended by force and how their cleavage can be tuned via deglycosylation, domain deletion, and point mutation.

### Small Angle Neutron Scattering Study of Green Fluorescent Protein under Macromolecular Crowding: A Tale of Two Dimers.

S. Qian<sup>1</sup>, Q. Zhang<sup>1</sup>, V. S. Urban<sup>1</sup>, H. M. O'Neill<sup>1</sup>, W. T. Heller<sup>1</sup>; <sup>1</sup>Biology and Soft Matter Division, Oak Ridge National Laboratory, Oak Ridge, TN

Proteins typically function in the crowded cellular environment where they interact with a dense mixture of other biological macromolecules. Concentrations can reach up to 400 mg/ml in the cytosol of some *E. coli*. Such conditions, often referred to as 'crowded' are in stark contrast to the very dilute solutions used in most biochemical and biophysical studies. Here, small-angle neutron scattering (SANS) was employed to study the structure and self-association of green fluorescent protein (GFP) in solutions containing human serum albumin (HSA) at concentrations from dilute (5 mg/ml) to crowded (200 mg/ml). HSA, a common protein in blood serum, affords a more realistic mimic of the biological environment than the more commonly used crowding agents, such as polyethylene glycol or Ficoll. By using perdeuterated GFP and hydrogenated HSA, it was possible to directly probe GFP in the solutions by matching the scattering length density of HSA with an appropriate D<sub>2</sub>O/H<sub>2</sub>O buffer mixture, thereby eliminating its (SANS) signal. At low HSA concentrations, GFP exists in a side-by-side dimeric conformation that is found when GFP is free in solution. As the concentration of HSA increases past 100 mg/mL, GFP transitions to an ensemble of states that is an equilibrium between a monomeric state and end-to-end dimeric configuration. This experiment is a good demonstration that SANS can be used to probe individual component within complex biological systems, assemblies and composites by exploiting the natural contrast difference between biomolecules. Furthermore, the high penetration power of neutrons and the lack of radiation damage make it useful to study biomolecules even in the cell.

2521

### Macromolecular crowding effects on cell-free protein synthesis are dependent on the concentration of free magnesium.

X. Ge<sup>1</sup>, D. Luo<sup>2</sup>, J. Xu<sup>1</sup>; <sup>1</sup>Arkansas Biosciences Institute and College of Agriculture and Technology, Arkansas State University, Jonesboro, AR, <sup>2</sup>Department of Biological and Environmental Engineering, Cornell University, Ithaca, NY

Cell-free synthetic biology is a promising approach for understanding, harnessing, and expanding the functions of natural biological systems without using living cells [1]. One of the most prominent example of cell-free biology is the cell-free protein synthesis (CFPS) which provides an open, versatile and rapid platform for protein synthesis [1,2]. However, CFPS is routinely carried out in relatively dilute solutions, where a common intracellular feature, macromolecular crowding is ignored [3]. We earlier investigated the CFPS under macromolecular crowding environments emulated with three different crowding agents, and found that these crowding agents substantially enhanced the transcription, but generally inhibited the translation.[3]. It has been proposed that such different responses might be attributed to the difference in other environmental factors, such as temperature and salt concentrations [3]. In this study, we further examined the macromolecular crowding effects on *in vitro* transcription, translation and coupled transcript/translation reaction at different concentrations of free magnesium ion (Mg<sup>++</sup>). We found that macromolecular crowding effects enhanced these *in vitro* reactions at low concentrations of free Mg<sup>++</sup>, but inhibited the reactions at high

concentrations of free Mg<sup>++</sup>. The results from this research may allow us to better mimic the biological process in an *in vitro* setting.

### Microenvironment of microtubules probed with fluorescence correlation spectroscopy.

M. J. Rossow<sup>1</sup>, M. A. Digman<sup>2</sup>, E. Gratton<sup>2</sup>, V. I. Gelfand<sup>1</sup>; <sup>1</sup>Northwestern University, Chicago, IL, <sup>2</sup>University of California Irvine, Irvine, CA

One aspect not completely understood regarding microtubule based transport is how motor proteins are able to move cargo through the cytoplasm when only a few are available to move each cargo and the force generated by each motor protein is small, 7 pN or less. This is surprising considering the high concentration of macromolecules and other proteins present in the cytoplasm through which cargo must move. To study the forces required to move organelle-sized particles through the cytoplasm, we have performed a series of measurements using magnetic tweezers. In these experiments, forces greater than 100 pN were required to move 0.3 μm magnetic beads in the cytoplasm. However, these experiments were performed on particles that had been injected into the cytoplasm and were not moving along microtubules. Transport of organelles at lower forces could be explained by spatial variation in the physical properties of the cytoplasm near microtubules. We have used fluorescent correlation spectroscopy (FCS) to compare the physical properties of the cytoplasm surrounding microtubules and elsewhere in the cell as a comparison. In PtK<sub>2</sub> cells expressing GFP-tubulin, fluorescently labeled 10 kD dextran was observed to have diffusion coefficients up to eight times higher near microtubules than elsewhere in the cell, demonstrating that microtubules are surrounded by a “high diffusion” zone. This spatial variation in the physical properties of the cytoplasm may facilitate transport of large cargo along microtubules.

### DNA target sequence identification mechanism for dimer-active protein complexes.

M. P. Landry<sup>1</sup>, X. Zou<sup>2</sup>, W. Huang<sup>3</sup>, K. Schulten<sup>2</sup>, Y. Chemla<sup>4</sup>; <sup>1</sup>Chemistry, University of Illinois at Urbana-Champaign, Urbana, IL, <sup>2</sup>Beckman Institute, University of Illinois at Urbana-Champaign, Urbana, IL, <sup>3</sup>Pathology, University of Utah, Salt Lake City, UT, <sup>4</sup>Physics, University of Illinois at Urbana-Champaign, Urbana, IL

Protein-DNA interactions are essential to cellular processes, many of which require proteins to recognize a specific DNA target-site. This search process is well-documented for monomeric proteins, but not as well understood for systems that require dimerization or oligomerization at the target site for activity. We present a single-molecule study of the target-search mechanism of Protelomerase TelK, a recombinase-like protein that is only active as a dimer. Interestingly, we observe that TelK undergoes 1D diffusion on non-target DNA as a monomer, as expected, but becomes immobile on DNA as a dimer or oligomer despite the absence of its target site. We further show that TelK condenses non-target DNA upon dimerization, forming a tightly bound

nucleo-protein complex. Together with simulations of dimer-active protein search, our results suggest a search model whereby monomers diffuse along DNA, and subsequently dimerize to form an active complex on target DNA. These results show that target-finding occurs faster than nonspecific dimerization at biologically relevant protein concentrations. This model may provide insights into the search mechanisms of proteins that are active as multimeric complexes for a more accurate and comprehensive model for the target-search process by sequence specific proteins.

### Using Sequencing to Measure DNA Looping Probability in E. Coli.

*S. Barnes*<sup>1</sup>, *D. Jones*<sup>1</sup>, *J. Kinney*<sup>2</sup>, *Y-J. Chen*<sup>1</sup>, *F. Weinert*<sup>1</sup>, *J. Boedicker*<sup>1</sup>, *R. Phillips*<sup>1</sup>; <sup>1</sup>California Institute of Technology, Pasadena, CA, <sup>2</sup>Cold Spring Harbor Laboratory, Cold Spring Harbor, NY

Many of the processes that make it possible to copy, control, access and rearrange the information contained in genomes require physical deformations of the underlying DNA substrate. However, the question of how such deformations in vivo depend upon the specific nucleotide sequences of the DNA remains largely unanswered. In this work, we harness the high-throughput potential of in vivo studies to explore the connection between sequence and deformation through the specific example of DNA looping in transcriptional regulation. The looping probability of randomly generated looping sequences will be reported via yellow fluorescent protein output from the gene subject to repression by looping. Sequence information will be gleaned from these cells using flow cytometry to sort cells into bins based upon their fluorescent output, which reflects looping probability. Sequencing will be performed upon cells displaying high and low looping probabilities, and mutual information will be used to find correlations between sequence and looping probability, and will serve as a springboard for studying the connection between sequence and physical deformations in other contexts.

### Quantitative dissection of gene regulation through DNA loop formation.

*J. Boedicker*<sup>1</sup>, *H. Garcia*<sup>2</sup>, *S. Johnson*<sup>3</sup>, *R. Phillips*<sup>1</sup>; <sup>1</sup>Applied Physics, Caltech, Pasadena, CA, <sup>2</sup>Physics, Caltech, Pasadena, CA, <sup>3</sup>Biochemistry and Molecular Biophysics, Caltech, Pasadena, CA

The study of genetic circuits has reached a state of maturity that permits direct and stringent comparison between theories of transcriptional regulation and the response of living cells. We have developed and tested such models of gene expression based on equilibrium statistical mechanics. The models require only a few input parameters: binding energies of proteins, copy numbers of molecular components, and the mechanical properties of DNA. These parameters are measured in simple control experiments and used to predict gene expression levels for genetic circuits involving different combinations of these parameters. Such first principles biological models require no fitting parameters and make quantitative and precise predictions about gene regulation over a wide range of parameter space.

Equations derived from these models define the input-output function of each genetic circuit, and predict how each system component modulates gene expression. We independently tuned each parameter of the model and experimentally tested whether the gene circuit responded as predicted. Model predictions were tested by creating these genetic circuits in E. coli, and using fluorescent reporters to quantify the level of gene expression for each circuit. We tuned

transcription factor copy number over two orders of magnitude and varied the operator binding energies resulting in several orders of magnitude change in dissociation constants.

Next we implemented the model to examine the role of DNA mechanical properties in the context of transcription factor-mediated loop formation. The tetrameric transcription factor Lac repressor is able to increase the level of gene repression by binding to two operators and looping the intervening DNA. We use this system to ask whether the sequence-dependent flexibility of the DNA in the loop influences gene expression. By incorporating DNA sequences with known sequence-dependent flexibilities into the looping region, we found that the intrinsic flexibility of the looping DNA does not influence repression. DNA sequences shown to be flexible *in vitro*, including in our own tethered particle motion assays, do not lead to increased repression. We resolve the lack of *in vivo* sequence dependence by theoretically and experimentally exploring the role of the DNA-bending protein HU in loop formation. We found that after knocking out HU, sequence-dependent loop formation is restored *in vivo*, and use the models to suggest how the presence of DNA-bending proteins buffers away the influence of sequence-dependent mechanics on gene regulation.

### **Bridging Length Scales of Chromatin Biophysics.**

*E. F. Koslover<sup>1</sup>, A. J. Spakowitz<sup>2</sup>; <sup>1</sup>Biophysics, Stanford University, Stanford, CA, <sup>2</sup>Chemical Engineering, Stanford University, Stanford, CA*

Eukaryotic cells must overcome the daunting challenge of packaging meters of DNA into a micrometer sized nucleus while retaining accessibility of the genome to transcriptional machinery. They do so by employing a hierarchical, dynamic chromatin structure which harnesses the physical properties of DNA and interacting proteins on a wide range of length scales. We use multi-scale modelling to address physical aspects of chromatin at different levels of the packaging hierarchy.

At the smallest scale of chromatin packing, DNA is wrapped around histone proteins to form nucleosomes. We generate a coarse-grained mechanical model for nucleosomal fluctuations during transcription by RNA polymerase. We show that unwrapping of nucleosomal DNA generates rapidly fluctuating forces on the polymerase and that the time scale and magnitude of these fluctuations dictate key features of the transcription kinetics. In addition to elucidating mechanical aspects of nucleosome structure and dynamics, our results imply a general biophysical principle. Namely, we highlight the important role of force fluctuations in determining biomolecular kinetics in the dynamic environment of a living cell.

On a large scale, arrays of nucleosomes are believed to condense into regular helical fibers under physiologic conditions.

We study how the elastic properties of DNA and nucleosome geometry impact the formation of such compact chromatin fibers. We demonstrate a wide variety of energetically accessible fiber structures, indicating that a multiplicity of different structures are likely present *in vivo*.

Zooming out to the scale of an entire genome presents particular modelling challenges, as gigabase lengths of DNA cannot be handled by the same techniques that capture individual nucleosomes. This disparity of length scales necessitates a systematic process for generating coarse-grained models to address longer length phenomena. We develop a generalizable procedure for coarse-graining of polymer models by mapping onto an effective shearable worm-like chain that maintains the correct statistics at long length scales.

We apply this procedure to study the thermodynamics of DNA with periodic kinks generated by bound proteins. We consider looping of DNA-nucleosome arrays on different length scales, demonstrating the crucial impact of local geometry on the distribution of loops. These calculations provide a jumping-off point for investigating the condensation of nucleosome arrays into dense chromatin structures.

These multi-scale studies further our understanding of how the complex hierarchy of chromatin packing and processing arises from the basic physical properties of DNA and interacting proteins.

**Measuring enzyme copy numbers and single-molecule reaction rates in living cells.**

*S. Uphoff<sup>1</sup>, R. Reyes-Lamothe<sup>2</sup>, F. Garza de Leon<sup>1</sup>, M. Leake<sup>1</sup>, D. Sherratt<sup>2</sup>, A. Kapanidis<sup>1</sup>;*  
<sup>1</sup>Physics, University of Oxford, Oxford, United Kingdom, <sup>2</sup>Biochemistry, University of Oxford, Oxford, United Kingdom

To gain direct insight into enzyme function and organization of reaction pathways, we adapted PALM super-resolution fluorescence microscopy as a general technique to quantify enzyme copy numbers, reaction rates, and their spatial distribution and movement at single-molecule resolution in living cells. Here, we discuss the relative merits and downsides of this technique compared to slimfield excitation microscopy at millisecond temporal resolution and conventional fluorescence imaging by means of two example applications.

(1) We investigated general organization principles of DNA repair pathways. Albeit essential for cell survival, DNA repair itself poses a threat to chromosome stability, generally involving toxic gapped or nicked DNA intermediates. Reaction rates of subsequent repair pathway steps hence have to be well balanced, depending on the copy number distributions, damage search mechanism, and the spatial distribution of repair sites and enzymes. Here, we provide a comprehensive quantitative account of the ubiquitous DNA synthesis and ligation steps by directly visualizing individual DNA Polymerase I (Pol) and DNA Ligase (Lig) enzymes searching and repairing DNA damage in live E.coli. Consistent with early reports, we measure ~400 and ~200 copies of Pol and Lig per cell. Upon DNA damage by mutagen methyl-methanesulfonate (MMS), cells showed a 4-5 fold increase in stationary Pol and Lig molecules within minutes of MMS exposure; individual tracks displayed binding and dissociation events. We quantified repair activity at the single-cell level over time and for varying MMS concentration and found that Pol and Lig exhibit balanced enzymatic activities in excess copy numbers to saturate substrates. This ensures a minimum presence of unbound DNA breaks and high repair capacity to prevent accumulation of toxic DNA repair intermediates.

(2) Combination of our general method with multi-color fluorescence microscopy further provided insight into the structure and function of MukBEF, Structural Maintenance of Chromosomes (SMC) complexes with a central role in E.coli chromosome separation. By distinguishing chromosome bound and diffusing molecules, we establish that MukBEF accumulates in 1-3 immobile clusters per cell that are further organized into sub-clusters with a size < 40 nm. Diffusion of the individual components MukB, E, and F outside clusters was similar despite differences in the individual molecular weights, suggesting that stoichiometric MukBEF complexes assemble in solution.

### Hematopoietic stem and progenitor cells contain functional subsets different in their NF- $\kappa$ B regulated cytokine producing capacity.

C. Ma<sup>1</sup>, J. Zhao<sup>1</sup>, J. Heath<sup>1</sup>, D. Baltimore<sup>1</sup>; <sup>1</sup>California Institute of Technology, Pasadena, CA

The ability of hematopoietic stem and progenitor cells (HSPCs) to replenish the hematopoietic repertoire and to maintain the proper numbers of various hematopoietic cells has long been considered their sole function. Little is known about direct immune effector function of HSPCs during an infection. In fact, whether HSPCs can directly sense an infection remains to be substantiated with direct evidence. In this study, we have combined both transgenic and genetic knockout mouse models with a novel single cell barcode proteomics microchip technology to tackle these questions (Ma, C. et al. *Nature Medicine*, 2011, 17, 738-743). We show that although long-term HSCs (as defined by L-K+S+CD150+CD48-) do not secrete cytokines upon TLR ligand stimulation, short-term HSCs and multipotent progenitor cells (MPPs) (as defined by L-K+S+) can produce copious amounts of cytokines upon direct Toll-like receptor (TLR)-4 and TLR-2 stimulation, indicating that L-K+S+ cells can directly participate in an immune response by producing a myriad of cytokines, upon bacterial infection. Within the population of L-K+S+ cells we detect multiple functional subsets of cells, specialized in either myeloid or lymphoid-like functions. Moreover, we show that the cytokine production by L-K+S+ cells is regulated by the NF- $\kappa$ B activity, as p50-deficient L-K+S+ cells show reduced cytokine production while microRNA (miR)-146a-deficient L-K+S+ cells show significantly increased cytokine production, which is rescued by the double knockout mouse model. The cytokine production in knockout models is less regulated and proteins have lower correlation than those in the wild type model. miR-146a deletion skews L-K+S+ cells toward a myeloid phenotype as well. This study has provided the first evidence of an immune effector function of HSPCs upon TLR stimulation that is regulated by the TLR-NF- $\kappa$ B signaling axis and suggested the existence of multiple functional subsets within HSPCs.

### Elucidating the Mechanism behind Stem-Cell Derived Hepatocytes using Transcriptome Analysis.

R. Raju<sup>1</sup>, D. Chau<sup>2</sup>, A. Yongky<sup>1</sup>, C. M. Verfaillie<sup>3</sup>, W. S. Hu<sup>1</sup>; <sup>1</sup>Department of Chemical Engineering, University of Minnesota, Minneapolis, MN, <sup>2</sup>Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, <sup>3</sup>Stem Cell Institute, Leuven, Belgium

The capability of human embryonic stem cells to differentiate into cell types of hepatic lineage holds great promise in hepatocyte transplantation for regenerative therapy of liver failure and in hepatocyte based drug toxicity testing. We have previously developed a four-step protocol mimicking the signaling in embryonic liver development using a combination of growth factors and cytokines. In addition to expression of hepatic-specific genes, mature hepatocyte function was demonstrated in albumin secretion, cytochrome p450 activity, as well as urea metabolism. We further demonstrated that these hepatocyte-like cells, when cultured as three dimensional spheroids, had increased expression and/or activities of liver specific genes as well as a larger subpopulation of cells exhibiting differentiated markers such as PEPCK and ASGPR. We also explored the possibility of expanding cells along the path of hepatic differentiation. At least in two stages, cells isolated from differentiation culture were successfully expanded by replating in sub-confluent conditions to retain the capability for further differentiation into the hepatic-like cells.

To evaluate the progress of hepatic differentiation, transcriptome analysis was performed on various cell populations isolated along the course of the protocol and compared to

transcriptome data from other published hepatic differentiation from primary human hepatocytes as well as fetal and adult livers. The transcript levels of a number of liver specific genes, such as albumin approached that of primary hepatocytes. However, these cells did not demonstrate a complete switch in expression of key metabolic isozymes, such as AldoA and AldoB, from the ES state to the hepatocyte state indicating incomplete differentiation. Gene Set Enrichment Analysis (GSEA), was employed to identify key functional classes of genes that are highly dynamic during differentiation. Results of the transcriptome analysis will then be used as a guide in our future optimization of embryonic stem cells differentiation to hepatic lineage.

#### Hot spots for allosteric regulation on protein surfaces.

K. A. Reynolds<sup>1</sup>, R. Ranganathan<sup>1</sup>; <sup>1</sup>University of Texas Southwestern Medical Center, Dallas, TX

Co-evolution analysis indicates a general architecture for natural proteins in which sparse networks of amino acids underlie basic aspects of structure and function. These networks, termed sectors, are spatially organized such that active sites are physically linked to particular surface sites distributed throughout the protein structure. This suggests that sectors represent an evolutionarily conserved "wiring" mechanism that effectively functionalize certain sites on the protein surface for the gain of allosteric regulation. Using the metabolic enzyme dihydrofolate reductase as a model system, we show that: (1) the sector is strongly correlated to a distributed network of residues undergoing millisecond conformational fluctuations associated with enzyme catalysis, and (2) sector-connected surface sites are statistically preferred locations for the emergence of allosteric control in vivo. Thus, perturbations at specific sector connected surface positions are able to rapidly initiate conformational control over protein function. These findings suggest that the heterogeneous sector architecture of proteins might enable the evolution of intermolecular communication and regulation.

#### *Saccharomyces cerevisiae* strains evolved for increased medium-chain alcohol tolerance.

S. A. Davis<sup>1</sup>, D. Tullman-Ercek<sup>2</sup>; <sup>1</sup>Chemistry, University of California, Berkeley, Berkeley, CA, <sup>2</sup>Chemical and Biomolecular Engineering, University of California, Berkeley, Berkeley, CA

Biofuels are a promising alternative to traditional fuel sources that are fraught with negative environmental impacts and rising costs. Medium-chain alcohols such as *n*-butanol and *n*-hexanol have higher energy densities and less corrosivity than ethanol, making them promising biofuel molecules<sup>1</sup>. However, these solvents are toxic and are thus produced at low levels<sup>2</sup>. A solution is to engineer or evolve production organisms that are tolerant to industrially relevant solvent concentrations. This will allow the cell to survive higher solvent concentrations and thus produce more biofuels. *Saccharomyces cerevisiae* is an attractive biofuel production host because it is genetically tractable, resistant to phage infection, and industrial fermentations are well established.

Toward the goal of highly tolerant production hosts, we have evolved a laboratory strain of *S. cerevisiae* to be more tolerant toward the medium-chain alcohol *n*-hexanol. These evolved strains display log-phase growth rates more than double that of the wild-type strain in the presence of toxic levels of *n*-hexanol. The phenotype is stable in the absence of solvent pressure, and is dominant: when mated with a non-tolerant yeast, the diploids have tolerance levels matching those of the tolerant haploid strains. Sporulation and tetrad analysis indicates that multiple genes are involved. The tolerance extends to other medium-length alcohols such

as *n*-pentanol and *n*-heptanol, but not *n*-butanol. Efforts to identify the genes responsible are underway, and will be useful for engineering effective biofuel production hosts.

**Novel positive allosteric modulators of the human  $\alpha 7$  nicotinic receptor modulate the antidepressant activity elicited by nicotine.**

K. M. Targowska Duda<sup>1</sup>, D. Feuerbach<sup>2</sup>, R-X. Gu<sup>3</sup>, Y. Ye<sup>4</sup>, D-Q. Wei<sup>3</sup>, K. Jozwiak<sup>1</sup>, H. R. Arias<sup>5</sup>; <sup>1</sup>Department of Chemistry, Medical University, Lublin, Poland, <sup>2</sup>Novartis Institutes for Biomedical Research, Basel, Switzerland, <sup>3</sup>College of Life Sciences and Biotechnology, Shanghai Jiao Tong University, Shanghai, China, <sup>4</sup>Department of Chemistry, Zhengzhou University, Zhengzhou, China, <sup>5</sup>Department of Medical Education, College of Medicine, California Northstate University, Elk Grove, CA

Major Depressive Disorder is extremely prevalent in the U.S. population (~20%) and one of the leading causes of disability and morbidity in the world. The aim of this study is to characterize the structural and functional interactions of novel positive allosteric modulators (PAMs) with different nicotinic acetylcholine receptors (AChRs), and to determine its modulatory activity on nicotine induced antidepressant effects in mutant mice. Ca<sup>2+</sup> influx results indicate that these compounds are not agonists of the human (h)  $\alpha 4\beta 2$ ,  $\alpha 3\beta 4$ ,  $\alpha 7$ , and  $\alpha 1\beta 1\gamma\delta$  AChRs. Compounds 2-4 are specific PAMs of h $\alpha 7$  AChRs, whereas compounds 1-4, 7, and 12 are noncompetitive antagonists of the other AChRs. Radioligand binding results show that these PAMs enhance [<sup>3</sup>H]epibatidine binding to h $\alpha 7$  AChRs, indicating that these compounds do not directly, but allosterically, interact with the h $\alpha 7$  agonist sites. Molecular dynamics and docking results suggest that the binding site for PAMs 2-4 is mainly located in the inner  $\beta$ -sheet of the  $\alpha 7$ - $\alpha 7$  interface, 12Å from the agonist locus. Two hydrogen bond interactions bridging both (+) and (-) subunit faces are found to be critical for the PAM activity at the h $\alpha 7$  AChR. Based on the forced swimming tests on mutant ( $\beta 4^{-/-}$ ) and wild-type ( $\beta 4^{+/+}$ ) mice, male vs female, we determined that: (1) the  $\beta 4$  subunit plays an important role in the antidepressant effect elicited by nicotine. The results indicated a statistically significant increase of the antidepressant effect of nicotine in  $\beta 4^{+/+}$  mice compared to  $\beta 4^{-/-}$  mice, and (2) PAM-2 modulates this activity in a gender distinct manner. The results indicated that PAM-2 enhances the antidepressant effect of nicotine in female  $\beta 4^{+/+}$  mice but diminishes it in male  $\beta 4^{+/+}$  mice. In  $\beta 4^{-/-}$  mice, there is a statistically significant increase of the antidepressant effect (chronic) of nicotine in PAM-2 treated mice compared to nicotine (only) treated mice. The receptor specificity and the modulatory action on nicotine-induced antidepressant activity elicited by PAMs 2-4 might be therapeutically important for the treatment of depressed patients with Alzheimer's disease.

**Integrin binding activity of Aaa-Gly-Xaa or Xaa-Gly-Aaa motif containing laminin peptides.**

F. Katagiri<sup>1</sup>, J. Kumai<sup>1</sup>, Y. Yamada<sup>1</sup>, S. Urushibata<sup>1</sup>, M. Ishikawa<sup>1</sup>, K. Hozumi<sup>1</sup>, Y. Kikkawa<sup>1</sup>, M. Nomizu<sup>1</sup>; <sup>1</sup>Tokyo University of Pharmacy and Life Sciences, Hachioji, Japan

Laminin  $\alpha$  chain ( $\alpha 1$ - $\alpha 5$  chains) has chain-specific diverse biological functions. The C-terminal globular domain of  $\alpha$  chain consists of five laminin-like globular modules (LG1-5) and plays a critical role in the biological activities. The LG modules of laminin  $\alpha$  chains consist of a 14-stranded  $\beta$ -sheet (A-N) sandwich structure. Previously, we designed 25 homologous peptides (G1EF1-G5EF5) derived from the loop regions between the E and F strands in the LG modules and identified their biological activities. The results suggested that the peptide containing

(acidic amino acid; Aaa)-Gly-(basic amino acid; Baa) motif in the middle of the sequence interacted with integrins, and the peptides containing Baa-Gly-Baa motif in the middle of the sequence interacted with syndecans. Previously, we pointed out the importance of Aaa residue to interact with integrins. Here, we extracted sequences including Aaa-Gly-Xaa or Xaa-Gly-Aaa motif in the LG modules of laminin  $\alpha$  chains except the E-F loop regions. We designed 55 peptides (40 of Aaa-Gly-Xaa; 15 of Xaa-Gly-Aaa) with 19 amino acid length and prepared by solid-phase peptide synthesis. We evaluated cell attachment activity of these peptides using human dermal fibroblasts (HDFs), and identified their integrins binding activity using EDTA or anti-integrin antibodies. Fourteen peptides (A1GG2320, A1GG2824, A1GG2916, A2GG2416, A2GG2841, A2GG2855, A4GG833, A4GG1049, A4GG1251, A4GG1254, A4GG1483, A4GG1544, A5GG3133 and A5GG3441) promoted HDF attachment and eleven of them (A1GG2320, A1GG2824, A2GG2416, A2GG2841, A4GG833, A4GG1049, A4GG1251, A4GG1254, A4GG1483, A4GG1544, and A5GG3441) inhibited by EDTA. Furthermore, the HDF attachments of eight peptides (A1GG2320, A2GG2416, A2GG2841, A4GG1251, A4GG1254, A4GG1483, A4GG1544, and A5GG3441) were inhibited by anti-integrin  $\beta$ 1 antibody and seven peptides had Aaa-Gly-Xaa motif (A1GG2320, A2GG2416, A2GG2841, A4GG1251, A4GG1254, A4GG1544, and A5GG3441). These results suggest that the Aaa-Gly-Xaa motif is critical for integrin binding.

#### **Imiquimod induces cancer cell apoptosis by damaging mitochondria through a TLR-independent pathway.**

*L. Li<sup>1</sup>, M. Coughlin<sup>1</sup>, Y. Feng<sup>2</sup>, J. Tallarico<sup>2</sup>, T. Mitchison<sup>1</sup>; <sup>1</sup>Systems Biology, Harvard Medical School, Boston, MA, <sup>2</sup>Novartis Institutes for BioMedical Research, Inc., Cambridge, MA*

Cancer cells differ from their normal counterparts in many ways, so we should be able to kill them selectively. To reveal targetable differences between cancer and normal cells, we used a chemical genetics approach, starting with a proven therapeutic drug imiquimod, that specifically kills virus-infected and cancerous skin cells while nearby normal cell are undamaged.

The current understanding of imiquimod's mechanism of action (MOA) is that imiquimod acts as a TLR7 agonist to induce cytokine releases in macrophages and maturation of dendritic cells. However, a more potent TLR7 agonist resiquimod has failed the phase III clinical trial due to lack of efficacy, indicating that TLR7 agonism is not imiquimod's only MOA, if at all. In addition, imiquimod was reported to be more potent at direct killing of cultured basal cell carcinoma and squamous cell carcinoma than resiquimod, suggesting an additional target in cancer cells that is more strongly affected by imiquimod.

Our preliminary study revealed that imiquimod treated cancer cells are more dependent on glucose for survival suggesting impaired mitochondria functions. Indeed, using fluorescence microscopy we observed that imiquimod, but not resiquimod causes mitochondria to swell. Characterization of the swollen mitochondria using electron microscopy showed degenerated cristae. To test whether the mitochondria damaging effect depends on membrane receptors, we tested imiquimod in an xenopus egg extract system. Without any plasma membrane components, imiquimod impaired mitochondria oxygen consumption, indicating that its target may reside in mitochondria. Our ongoing research will hopefully elude this target that is crucial to cancer cells, but dispensable to normal cells.

**(+)-Negamycin derivatives promoting premature termination codon-readthrough.**

K. Takayama<sup>1</sup>, A. Taguchi<sup>1</sup>, M. Shiozuka<sup>2</sup>, M. Kotake<sup>1</sup>, K. Hamada<sup>1</sup>, Y. Yamazaki<sup>1</sup>, F. Yakushiji<sup>1</sup>, R. Matsuda<sup>2</sup>, Y. Hayashi<sup>1</sup>; <sup>1</sup>Department of Medicinal Chemistry, Tokyo University of Pharmacy and Life Sciences, Hachioji, Japan, <sup>2</sup>Department of Life Science, University of Tokyo, Tokyo, Japan

(+)-Negamycin **1** is a dipeptidic antibiotic containing a hydrazide structure. Although (+)-**1** was not clinically developed due to some toxicity, it was recently reported that (+)-**1** restored dystrophin expression in the muscles of *mdx* mice, an animal model of Duchenne muscular dystrophy (DMD) (Arakawa, M. *et al.*, *J. Biochem.*, 2003). DMD is the most severe form of dystrophinopathy caused by a mutation in the dystrophin gene, which codes an important structural protein dystrophin within muscle tissue. About 10-20% of this congenital disease is caused by nonsense mutations possessing the premature termination codons (PTCs). Hence, a promising approach for the treatment of DMD is the use of drugs to force PTC readthrough, and the potent derivatives of (+)-**1** would be a promising therapeutic candidate for diseases caused by nonsense mutations. Based on our own efficient total synthetic method of (+)-**1** (Hayashi, Y. *et al.*, *Chem. Commun.*, 2008; Nishiguchi, S. *et al.*, *Tetrahedron*, 2010), structure-activity relationship (SAR) study was performed to discover derivatives with a potent readthrough-promoting activity. The biological evaluation was conducted by using the double reporter plasmid possessing PTC between beta-galactosidase and luciferase genes. We found a derivative, (5*R*)-5-hydroxy-6-aminohexanoyl-glycine exhibited not antimicrobial activity but a similar readthrough activity to (+)-**1**, suggesting that the PTC readthrough mechanism can be distinguished from the antimicrobial mechanism (Taguchi, A., Hayashi, Y. *et al.*, *ACS Med. Chem. Lett.*, 2012). Moreover, we synthesized 5-*epi*-negamycin and found that this analog exhibited a similar activity to (+)-**1** in *in vitro* readthrough assay. This result hence prompted us to synthesize a 5-dehydro-derivative, e.g., 5-dehydro-3-*epi*-negamycin **2**, which is a natural product with little antimicrobial activity. Surprisingly, we found that **2** showed a higher *in vitro* readthrough-promoting activity than (+)-**1**. This result suggests that Mother Nature independently evolved readthrough-promoting products like suppressor tRNA, in distinction from aminoglycosides, which show both antimicrobial and readthrough-promoting activities.

**Assessing cytotoxic effect of phthalates on mesenchymal stem cells through analysis of impedance fluctuations.**

Y-T. Lai<sup>1</sup>, T-H. Tung<sup>1</sup>, H-N. Hsieh<sup>1</sup>, C-M. Lo<sup>1</sup>; <sup>1</sup>Biomedical Engineering, National Yang-Ming University, Taipei, Taiwan

Phthalates (PAEs) are a family of compounds widely used in the manufacturing industry and in the production of plastics. The human exposure to these compounds can be through ingestion, inhalation, or even directly by certain medical procedures. Due to the intensive and long term use of PAEs in plastic industry and medication, studies on the connection between the PAEs exposure of pregnant women and its toxic influence on the fetus are urgently needed since data are limited to date. The use of mesenchymal stem cells (MSCs) as *in vitro* model systems has great potential to help develop a biologically based risk assessment of toxic chemical exposure to human beings. In this study we have applied electric cell-substrate impedance sensing to investigate the cytotoxic effect of diethyl phthalate (DEP), dibutyl phthalate (DBP) and their metabolites (MEP and MBP) on MSCs isolated from the human umbilical cord. The basic principle of electric cell-substrate impedance sensing is to monitor the changes in electrical impedance of adherent cells grown on gold-film electrodes. To detect the changes of cell micromotion in response to the challenge of different concentrations of PAEs, the time-series

impedances of cell-covered electrodes were monitored and the values of variance and Hurst coefficient were calculated to verify the difference. These measures describe the motile and persistent behavior of these cells in culture. At high concentrations of PAEs such as 3000 ppm and metabolites such as 80 ppm, a drastic drop of resistance due to the increase of intercellular space was observed almost immediately following the addition. Micromotion measurements of MSC-covered electrodes were taken 20 h after exposure to different concentrations of PAEs. Variance and standard deviation of the increments were used to characterize the level of fluctuations. While a dose-dependent relationship was generally observed from the overall resistance of the MSC monolayer, the analysis of impedance fluctuations distinguished DEP levels as low as 100 ppm and metabolite levels as low as 40 ppm. Our results suggest that 3000 ppm of PAEs and 50 ppm of metabolite can cause a decrease of junctional resistance between cells and the reduction in micromotion.

**Dose-Dependent p21(Cip1/Waf1) DNA Damage Response.***K. W. Overton<sup>1</sup>, C. L. Wang<sup>1</sup>; <sup>1</sup>Chemical Engineering, Stanford University, Stanford, CA*

p21(Cip1/Waf1) is a member of the Cyclin-dependent kinase inhibitor (CKI) class of proteins involved in arresting the cell cycle in response to DNA damage. Previous studies have shown that the N-terminal domain of p21 is involved in binding to and inhibiting the activity of Cyclin-CDK complexes, and the C-terminal domain of p21 binds to and inhibits proliferating cell nuclear antigen (PCNA), a DNA polymerase auxiliary factor involved in DNA synthesis and repair.

Our lab has developed genetic tools and methods to evaluate cellular responses over varying levels of gene expression. Recently, we have developed a library of expression vectors that control the level of protein translation. We have used this vector library to express exogenous p21 levels in an Hct116 human colon cancer cell line in which the endogenous p21 has been inactivated by gene-targeting. We were able to generate a full range of p21 expression levels, including those greater than the p21 levels induced by ionizing radiation and those below levels observed in undamaged wild-type Hct116 cells. This wide range of expression allows us to monitor the behavior of cells exposed to varying amounts of p21, including levels that are physiologically relevant.

Our results show that cells expressing exogenous wild-type p21 are not actively cycling through S phase. To explore the underlying mechanism of p21 expression strength affecting cell cycle arrest, we made two mutant versions of the p21 gene—one that does not bind to Cyclin/CDK complexes (p21 CDK-/PCNA+) and one that does not bind to PCNA (p21 CDK+/PCNA-). While the CDK+/PCNA- mutant significantly inhibited the cell cycle at higher levels of expression, the CDK-/PCNA+ mutant inhibited cell cycle progression only at low levels. Additionally, we have found that wild-type Hct116 cells exposed to ultraviolet (UV) irradiation undergo a UV dose-dependent decrease in p21 levels along with an increase in levels of ubiquitinated PCNA—a marker of trans-lesion synthesis (TLS) DNA repair—at one hour post-UV exposure. This trend is reversed at 24 hours, with high levels of p21 and low levels of ubiquitinated PCNA present at high UV doses, likely indicating that repair mechanisms are no longer attempting to fix the DNA damage. Cells exposed to higher UV doses also exhibited a decrease in pro-caspase 3 levels at 24 hours post-UV exposure, suggesting that the apoptosis pathway may be activated.

**The Structural Basis for Redox-Dependent Conformational Switching in the INAD PDZ5 Domain.***K. I. White<sup>1</sup>, R. Ranganathan<sup>1</sup>; <sup>1</sup>Green Center for Systems Biology, UT Southwestern Medical Center, Dallas, TX*

General biophysical principles guiding the emergence of function in natural proteins remain elusive. Here, we seek to establish the rules for specifying a complex allosteric activity in the INAD scaffolding protein involved in *Drosophila melanogaster* phototransduction. Light stimulation drives a redox-based conformational switch within the fifth PDZ domain (PDZ5) of INAD, and this activity plays a critical role in mediating rapid signal transduction *in vivo* through the modulation of binding to downstream targets [1]. How does the domain trigger the conformational switch in response to environmental signals, and what is the minimal set of residues in PDZ5 needed to encode this behavior? One approach to this problem is to attempt transplantation of redox switching through stepwise mutation of an unrelated, redox-insensitive PDZ domain. Structural and biophysical data show that simply introducing a pair of cysteines is insufficient to recapitulate redox switching over biologically relevant regimes, suggesting that a more distributed group of residues underlies this process. In this regard, the statistical coupling analysis (SCA) [2, 3] reveals a set of collectively co-evolving residues in the PDZ family that may represent the unit of redox sensitivity and conformational switching. Starting with an unrelated, redox-insensitive PDZ domain (PSD95 PDZ3), I have generated a series of chimeric constructs that represent a gradual transplantation of INAD PDZ5 residues at SCA-identified positions, and preliminary data demonstrate the emergence of PDZ5-like redox properties with only a handful of mutations in addition to the requisite cysteines. The identification of the minimal set of these positions needed and their sufficiency for redox-dependent conformational switching remains as an open question for further study.
