ABSTRACT: Canonical models of single-field, slow-roll inflation do not lead to appreciable non-Gaussianity, unless derivative interactions of the inflaton become uncontrollably large. We propose a novel slow-roll scenario where scalar perturbations propagate at a subluminal speed, leading to sizeable equilateral non-Gaussianity, $f_{\text{NL}}^{\text{equil}} \propto 1/c_s^4$, largely insensitive to the ultraviolet physics. The model is based on a low-energy effective theory characterized by weakly broken invariance under internal galileon transformations, $\phi \rightarrow \phi + b_\mu x^\mu$, which protects the properties of perturbations from large quantum corrections. This provides the unique alternative to models such as DBI inflation in generating strongly subluminal/non-Gaussian scalar perturbations.

1 Introduction

The simplest, textbook version of inflation consists of a single canonical scalar field — the inflaton — slowly rolling down a sufficiently flat potential. It is a common feature of these models that the magnitude of non-Gaussianity is suppressed [1] well below the observable level for any foreseeable future; see, e.g., [2].

Generically, in the low-energy inflationary effective field theory (EFT), there are additional higher-derivative corrections to the canonical action [3], and one may wonder whether these can impact non-Gaussianity in any significant way. For example, consider the following Lagrangian

$$\mathcal{L} = \sqrt{-g} \left[-\frac{1}{2}(\partial\phi)^2 - V(\phi) + \frac{(\partial\phi)^4}{\Lambda^4} + \dots \right], \tag{1.1}$$

where $V(\phi)$ denotes the inflaton potential and the last term provides a higher-order correction in the derivative expansion, governed by the EFT cutoff Λ . The virtue of such terms is that they do not renormalize the potential, while they do contribute to the non-Gaussianity [4],

$$f_{\text{NL}} \sim \frac{\dot{\phi}_0^2}{\Lambda^4}, \tag{1.2}$$

where ϕ_0 denotes the background expectation value of ϕ and f_{NL} is the nonlinearity parameter of scalar perturbations [5]. It is clear from eq. (1.2) that having $f_{\text{NL}} \gtrsim 1$ in this model implies going beyond the (at least apparent) regime of validity of the low-energy effective theory, which requires $(\partial\phi)^2 \ll \Lambda^4$. Therefore, unless the infinite number of derivative operators in the ellipses of eq. (1.1) can be resummed, one cannot trust values of non-Gaussianity greater than one. An example of such a resummation is provided by Dirac-Born-Infeld (DBI) inflation [6, 7], where a higher-dimensional spacetime symmetry (nonlinearly realized on ϕ) protects the coefficients of the leading derivative operators from large quantum corrections. For a small speed of sound of scalar perturbations, $c_s^2 \ll 1$, DBI inflation predicts equilateral non-Gaussianity [8], with the amplitude $f_{\text{NL}}^{\text{equil}} \sim 1/c_s^2$ [7, 9].

In this article we propose a novel inflationary scenario where the energy density of the early universe is dominated by the potential of a slowly-rolling scalar field, similarly to ordinary slow-roll theories. Yet, a definite set of higher-derivative interactions of the inflaton become relevant, leading to observably large non-Gaussianity. Nevertheless, the theory is predictive, since all the rest of the operators in the derivative expansion remain *naturally* small in the full quantum theory. These properties follow from the *weakly broken* [10] invariance under internal *galileon transformations* [11],

$$\phi \rightarrow \phi + b_\mu x^\mu, \tag{1.3}$$

which becomes exact in the limit $M_{\text{Pl}} \rightarrow \infty$. While not an exact symmetry in the presence of gravity, (1.3) still significantly constrains the form of quantum corrections to the classical action. We refer the reader to ref. [10] for a thorough discussion of the UV structure of the theory.

While the symmetry (1.3) has appeared in a variety of physical contexts, ranging from modified gravity [11–14] to scattering amplitudes [15], here we use it as a guideline for constructing largely UV-insensitive models of the early universe. The same symmetry underlies the model of Galileon inflation [16] based on the covariant galileon [17] lagrangian.¹ That scenario is, however, very different from the one presented in this article because in ref. [16] the background evolution is fully controlled by the higher-derivative operators, the potential being absent or negligible. This difference gives rise also to important consequences for the dynamics of perturbations, as we will discuss in the section on non-Gaussianity.

To our knowledge, (1.3) is the only alternative to shift and DBI-like symmetries for protecting the coefficients of strongly-coupled higher-derivative operators against large quantum corrections. Just like in DBI inflation, enhanced scalar non-Gaussianity is generically associated with a reduced speed of sound of perturbations in our model; however, the enhancement is much stronger compared to the DBI case, the amplitude of equilateral non-Gaussianity growing as $f_{\text{NL}}^{\text{equil}} \propto 1/c_s^4$ for small c_s^2 .

2 The model

The theory we wish to study below is defined as a combination of an inflationary potential and the four Lagrangian terms [10], which, barring the factors of $\sqrt{-g}$, can be written as follows

$$L_2 = \Lambda_2^4 G_2(X), \tag{2.1}$$

$$L_3 = \Lambda_2^4 G_3(X)[\Phi], \tag{2.2}$$

$$L_4 = M_{\text{Pl}}^2 G_4(X)R + 2\Lambda_2^4 G_4'(X) ([\Phi]^2 - [\Phi^2]), \tag{2.3}$$

$$L_5 = M_{\text{Pl}}^2 G_5(X)G_{\mu\nu}\Phi^{\mu\nu} - \frac{1}{3}\Lambda_2^4 G_5'(X) ([\Phi]^3 - 3[\Phi][\Phi^2] + 2[\Phi^3]). \tag{2.4}$$

¹Note that the covariant galileon is a particular case of more general theories with WBG invariance, obtained by setting $G_2(X) \propto X$, $G_3(X) \propto X^2$ and $G_4(X) \propto X^2$ in eqs. (2.1)–(2.4).

Here, Φ is a matrix, consisting of second derivatives of the inflaton, $\Phi_\nu^\mu \equiv \nabla^\mu \nabla_\nu \phi / \Lambda_3^3$, and the brackets $[\dots]$ denote the trace operator. Moreover, G_a are arbitrary dimensionless functions of the dimensionless variable² $X \equiv -g^{\mu\nu} \nabla_\mu \phi \nabla_\nu \phi / \Lambda_2^4$. For simplicity, we will assume that these functions can be Taylor-expanded around zero, $G_a(X) = \sum_{n=0}^\infty c_a^{(n)} X^n$. Furthermore, the two scales in the theory are related to each other as $\Lambda_2^4 = M_{\text{Pl}} \Lambda_3^3$, so that the smaller of these, Λ_3 , can be regarded as the genuine cutoff of the underlying low-energy EFT (we assume M_{Pl} is the parametrically highest scale in the problem).

In the limit $M_{\text{Pl}} \rightarrow \infty$, the Lagrangian terms in (2.1)–(2.4) reduce to the *galileons* of ref. [11], which are exactly invariant (up to a total derivative) under (1.3). In this limit, there is a non-renormalization theorem, according to which the galileon operators are not corrected, at least perturbatively, by quantum loops [18]. For a finite Planck mass, the operators (2.1)–(2.4) break the galileon symmetry, but only *weakly* [10]. The defining property of the theories with weakly broken invariance under (1.3) is a generalization of the non-renormalization theorem of ref. [18], which renders the quantum corrections to the coefficients $c_a^{(n)}$ suppressed by positive (integer) powers of the tiny ratio Λ_3/M_{Pl} [10]. In addition, these theories belong to the so-called Horndeski class of scalar-tensor models [19], characterized by second-order equations of motion both for the scalar and the metric [20–22].

It has been shown in ref. [10] that the properties of the theories with weakly broken galileon symmetry imply the possibility of a moderately coupled, yet predictive, regime characterized by

$$X = \frac{\dot{\phi}_0^2}{\Lambda_2^4} \lesssim 1, \quad Z \equiv \frac{H \dot{\phi}_0}{\Lambda_3^3} \lesssim 1, \tag{2.5}$$

for a homogeneous ϕ -profile on a FRW background with the Hubble rate H . From now on, X will be understood as evaluated on the background solution. Despite the moderate coupling, quantum corrections are under control when the scalar background profile satisfies (2.5) — even in the case that these inequalities are saturated — and the predictions of the classical theory can be trusted.

3 The slow-roll backgrounds

As noted above, we will be interested in the potentially-dominated models of inflation, characterized by weakly broken invariance under the galileon transformations (we will refer to these models as ‘WBG’ inflation below). These are governed by the following Lagrangian

$$\mathcal{L} = \sqrt{-g} \left[\frac{M_{\text{Pl}}^2}{2} R - \frac{1}{2} (\partial\phi)^2 - V(\phi) + \sum_{i=2}^5 L_i + \dots \right], \tag{3.1}$$

where, since we have extracted the canonical scalar and graviton kinetic terms, G_2 is assumed to start at least quadratic in X , while G_3 can have a linear piece. From now on we will set $G_4 = G_5 = 0$ for the sake of simplicity; generalization to the case of nonzero

²We use the ‘mostly plus’ signature for the metric.

G_4 and G_5 is straightforward and will be commented on where appropriate. The ellipses in (3.1) denote an infinite number of other operators, present in the low-energy effective theory. We will assume that the potential $V(\phi)$ satisfies the ordinary slow-roll conditions, $\epsilon_V \ll 1$ and $|\eta_V| \ll 1$, where the (potential-based) slow-roll parameters ϵ_V and η_V are defined as

$$\epsilon_V \equiv \frac{M_{\text{Pl}}^2}{2} \left(\frac{V'}{V} \right)^2, \quad \eta_V \equiv M_{\text{Pl}}^2 \frac{V''}{V}. \quad (3.2)$$

The previous analysis of quantum loops, leading to the non-renormalization theorem summarized above, has concentrated on the case with a vanishing potential [10]. It is straightforward to show that the same results remain intact also in the presence of a nonzero, but sufficiently flat $V(\phi)$, satisfying (3.2).

For the flat FRW ansatz, $ds^2 = -dt^2 + a^2(t)d\vec{x}^2$, the two Friedmann equations that follow from (3.1) read

$$3M_{\text{Pl}}^2 H^2 = V - \Lambda_2^4 X \left[\frac{1}{2} + \frac{G_2}{X} - F(X, Z) \right], \quad (3.3)$$

$$2M_{\text{Pl}}^2 \dot{H} = -\Lambda_2^4 X F(X, Z) + 2M_{\text{Pl}} X G_3 \ddot{\phi}_0, \quad (3.4)$$

where $H \equiv \dot{a}/a$ and the function $F(X, Z) \equiv 1 + 2G_2' - 6ZG_3'$ has been introduced for later convenience. Moreover, in the slow-roll regime the homogeneous equation of motion of ϕ reduces to

$$3H\dot{\phi}_0 F(X, Z) \simeq -V'(\phi_0). \quad (3.5)$$

We are interested in a regime where higher-derivative operators in (3.1) become important, while the quantum corrections are still under control. To this end, we assume $Z \sim 1$, which also fixes the magnitude of the parameter X . Indeed, from the definition of X and Z , eq. (2.5), it follows that $\sqrt{X} = \Lambda_2^2 Z / (M_{\text{Pl}} H)$; making use of eq. (3.4), one immediately obtains $X \sim \sqrt{\epsilon}$, where $\epsilon \equiv -\dot{H}/H^2$.

Note the order-unity slowly varying function of time $F(X, Z)$ in eqs. (3.3)–(3.5), which is strictly one in canonical slow-roll inflation. Apart from this minor modification, all the equations that describe the background solution are similar to those of ordinary slow-roll models (up to corrections of higher order in ϵ_V and η_V). In particular, unlike e.g. the DBI case, the usual flatness conditions $\epsilon_V \ll 1$ and $|\eta_V| \ll 1$ need to hold for sustaining the quasi-de Sitter phase in our model. It is precisely for this reason that we refer to it as “slow-roll”.

Inflationary models based on particular subsets of the Lagrangian terms in (2.1)–(2.4), *G-inflation* and *Galileon-inflation*, have been studied in refs. [16, 23] respectively. However, these references have focused on kinetically-driven inflation, corresponding to $\Lambda_2^4 \sim M_{\text{Pl}}^2 H^2$ and $X \sim Z \sim 1$ in our notation³ (see also table 1 below). This results in several differences. For example, while in the model presented here, just as in slow-roll models, there is a built-in mechanism for ending inflation (when the inflaton rolls down

³These references have also considered the “Vainshtein” regime $Z \gg 1$, in which case the structure of the EFT has been studied in [24, 25].

sufficiently low on the potential), and e.g. for the monomial potentials the scalar tilt n_s is generically related to the number of inflationary e-folds in the standard way, $n_s - 1 \sim 1/N$, all these features are absent from the model discussed in ref. [16].

At the level of perturbations, our scenario is of course very different from canonical slow-roll inflation; for example, unlike the latter, the scalar perturbations become strongly coupled at an energy scale parametrically smaller than M_{Pl} , something we discuss in greater detail below.

It follows from the Friedmann equations that the contributions from the derivative operators in (3.1) to the inflationary energy density and pressure are proportional to $X \sim \sqrt{\epsilon}$. One may wonder therefore, whether loop corrections can outweigh these contributions for small values of ϵ . For $Z \sim 1$, the leading quantum corrections to the background stress tensor scale as $\sim \Lambda_3^4$ [10]. This should be much smaller than $\Lambda_2^4 \sqrt{\epsilon}$, which implies a lower bound on the slow-roll parameter, $\epsilon \gg (H/M_{\text{Pl}})^2$. This is the same bound on ϵ as the one that arises from requiring quantum fluctuations of the inflaton to be small [26, 27].

4 Non-gaussianity

Inflationary theories can be conveniently studied in a model-independent way using the EFT for inflationary perturbations [28, 29].⁴ To this end, we decompose the metric in the ADM variables,

$$ds^2 = -N^2 dt^2 + \gamma_{ij} (N^i dt + dx^i) (N^j dt + dx^j) , \quad (4.1)$$

and work in the unitary gauge, where the constant-time hypersurfaces are chosen to coincide with those of uniform ϕ . The perturbed quantities are defined as $\delta N \equiv N - 1$, and $\delta K \equiv K - 3H$, where K denotes the trace of the extrinsic curvature of equal-time hypersurfaces. The action in eq. (3.1) (with $G_4 = G_5 = 0$) can be expanded to the cubic order in perturbations in the following way [30]

$$S = \int d^4x \sqrt{-g} \left[\frac{M_{\text{Pl}}^2}{2} R - M_{\text{Pl}}^2 \dot{H} \frac{1}{N^2} - M_{\text{Pl}}^2 (3H^2 + \dot{H}) + \frac{M_2^4}{2} \delta N^2 + M_3^4 \delta N^3 - \hat{M}_1^3 \delta K \delta N + \hat{M}_2^3 \delta K \delta N^2 \right] , \quad (4.2)$$

where M_2 , M_3 , \hat{M}_1 and \hat{M}_2 are functions of time of canonical dimension one. In terms of the functions G_2 and G_3 introduced in eqs. (2.1) and (2.2), these are

$$\begin{aligned} M_2^4 &= -2\Lambda_2^4 X \left[3ZG'_3 + 6ZXG''_3 - 2XG''_2 - YG'_3 \right] , \\ M_3^4 &= -2\Lambda_2^4 X \left[3XG''_2 + \frac{2}{3}X^2G'''_2 - Z(4G'_3 + 11XG''_3 + 2X^2G'''_3) + YG'_3 \right] , \\ \hat{M}_1^3 &= -2\frac{\Lambda_2^4 X}{H} ZG'_3 , \quad \hat{M}_2^3 = -2\frac{\Lambda_2^4 X}{H} Z(2G'_3 + XG''_3) , \end{aligned} \quad (4.3)$$

⁴One of the virtues of this approach is that it takes advantage of the fact that the perturbations can be weakly coupled even if the background solution is strongly coupled. As a result, one can keep full control over the $f_{\text{NL}} > 1$ regime, see the discussion in the end of the present section.

Table 1. Magnitudes of the quadratic operators in (4.2) in units of $M_{\text{Pl}}^2 H^2$ in various inflationary models.

where $Y \equiv \ddot{\phi}_0 / \Lambda_3^3$. One can see from (4.3), that approximate invariance under galileon transformations imposes the following (radiatively stable) hierarchy among the various EFT coefficients:

$$M_2^4 \sim M_3^4 \sim M_{\text{Pl}}^2 \dot{H}, \quad \hat{M}_1^3 \sim \hat{M}_2^3 \sim \frac{M_{\text{Pl}}^2 \dot{H}}{H}. \quad (4.4)$$

This is in stark contrast to what happens e.g. in solely shift-symmetric theories, where the coefficients that stem from higher-derivative operators such as \hat{M}_1^3 and \hat{M}_2^3 , are much stronger suppressed. The latter hierarchy motivates to define the dimensionless, order-one coefficients

$$\alpha_{1,3} \equiv -\frac{M_{2,3}^4}{2M_{\text{Pl}}^2 \dot{H}}, \quad \alpha_{2,4} \equiv -\frac{\hat{M}_{1,2}^3 H}{2M_{\text{Pl}}^2 \dot{H}}, \quad (4.5)$$

convenient for describing the parameter space of the theories at hand. The magnitude of the EFT coefficients in (4.4) is different from all the other single-field models of inflation, as summarized in table 1 and it is what characterises the phenomenology of the model.

At sufficiently high energies (encompassing the Hubble scale), the dynamics of scalar perturbations is fully dominated by the dynamics of the adiabatic mode π , defined through $\phi(\vec{x}, t) = \phi_0(t + \pi(\vec{x}, t))$ [28, 29]. In the *decoupling limit* corresponding to this regime, the scalar part of the action (4.2) reads

$$S_\pi = \int d^4x a^3 (-M_{\text{Pl}}^2 \dot{H}) \left[(1 + \alpha_1) \left(\dot{\pi}^2 - c_s^2 \frac{(\partial\pi)^2}{a^2} \right) + (\alpha_2 - \alpha_1) \dot{\pi} \frac{(\partial\pi)^2}{a^2} - 2(\alpha_1 + \alpha_3) \dot{\pi}^3 + 2 \frac{\alpha_2 - \alpha_4}{H} \dot{\pi}^2 \frac{\partial^2 \pi}{a^2} + \frac{\alpha_2}{H} \frac{(\partial\pi)^2 \partial^2 \pi}{a^4} \right], \quad (4.6)$$

where the speed of sound is

$$c_s^2 \equiv \frac{1 + \alpha_2}{1 + \alpha_1}. \quad (4.7)$$

It follows from eq. (4.7) that if, for whatever reason, the parameter α_2 happens to be close to -1 , one can have strongly subluminal scalar perturbations. Most importantly, the approximate galileon invariance guarantees that such an ‘accidental’ arrangement of the

parameters is respected by loop corrections. This is qualitatively different from how the small c_s^2 arises in models such as DBI inflation, as we discuss in detail below.⁵

It is worth stressing at this point that the operators in the last line of (4.6) can be rewritten in terms of those in the second line via a perturbative field redefinition [33]. This simply amounts to using the linear equation of motion in (4.6). After straightforward manipulations, one finds⁶

$$S_\pi^{(3)} = \int d^4x a^3 (-M_{\text{Pl}}^2 \dot{H}) \left[\gamma_1 \dot{\pi} \frac{(\partial\pi)^2}{a^2} + \gamma_2 \dot{\pi}^3 \right]. \quad (4.8)$$

The two operators in (4.8) are precisely those appearing in the decoupling limit of DBI theories and the bispectrum they produce is close to the equilateral shape [8]. The genuine difference arises once the *magnitude* of non-Gaussianity is concerned: instead of the $f_{\text{NL}}^{\text{equil}} \sim 1/c_s^2$ behaviour characteristic of DBI inflation [9], in theories with weakly broken galileon symmetry non-Gaussianity scales as $f_{\text{NL}}^{\text{equil}} \sim 1/c_s^4$ in the small- c_s^2 limit. The latter scaling is due to the last operator in (4.6), whose precise contribution to the three-point function of the curvature perturbation ζ reads [16, 34]⁷

$$B_\zeta(k_1, k_2, k_3) = -\frac{1}{16} \frac{H^8}{A^2} \frac{\alpha_2}{1 + \alpha_1} \frac{1}{c_s^{10}} \frac{k_1^2(k_1^2 - k_2^2 - k_3^2)}{k_t(k_1 k_2 k_3)^3} \times \left(1 + \frac{\sum_{i>j} k_i k_j}{k_t^2} + 3 \frac{k_1 k_2 k_3}{k_t^3} \right) + 2 \text{ perms} . \quad (4.9)$$

Here, A denotes the normalization of the π -kinetic term in the decoupling limit, $A \equiv (-M_{\text{Pl}}^2 \dot{H})(1 + \alpha_1)$. The amplitude of non-Gaussianity can be directly read off from eq. (4.9)

$$f_{\text{NL}}^{\text{equil}} = \frac{5}{18} \frac{k_*^6 B_\zeta(k_*, k_*, k_*)}{\Delta_{\zeta_*}^2} = \frac{65}{162} \frac{\alpha_2}{1 + \alpha_1} \frac{1}{c_s^4}, \quad (4.10)$$

where $\Delta_\zeta \equiv k^3 P_\zeta(k) = H^4/(4Ac_s^3)$ is the dimensionless power spectrum, evaluated at a fiducial momentum scale k_* . A significantly reduced speed of sound, $\alpha_2 \simeq -1$ (see eq. (4.7)), implies a *negative* f_{NL} . However, due to the strong dependence of f_{NL} on c_s , even slightly subluminal perturbations can produce a sizeable amount of non-Gaussianity; for example, a 10 % tuning of the α_2 parameter can give rise to $f_{\text{NL}}^{\text{equil}} \simeq -70$ for $\alpha_1 = 1$ and $\alpha_2 = -0.9$.

⁵In the limit $X \rightarrow 0$, using eq. (4.3) with $G_4 = G_5 = 0$ in eq. (4.5), one finds $\alpha_1 = 3\alpha_2$. This gives a negative kinetic term to π for $\alpha_2 \simeq -1$. The parameter X need not be very small, however; it is of order $X \sim \sqrt{\epsilon} \simeq$ a few $\times 0.1$ in e.g. slow-roll models with monomial potentials. Moreover, the relation $\alpha_1 = 3\alpha_2$ no longer holds for $G_4 \neq 0$ or $G_5 \neq 0$.

⁶Explicitly, the coefficients γ_1 and γ_2 read

$$\begin{aligned} \gamma_1 &\equiv (c_s^2 - 1) \left(1 + \frac{2}{c_s^2} \right) + (1 + c_s^2) \alpha_1, \\ \gamma_2 &\equiv 2 \left(1 - \frac{1}{c_s^2} \right) \left(2 + \frac{1}{c_s^2} \right) + \frac{2}{c_s^2} (\alpha_1 - 2\alpha_4) + 2\alpha_1 - 2\alpha_3. \end{aligned}$$

⁷We follow the standard definition of the comoving curvature perturbation, $g_{ij} = a^2 e^{2\zeta} \delta_{ij}$. The three-point function is defined as $\langle \zeta(\vec{k}_1) \zeta(\vec{k}_2) \zeta(\vec{k}_3) \rangle = (2\pi)^3 \delta^{(3)} \left(\sum_i \vec{k}_i \right) B_\zeta(k_1, k_2, k_3)$, and $k_t \equiv k_1 + k_2 + k_3$.

We stress that such a tuning is not ‘unnatural’ as a result of the non-renormalization theorem outlined above.

Note that since at the zeroth order in the slow-roll parameter ϵ Galileon inflation [16] describes a perfect de Sitter space, small speed of sound requires $|H\hat{M}_1^3/M_2^4| \propto c_s^2$. Non-Gaussianity in this model scales as $f_{\text{NL}} \propto \hat{M}_1^3/c_s^4$ in the small c_s^2 limit, which effectively implies $f_{\text{NL}} \sim 1/c_s^2$ [35, 36], in contrast to (4.10). This is no longer true once L_4 and L_5 are included, in which case $f_{\text{NL}} \propto c_s^{-4}$ also in Galileon inflation.⁸

If the theory (4.6) is to be predictive, it is crucial that π is weakly coupled at energies of the order of the inflationary Hubble rate, $\Lambda_\star \gg H$, where Λ_\star is the energy scale at which perturbative unitarity is violated in the $2 \rightarrow 2$ scattering of π . In the $c_s^2 \ll 1$ limit, Λ_\star is set by the last interaction term in the action (4.6), and is estimated as⁹ $\Lambda_\star \sim \Lambda_3 c_s^{11/6}$. For $\alpha_1 \simeq 1$ and $\alpha_2 \simeq -1$, using the experimental value $\Delta_\zeta \simeq 5\pi^2 \times 10^{-9}$, one finds

$$\Lambda_\star^3 \sim \frac{\mathcal{O}(50)}{|f_{\text{NL}}^{\text{equil}}|} (8H)^3. \tag{4.12}$$

Even for the largest $f_{\text{NL}}^{\text{equil}}$ compatible with the current observational bounds [5], the strong coupling scale is fairly above H , but well below the symmetry breaking scale [41], $\Lambda_b^3 \sim \mathcal{O}(5) |f_{\text{NL}}^{\text{equil}}| \Lambda_\star^3$.

We close this section with a remark concerning the regime of validity of the decoupling limit. For the small values of the speed of sound we are interested in, one should be careful with mixing terms that involve spatial derivatives. For example, consider the $\delta N \delta K$ operator in eq. (4.2). The most important mixing of scalar modes with gravity that arises from this operator is suppressed by a factor of ϵ/c_s^2 compared to the π -kinetic term at horizon crossing. Therefore, the validity of the decoupling limit analysis requires that $c_s^2 \gtrsim \epsilon$ hold, which puts an upper bound ($f_{\text{NL}} \lesssim 1/\epsilon^2$) on the amplitude of non-Gaussianity attainable within the decoupling limit.

5 Discussion

In ‘ordinary’ inflationary theories, the statistical properties of perturbations are mostly determined by operators with the least number of derivatives, i.e. $(\partial\phi)^{2n}$ or, in the EFT

⁸Refs. [37–39] have explored the space of theories that includes the theories studied in this paper. However, these works have concentrated on the opposite regime, $Z \gg 1$, which from our standpoint is theoretically unjustified due to large quantum corrections. As a result, the $f_{\text{NL}}^{\text{equil}} \propto 1/c_s^4$ behaviour for $G_4 = G_5 = 0$ has not been noticed in those papers as well. See ref. [40] for other interesting effects, associated with weakly broken galileon invariance that have gone previously unnoticed in the literature.

⁹The power $c_s^{11/6}$ can be obtained as follows: looking at the action (4.6), one can cast the kinetic term of the π field in a Lorentz-invariant form via rescaling time $t \rightarrow t/c_s$, so that the canonically normalized field in the rescaled coordinates is $\pi_c = \sqrt{M_{\text{Pl}}^2 \dot{H} c_s} \pi$. The two-by-two scattering of π_c from an exchange diagram involving the last vertex in (4.6) reads

$$\mathcal{A} \propto \frac{\vec{k}^6}{M_{\text{Pl}}^2 H^2 \dot{H} c_s^5} = \frac{\vec{k}^6}{\Lambda_3^6 c_s^5}. \tag{4.11}$$

The momentum strong coupling scale is thus $|\vec{k}_\star| \sim \Lambda_3 c_s^{5/6}$, which translates into the following frequency strong coupling scale $\Lambda_\star = |\vec{k}_\star|_{c_s} = \Lambda_3 c_s^{11/6}$.

language, by operators of the form $(\delta N)^n$. The prototype example of this is provided by theories such as DBI (or *ghost* [31, 32]) inflation, where the background can be consistently strongly coupled, with an infinite number of operators of the above type becoming relevant for its dynamics. In the EFT of eq. (4.2), this corresponds to the large coefficient M_2^4 or, equivalently, to $\alpha_1 \gg 1$ in the notation of eq. (4.5), and implies a parametrically suppressed speed of sound, $c_s^2 \simeq 1/\alpha_1$, see eq. (4.7) (higher-derivative operators are effectively negligible in DBI inflation, so one can set $\alpha_2 \simeq 0$). Despite the strong coupling, the symmetries of DBI theories protect the structure of the Lagrangian from large quantum corrections. This mechanism of obtaining strongly sub-luminal scalar perturbations has been extensively studied in the literature (see, e.g., [7, 9, 41–43]) and provides an attractive way of generating large equilateral non-Gaussianity in single-field inflation.

In this work we have proposed an alternative scenario that allows for strongly sub-luminal scalar perturbations within a well-defined low-energy EFT. Our model relies on moderate coupling, i.e. $\alpha_i \sim 1$, as a result of which more than one operator in eq. (4.2) become large enough to affect the scalar perturbations significantly. In the simplest realization considered above, the scalar two- and three-point functions are determined by the operators δN^2 and $\delta N \delta K$. Instead of the $\alpha_1 \gg 1$, $\alpha_2 \ll 1$ case characteristic of DBI inflation, our mechanism relies on an adjustment of the order-unity α_1 and α_2 , which results in a somewhat reduced speed of sound in (4.7). The theories we have studied in this work not only allow for such an adjustment, but also provide a way to protect it against loop corrections. The central reason behind the robustness of the classical theory is the *weakly broken* galileon symmetry [10], which inherits the remarkable quantum properties of the galileon operators [11], exactly invariant under (1.3). Our model completes the classification of single-field inflationary theories with (sub)luminal perturbations according to the magnitudes of quadratic operators in the EFT of inflation, see table 1.

Acknowledgments

We thank Daniel Baumann, Paolo Creminelli and Greg Gabadadze for valuable discussions and comments on the manuscript. The work of D.P. is supported in part by MIUR-FIRB grant RBFR12H1MW and by funds provided by *Scuola Normale Superiore* through the program “*Progetti di Ricerca per Giovani Ricercatori*”. The work of E.T. is supported in part by MIUR-FIRB grant RBFR12H1MW. F.V. acknowledges partial support from the grant ANR-12-BS05-0002 of the French Agence Nationale de la Recherche.
